Complications of surgical repair should be limited, including wound infection and pneumothorax. A multicenter study of repair of pectus excavatum reported low and equivalent frequency of complications after either open or minimally invasive (Nuss) repair.[19] Use of electrocautery can avoid the need for blood transfusion in most cases. Most pneumothoraces can be simply observed, unless they are large enough to produce pulmonary impairment. Recurrence is the bane of this procedure and can occur regardless of the technique used. Use of strut fixation of the sternum to optimize early results, and delay of repair until the child is well into his or her pubertal growth spurt are both seen as methods to decrease the risk of recurrence. Growth of the chest may produce the opportunity for remodeling of the chest wall and subsequent recurrence. No randomized study of strut fixation versus no strut fixation has been performed, and it is doubtful that such a study could ever be completed. In large series with adequate follow-up, recurrence is reported to occur in 5% to 15% of cases.[24,98–101] Progressive deterioration of the repair over time is well described, particularly during the interval of rapid growth at puberty.[102–104] Rigid fixation is fairly uniformly applied to patients with Marfan syndrome because of their well-recognized high risk of recurrence.[105]

One serious complication has been noted in children who undergo repair at an early age, generally younger than 4 years—impaired growth of the ribs after resection of the costal cartilages, which produces a bandlike narrowing of the midchest (Fig. 62-3). In some cases, the first and second ribs have relative overgrowth, producing anterior protrusion of

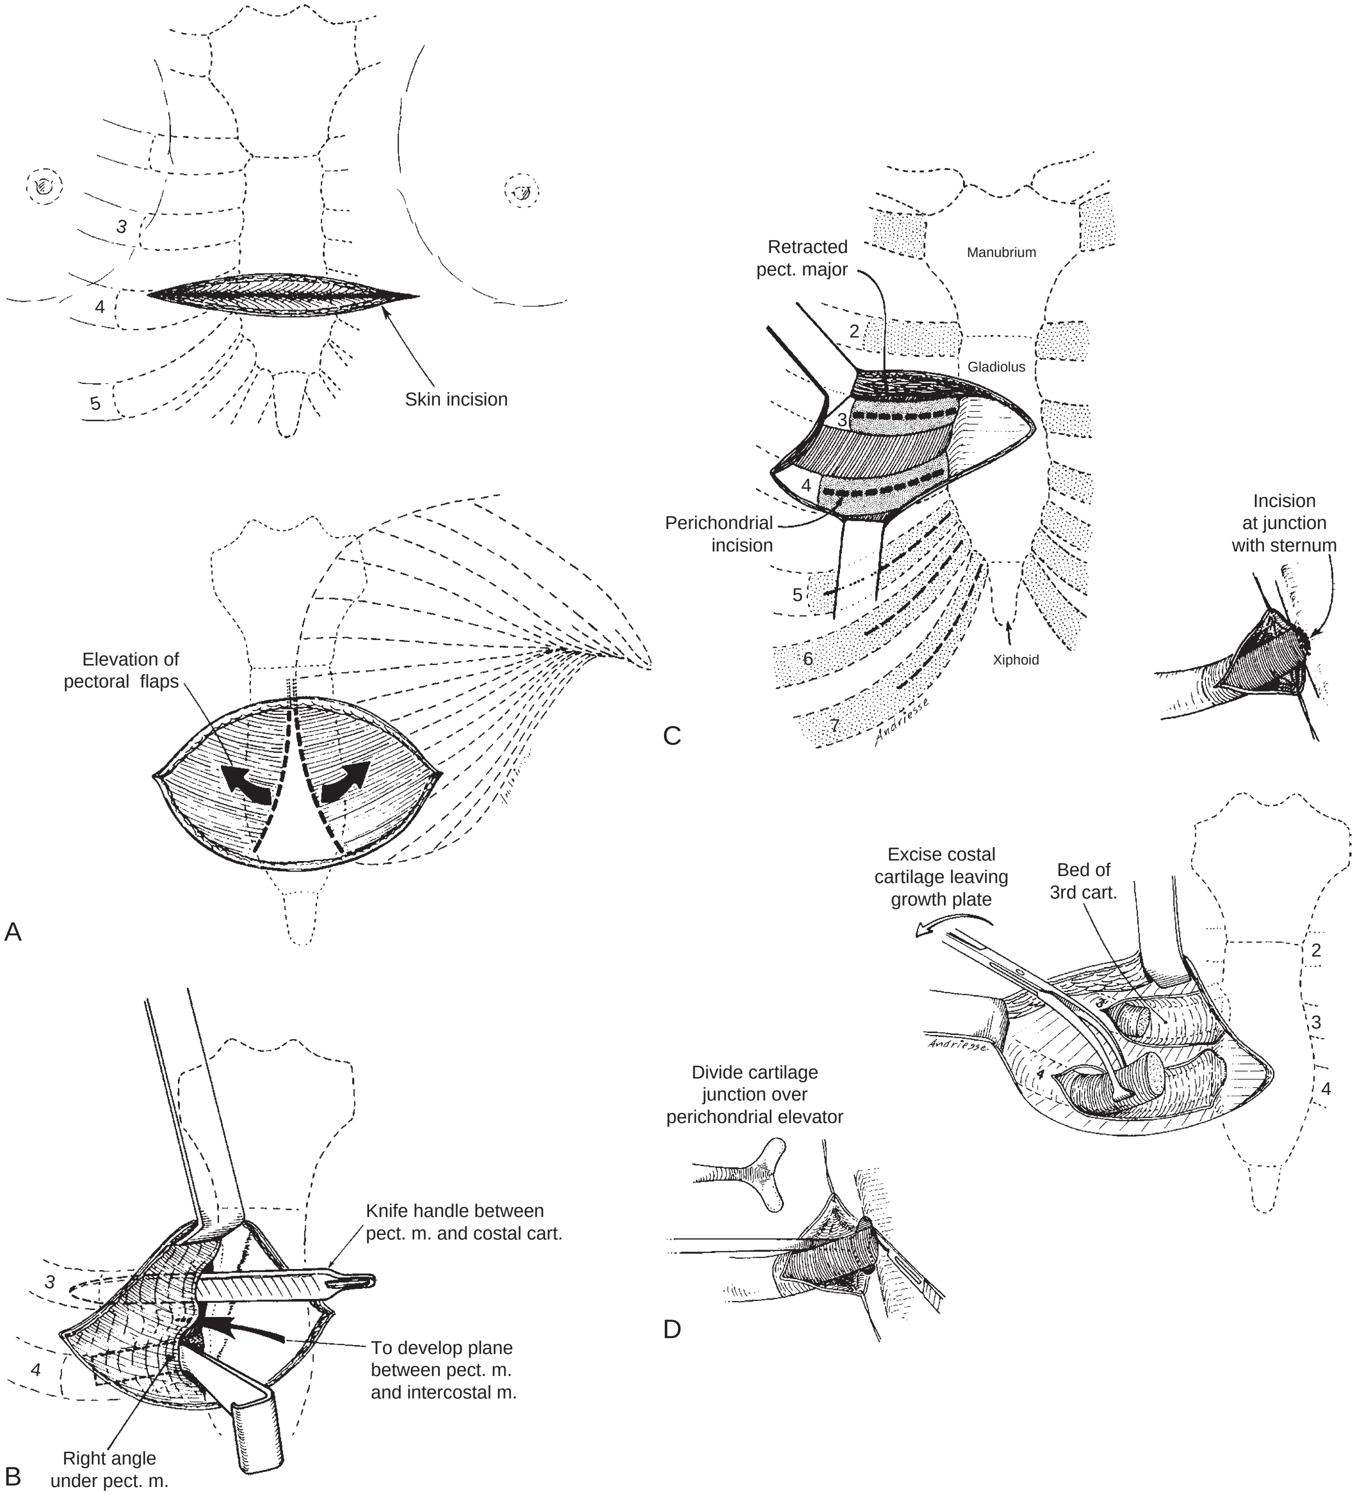

**FIGURE 62-2** Surgical technique for pectus excavatum repair. **A,** A transverse incision is placed below and well within the nipple lines at the site of the future inframammary crease. Skin flaps are mobilized using electrocautery, primarily in the midline to the angle of Louis superiorly and to the xiphoid inferiorly. The pectoralis major muscle is elevated from the sternum, along with portions of the pectoralis minor and serratus anterior muscles. **B,** The correct plane of dissection of the pectoral muscle flap is defined by passing an empty knife handle directly anterior to a costal cartilage after the medial aspect of the muscle is elevated with electrocautery. The knife handle is then replaced with a right-angle retractor, which is pulled anteriorly. The process is then repeated anterior to an adjoining costal cartilage. The lateral extent of muscle dissection and elevation is to the costochondral junctions of the third to fifth ribs. Anterior distraction of the muscles during the dissection facilitates identification of the avascular areolar plane and avoids entry into the intercostal muscle bundles. **C,** Subperichondrial resection of the costal cartilages is achieved by incising the perichondrium anteriorly. It is then dissected away from the costal cartilages in the bloodless plane between the perichondrium and the costal cartilage. Cutting back the perichondrium 90 degrees in each direction at its junction with the sternum (*inset*) facilitates visualization of the back wall of the costal cartilage. **D,** The cartilages are divided at the junction of the sternum with a knife. A Welch perichondrial elevator is held posterior to the cartilage to protect the mediastinum (*inset*). The divided cartilage can then be held with an Allis clamp and elevated, and the costal cartilage is excised, preserving a 5- to 10-mm margin on the rib to protect the costochondral junction and the longitudinal growth plate. Segments of the sixth and seventh costal cartilages are resected to the point where they flatten to join the costal arch. Familiarity with the cross-sectional shape of the medial ends of the costal cartilages facilitates their removal. The second and third cartilages are broad and flat, the fourth and fifth are circular, and the sixth and seventh are narrow and deep.

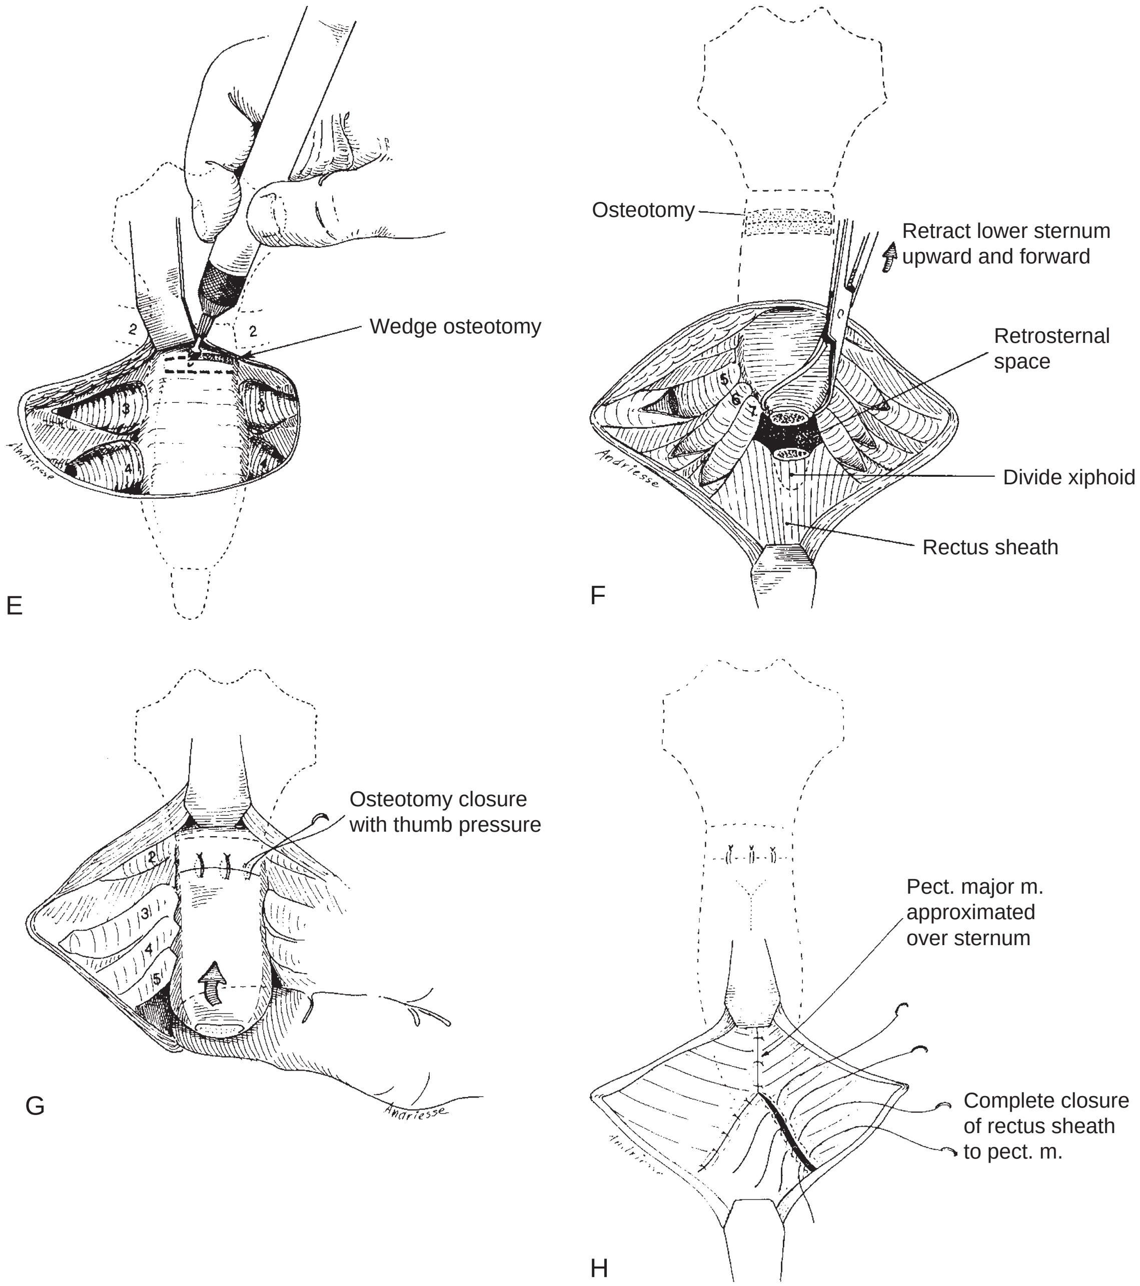

**FIGURE 62-2—CONT'D** **E,** The sternal osteotomy is created above the last deformed cartilage at the point of posterior angulation of the sternum. This is generally above the insertion of the third cartilage, or occasionally the second. Two transverse sternal osteotomies are created through the anterior cortex with a Hall air drill (Zimmer USA, Warsaw, Ind.) 2 to 4 mm apart. The short intervening segment of anterior cortex is then removed, along with the underlying cancellous bone. **F,** The base of the sternum and the rectus muscle flap are elevated with two towel clips, and the posterior plate of the sternum is fractured. The xiphoid can be divided from the sternum with electrocautery, allowing entry into the retrosternal space. This step is not necessary with the use of a retrosternal strut. Preservation of the attachment of the sheaths and xiphoid avoids an unsightly depression, which can occur below the sternum. **G,** When a strut is not used, the osteotomy is closed with several heavy silk sutures as the sternum is elevated to an overcorrected position with the assistant's thumb. **H,** A single-limb medium Hemovac drain (Snyder Laboratories, New Philadelphia, Ohio) is brought through the inferior skin flap to the left of the sternum and placed in a right parasternal position to the level of the highest costal cartilage resection. The pectoral muscle flaps are secured to the midline of the sternum, advancing the flaps to achieve coverage of the entire sternum. The rectus muscle flap, if divided, is joined to the pectoral muscle flaps.

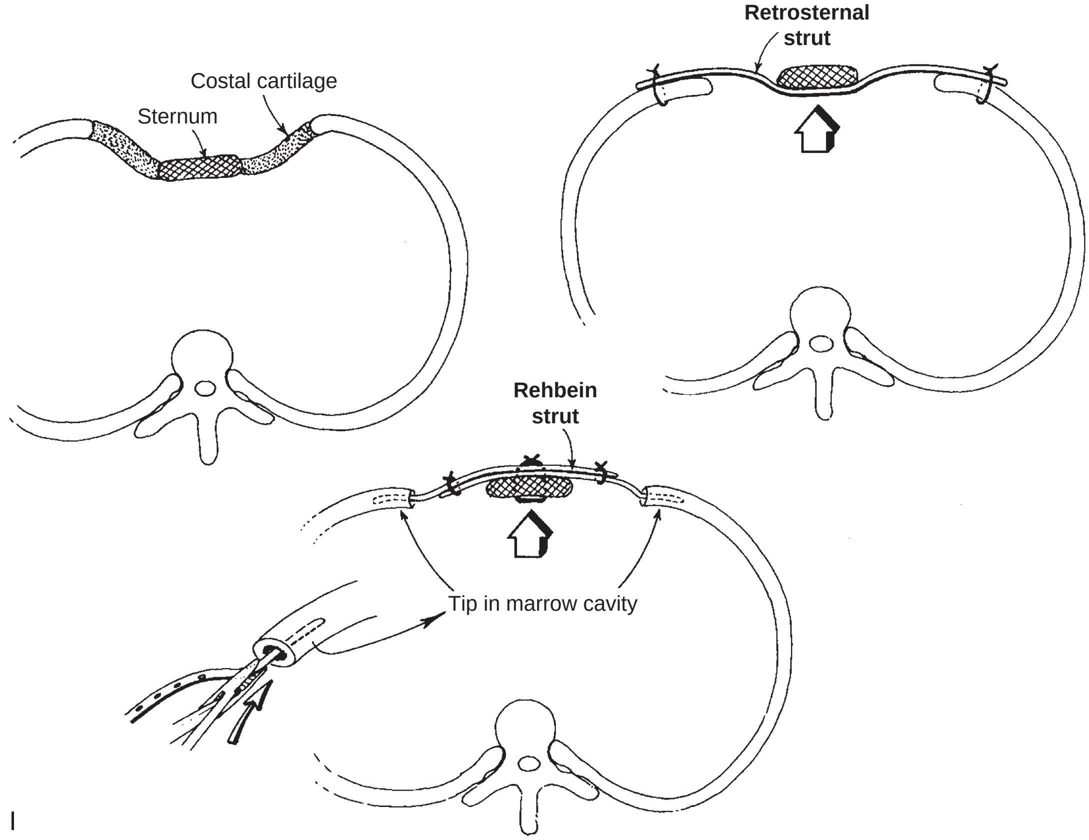
*Continued*



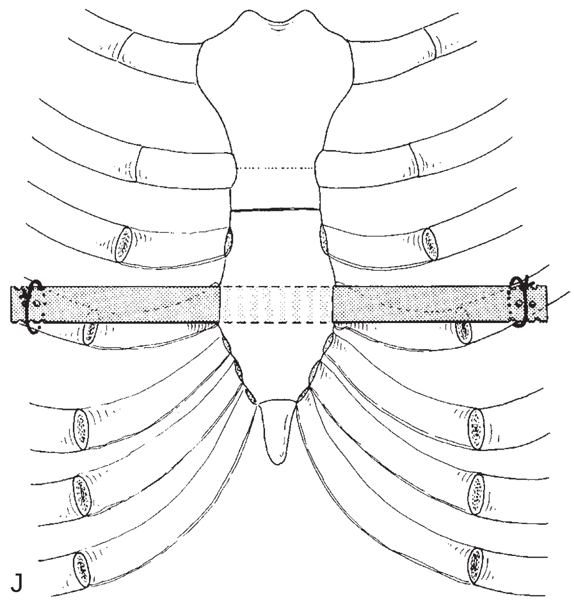


FIGURE 62-2—CONT'D **I,** Use of both retrosternal struts and Rehbein struts is demonstrated. The Rehbein struts are inserted into the marrow cavity (*inset*) of the third or fourth ribs and are then joined to each other medially to create a metal arch anterior to the sternum. The sternum is sewn to the arch to secure it in a forward position. The retrosternal strut is placed behind the sternum and is secured to the rib ends laterally to prevent migration. **J,** Anterior depiction of the retrosternal strut. The perichondrial sheath, to either the third or fourth rib, is divided at its junction with the sternum, and the retrosternal space is bluntly dissected to allow passage of the strut behind the sternum. An adequate space must be created to avoid injury to the pericardium. The strut is secured with two pericostal sutures laterally to prevent migration. (**A** to **H,** From Shamberger RC, Welch KJ: Surgical repair of pectus excavatum. J Pediatr Surg 1988;23:615-622. **I** and **J,** From Shamberger RC: Chest wall deformities. **FIGURE 62-3** **A,** Eighteen-year-old man 15 years after open pectus excavatum repair with a central broad recurrence and relative overgrowth of the upper unresected costal cartilages and ribs. **B,** Lateral radiograph demonstrates the sternum (*arrow*) lying parallel to the spine and the relative protrusion of the upper ribs.

the upper sternum. In 1990, Martinez first described this deficiency in thoracic growth after repair of pectus excavatum during the preschool years.[106] In 1995, Haller reported this occurrence in three boys who presented in their teens after resection of the costal cartilages at an early age, labeling this complication acquired Jeune disease.[107] Haller and colleagues[107] attributed this complication to injury during surgical repair of the costochondral junctions, the longitudinal growth centers for the ribs.

Martinez[106] demonstrated experimentally in 6-week-old normal rabbits that resection of the costal cartilage produced a marked impairment in chest growth, particularly the AP diameter, during a 5.5-month period of observation. Less severe impairment occurred if only the medial three fourths of the costal cartilage was resected, preserving the growth centers at the costochondral junction. This impairment was attributed to fibrosis and scarring within the perichondrial sheaths. Perichondrial sheaths, bone, or other prosthetic tissues that cannot grow should not be joined posterior to the sternum, because they will form a bandlike stricture across the chest. This complication can be avoided by delaying surgery until the children are older.

Preservation of the costochondral junction by leaving a segment of the cartilage on the osseous portion of the rib may partially minimize growth impairment. Weber and Kurkchubasche[108] described a method of improving the severe pulmonary impairment encountered in one patient with acquired Jeune syndrome. A sternotomy was performed and wedged open permanently with rib struts. The pleura was opened bilaterally, along with subperichondrial resection of six ribs. Pulmonary function was improved after the procedure. A subsequent report involving 10 patients further substantiates the efficacy of this technique to improve pulmonary function in 8 of the 10 patients.[109]

Fracture of struts left in place for extended periods has been reported, with erosion of the strut into the myocardium.[110] For this reason, most struts should be removed after an adequate interval to allow complete healing of the chest wall (e.g., 3 to 6 months).

# Surgical Technique (Nuss Procedure)

## PREOPERATIVE CONSIDERATIONS

Using a bar to correct pectus excavatum requires that attention be given to the bar. First, the patient should not be allergic to the components of the stainless steel bar. If there is a history of allergy to metal, patch testing should be done. If allergy is identified, a titanium bar can be used. The titanium bar is not as malleable as steel, and must be bent at the factory with CAD/CAM (computer-assisted design/computer-assisted manufacturing) technology using a copy of the patient's CT scan or

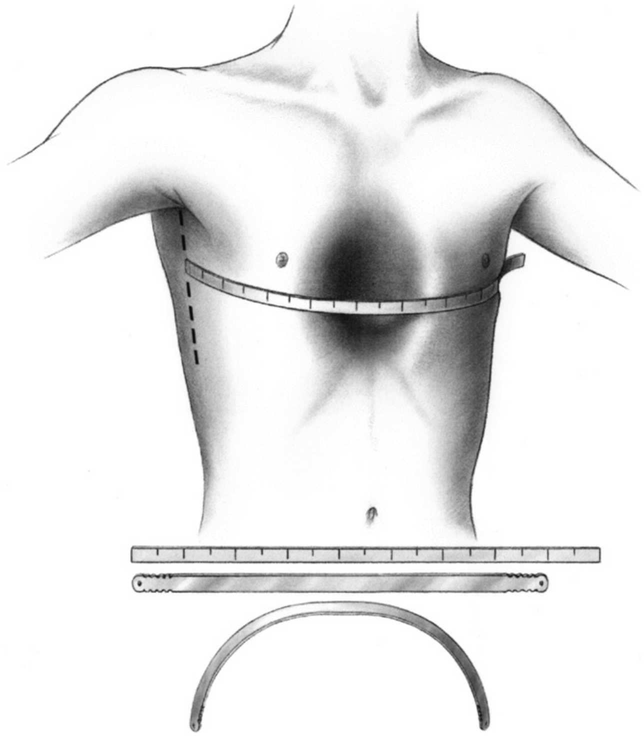

FIGURE 62-4 The bar should be 2 cm (1 inch) shorter than the distance from right to left midaxillary lines. The bar should be bent as shown, with a 2- to 4-cm flat section in the middle. The correct bar length should be decided in advance. Positioning is important. Both arms are abducted at the shoulder to make an angle of 75 degrees with the torso. Elbows are slightly flexed.

MRI. Titanium is also 4 times as expensive as steel and so is not used in every instance. The correct size bar should be determined well in advance. The bar should be 2.5 cm (1 inch) shorter than the distance from the right to left midaxillary line. The correct size and shape of the bar are crucial to success of the operation. The stainless steel pectus support bar is bent to conform to the patient's chest configuration, leaving a 2-cm section flat to support the sternum (Fig. 62-4). Bending the bar into an arch allows sustained load bearing of the bar. If the central flat section of the bar is too long, there will be undercorrection.

### OPERATION OVERVIEW

Operation is performed under general anesthesia. In Norfolk, we no longer use epidural analgesia supplementation, following two episodes of lower extremity paralysis that could not be explained despite exhaustive evaluation; these occurred after more than 1,000 uncomplicated epidural placements. Antibiotics are administered perioperatively, just as for open operation.

Careful attention to positioning and thoracoscope placement inferior to the proposed position of the bar facilitate good visualization (Fig. 62-5 illustrates the surgical technique). Some surgeons prefer to approach the mediastinal tunneling from the left rather than the right side. Other surgeons make a third incision over the xiphoid and then apply a towel clip or bone hook to elevate the sternum (Fig. 62-6); others do a finger dissection under the sternum before inserting the introducer (Fig. 62-7).

In younger and smaller patients, a single bar is adequate to correct the deformity. But in older or larger patients, especially if they have a severe deformity, a second bar should be added without hesitation. Sternal elevation using the introducer device improves the result by moving the sternum and cartilages and allowing easier rotation of the bar. Great care should be taken to prevent the bar from moving after operation by securing it to the underlying ribs with heavy absorbable suture. Using the thoracoscope, a wound closure device such as the Endoclose autosuture (Covidien, Mansfield, Mass.) can feed a double thickness of heavy suture safely, avoiding vascular and intercostal nervous structures (Fig. 62-8).

### POSTOPERATIVE MANAGEMENT

In the recovery room, smooth emergence from anesthesia, avoiding thrashing or wriggling movements, is ensured. Patients are usually discharged home on the fourth or fifth postoperative day. Patients may return to school after 2 weeks but may not participate in sports for 6 weeks after surgery. After 6 weeks, patients are encouraged to resume their pectus breathing and posture exercises and to participate in aerobic sports activities (e.g., soccer, basketball, swimming). Heavy contact sports (e.g., boxing, football, ice hockey) are prohibited until the bar is removed.

### TIMING OF REMOVAL OF THE BAR

The pectus bar should be left in place for at least 2 years. Patients are evaluated on an annual basis, and their growth and activity level are monitored. Patients between the ages of 6 and 10 years often do not grow rapidly, and they tolerate the bar well for 3 or even 4 years. In contrast, teenagers who undergo a massive growth spurt may require removal of the bar after 2 years.

We consider the exercise programs to be just as important as the surgery. Deep breathing with breath-holding for 10 to 15 seconds and aerobic activities, such as running (e.g., soccer, basketball) and swimming, are vigorously encouraged (Fig. 62-9).

## Complications

### EARLY COMPLICATIONS[15,69,111]

There were no deaths and no cardiac perforations during the 1,215 repairs performed at our institution over the last 21 years. Chest tube drainage was necessary in 4% of cases. Hemothorax requiring drainage occurred after 7 repairs (0.6%). Three were in the perioperative period, and 4 occurred months later; two of these late cases were explained by external trauma, and two were not. Three pleural effusions required treatment by either chest tube or aspiration (0.3%).

Pericarditis requiring treatment with indomethacin occurred after four repairs (0.4%), with one requiring pericardiocentesis. Pneumonia occurred after 6 repairs (0.5%). Fifteen percent of patients had transient Horner syndrome at varying times during thoracic epidural administration. Early superficial wound infection was noted in 11 patients (1%).

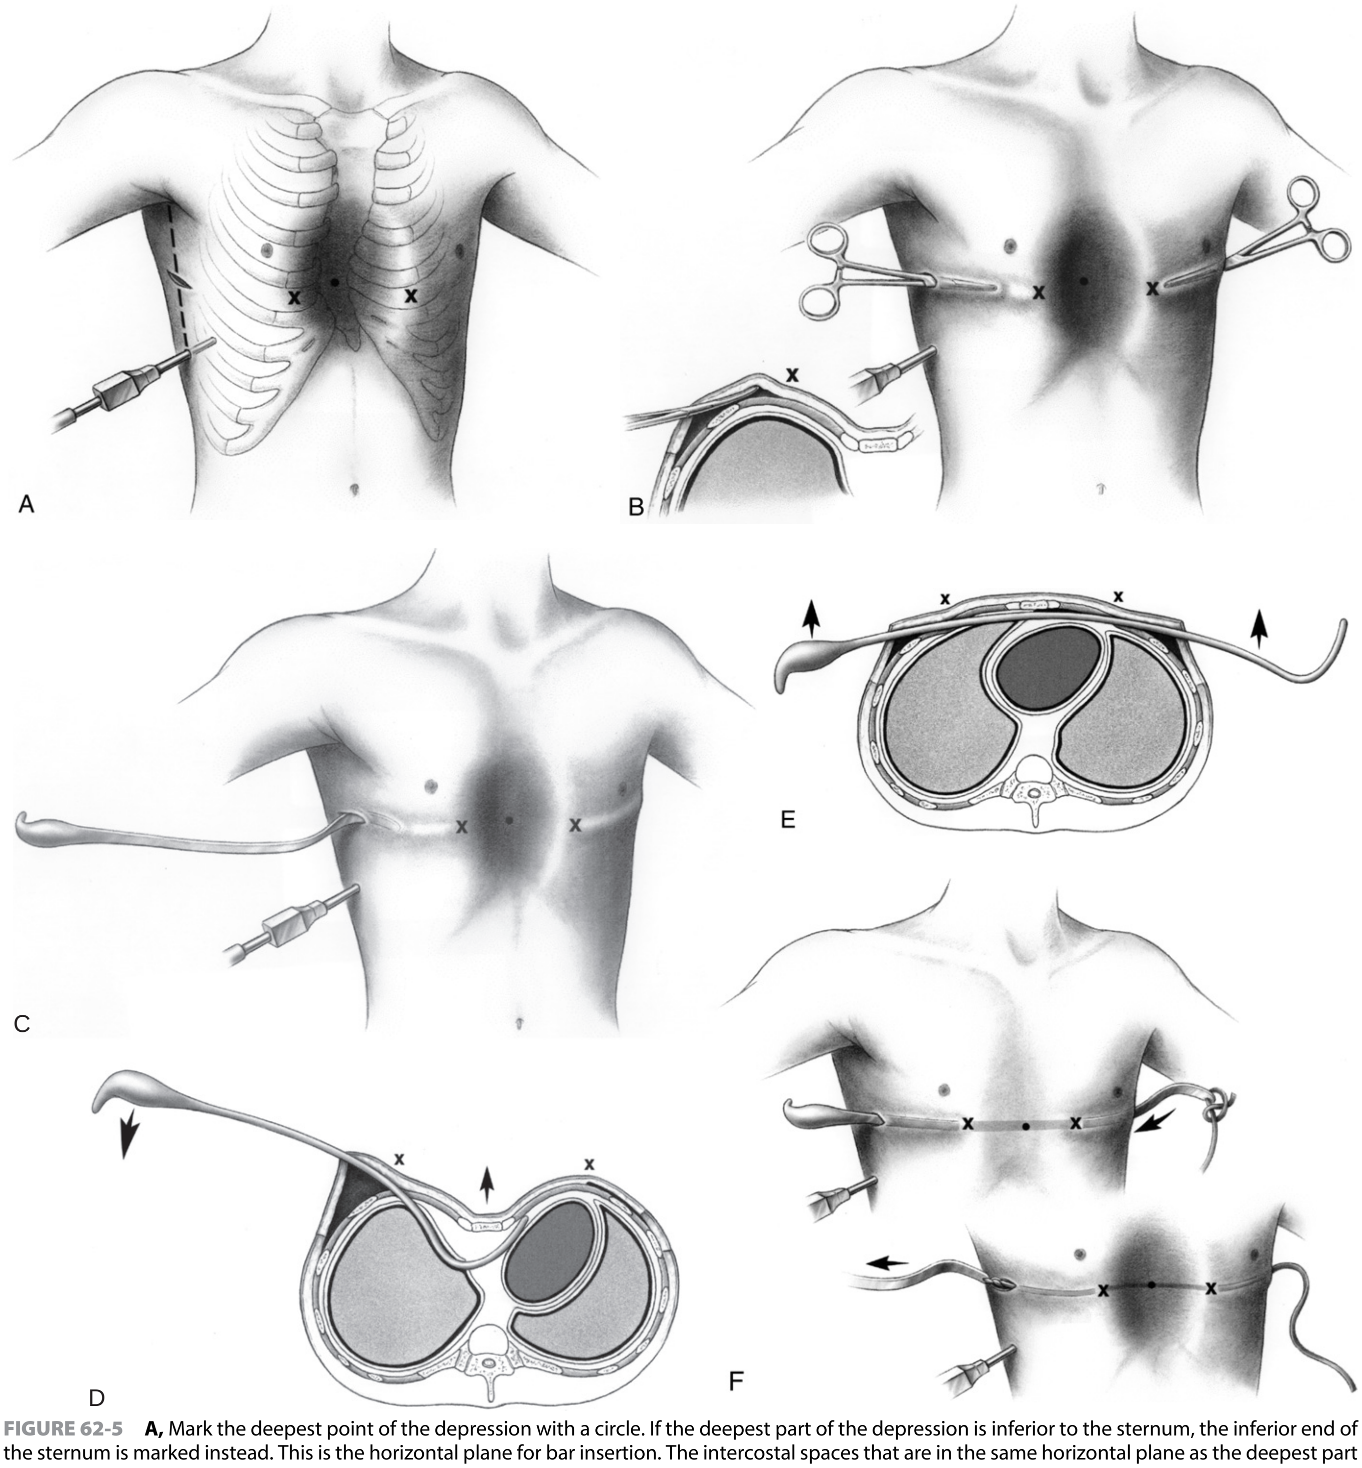

**FIGURE 62-5** **A,** Mark the deepest point of the depression with a circle. If the deepest part of the depression is inferior to the sternum, the inferior end of the sternum is marked instead. This is the horizontal plane for bar insertion. The intercostal spaces that are in the same horizontal plane as the deepest part of the depression are marked with an X. These entry and exit points on each side of the sternum should be medial to the top of the pectus ridge. These marks should all be in the same horizontal plane. The thoracoscope is inserted two intercostal spaces below the incision site. A thorough inspection of the right hemithorax and mediastinum is performed, ensuring that there is no contraindication for repair. The pressure is applied with a finger to the intercostal spaces marked for bar insertion to ensure that the external markings line up well with the internal anatomy. **B,** After confirming by thoracoscopy that the internal and external anatomy match up well, bilateral thoracic skin incisions are made, and a deep subcutaneous tunnel is raised anteriorly toward the intercostal space (marked with an X) medial to the top of the pectus ridge. If the site chosen is beneath the pectoralis major muscle, a subpectoral plane is developed. **C,** A Lorenz introducer is inserted into the subcutaneous tunnel on the right. Under thoracoscopic guidance, it is pushed through the right intercostal space marked with an X. **D,** Under thoracoscopic guidance, a transthoracic substernal tunnel is created by dissecting the pleura and pericardium off the undersurface of the sternum with the introducer. The scope position must be advanced and adjusted as the dissection proceeds from right to left, but there should be excellent visualization. A 30-degree angled scope may facilitate this process. The introducer is pushed through the left intercostal space (marked with an X) and advanced out of the left lateral thoracic incision. **E,** The sternum is elevated out of its depressed position by lifting the introducer on each side while applying pressure to the lower costal margin. The lifting is repeated until the pectus excavatum is corrected. **F,** After correcting the pectus excavatum, umbilical tape is attached to the end of the introducer, which is then slowly withdrawn from the chest, thereby pulling the umbilical tape through the transthoracic tunnel.

*Continued*

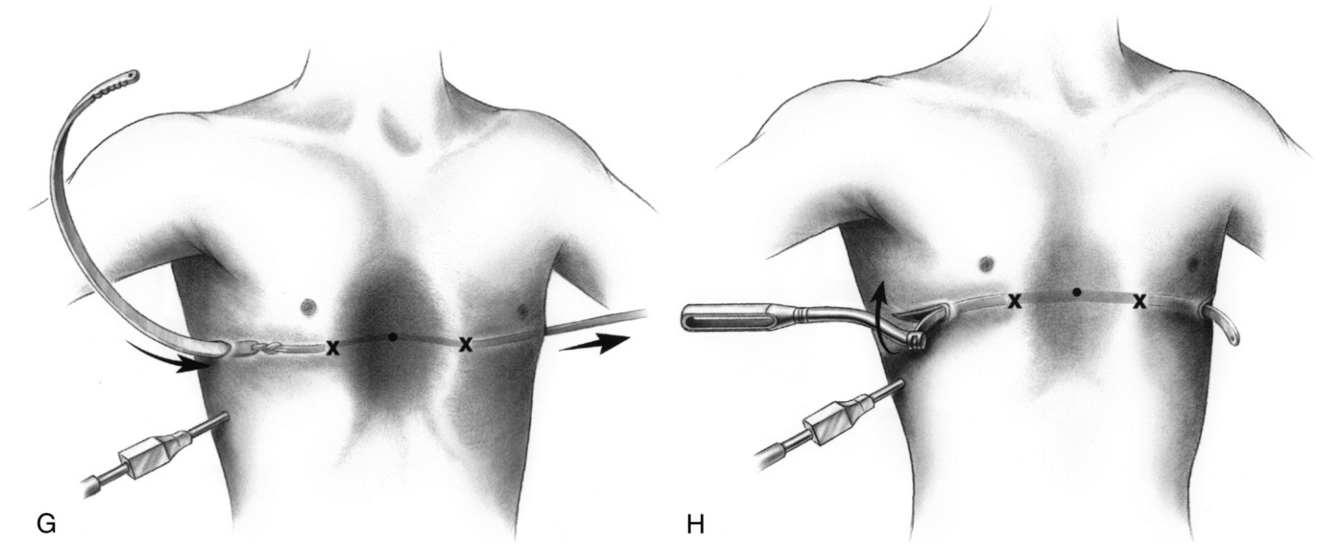

**FIGURE 62-5—CONT'D** **G,** The previously prepared pectus support bar is tied to the umbilical tape and, under thoracoscopic guidance, is pulled through the substernal tunnel, with the convexity facing posteriorly. **H,** When the bar is in position, it is rotated 180 degrees using the bar flipper.

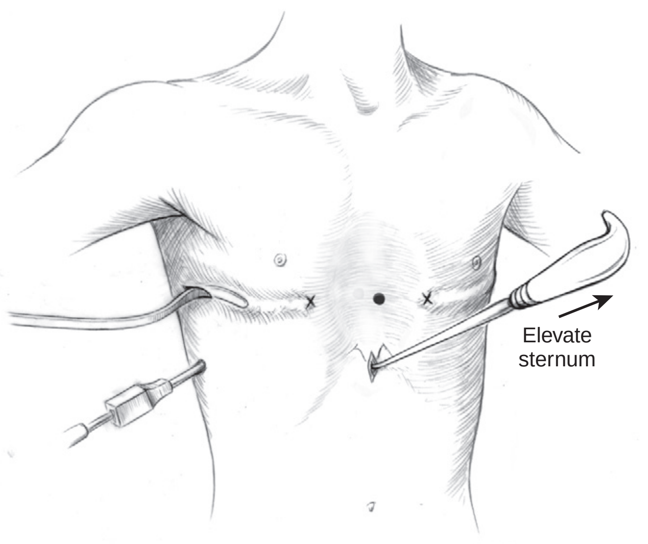

**FIGURE 62-6** Lifting the sternum with a bone hook improves the view of dissection between the sternum and pericardium.

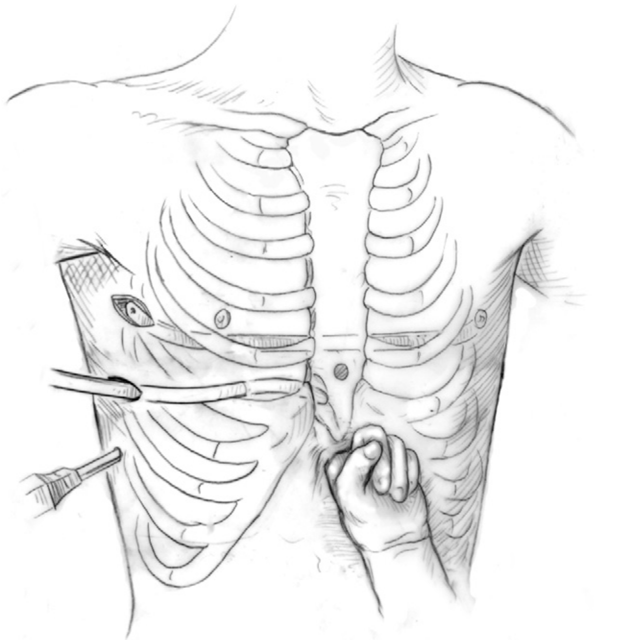

**FIGURE 62-7** Inserting a finger posterior to the sternum can allow dissection between the sternum and pericardium. The finger can guide the introducer across from right to left. Pneumothorax (which facilities thoracoscopy) is difficult to maintain after this opening is created, until the wound is closed.

### LATE COMPLICATIONS

Sixty-four patients (5.7%) experienced bar displacement. The incidence of bar displacement has fallen dramatically as we have gained experience with the procedure, and the incidence of bar displacement is now less than 1%. Deep infection, involving the bar (not superficial wound infection) occurred in six patients (0.5%), requiring early bar removal in three (0.2%).

Allergy to the bars has occurred in about 3% of patients overall but has been almost entirely prevented by patch testing after our group recognized and reported the problem.[112] These presented as rashes in the area of the bar or the stabilizer, sterile abscesses at the incision site, and pleural and/or pericardial effusions. Of all our primary surgery patients, 22 (2.0%) developed a moderate overcorrection of their deformity, and 4 (0.4%) developed a true carinatum deformity. We believe that the incidence of this problem has diminished with increased experience in bending the bar.

## Results

Of 1215 patients, 1123 had primary surgery (not re-do) operations. Of those, 790 have had the bar removed. A good or excellent result was obtained in 96%, fair in 1.4%, and

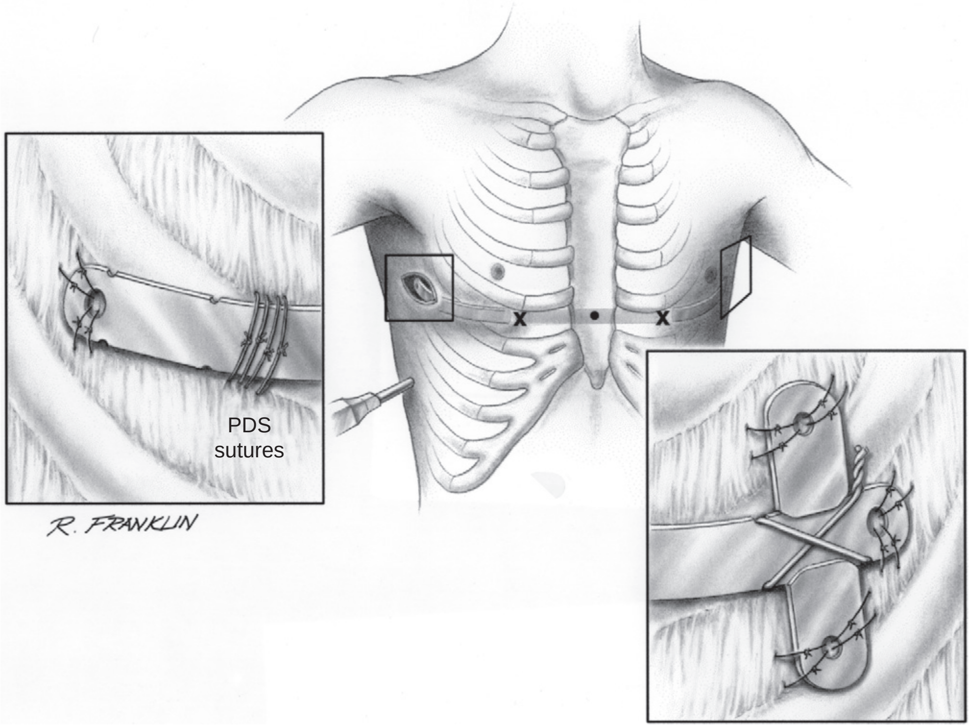

FIGURE 62-8 Stabilization of the bar is essential. A stabilizer is inserted on the left (the right may also be used) end of the bar and secured to the bar with No. 3 surgical steel wire. If the bar does not seem stable, usually a second bar rather than a second stabilizer is called for. On the right side, heavy absorbable sutures (0 or 1 polydioxanone sutures [PDS]) are placed around the bar and underlying rib. These are placed with an EndoCatch needle (Covidien, Mansfield, Mass.) with thoracoscopic guidance. In addition, heavy (0) absorbable (Vicryl) sutures are placed through the holes in the bar and stabilizer and in the underlying fascia. Hebra and colleagues advocate placing a suture adjacent to the sternum.[110a]

poor in 0.8%. Recurrence requiring re-do operation occurred in 11 patients (1.4%).

## Protrusion Deformities: Pectus Carinatum

Pectus carinatum consists of a spectrum of deformities that are less frequent than pectus excavatum by a ratio of 1:5 in North America.[60] In a recent report of 7,878 children from Buenos Aires, Argentina, it comprised 55% of chest wall deformities.[30] A recent report from Manaus, Brazil found the frequency to be half that of pectus excavatum (prevalance of pectus carinatum was 0.675% in 1332 11- to 14-year-old students).[4] It occurs more frequently in boys than in girls (4:1), as does pectus excavatum. In many of the children, the deformity is not appreciated until after the 11th birthday. A mild deformity noted at birth or in early childhood often worsens as the child grows, particularly at puberty. As a result, most children present for treatment as teenagers.

### CAUSE

The origin of pectus carinatum is no better established than that of pectus excavatum. Early investigators implicated abnormal development of the diaphragm, but this has never been confirmed.[10,12] Others proposed that excessive growth of the ribs or costal cartilages produces either pectus carinatum or pectus excavatum.[100] Two associations provide

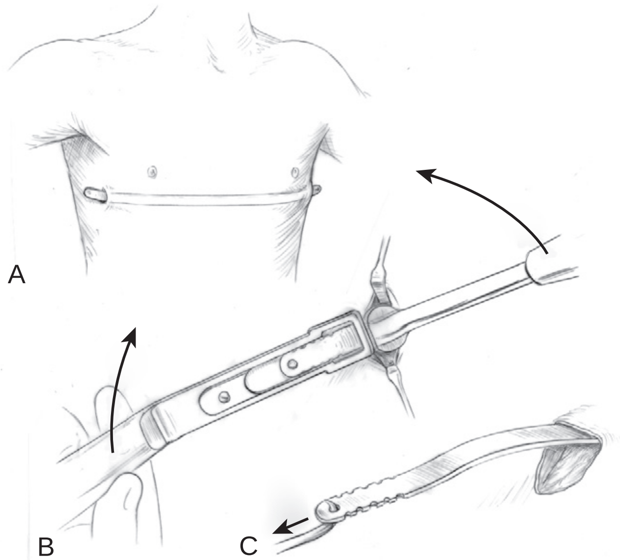

FIGURE 62-9 The bar and stabilizer are removed 2 or 3 years after insertion under general anesthesia. Position the patient supine, with both arms abducted at the shoulder. **A,** Bar removal is performed by opening both lateral incisions. The fibrous scar encasing the bar is freed from the serrations and holes in the bar and stabilizer. Rongeurs are used to remove any reactive bony overgrowth holding the bar. When this is done, the bar should move easily in the fibrous tunnel, with finger pressure at the end of the bar. **B,** Finger pressure is used to push the bar inside its sheath so that more protrudes from one side. The Malti bender is used to flatten the bar. The bar is then pushed with finger pressure on the end of the bar so that the other side protrudes from the skin. Then the other side is flattened. **C,** A bone hook is used to pull the bar out. It should come out with minimal resistance.

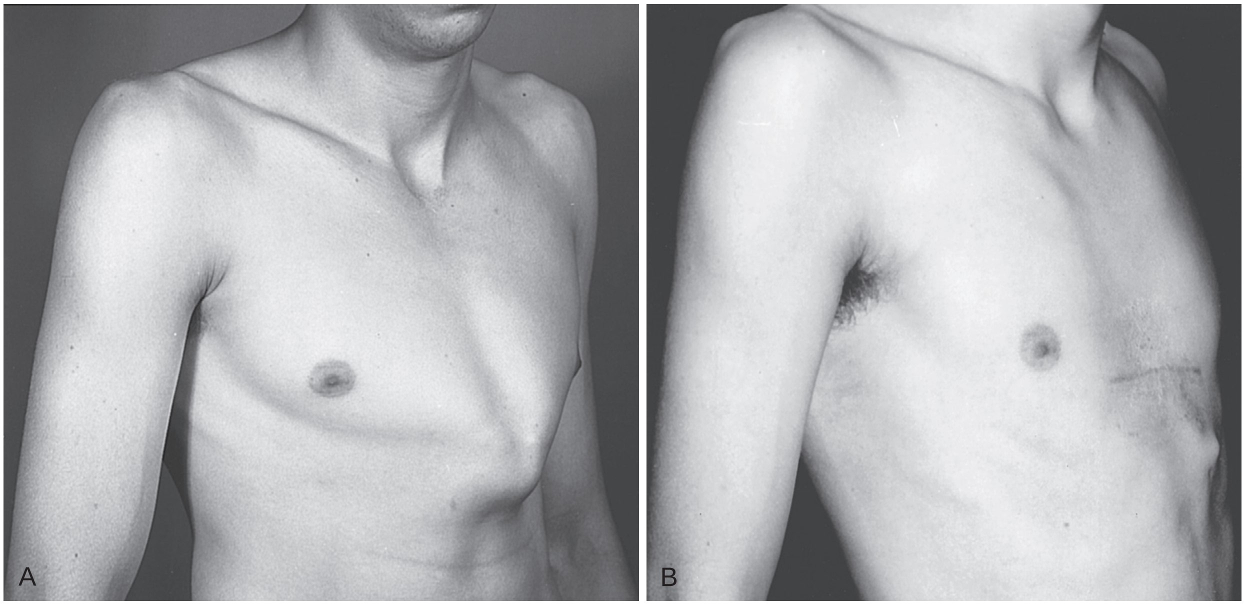

FIGURE 62-10 **A,** Nineteen-year-old man with symmetric chondrogladiolar pectus carinatum. **B,** Postoperative photograph shows correction of the protruding sternum and costal cartilages. (From Shamberger RC: Chest wall deformities. In Shields TW [ed]: General Thoracic Surgery, ed 5. Philadelphia, Lippincott Williams & Wilkins, 2000.)

some clues to its origin: (1) a family history of chest wall deformity has been identified in 26% of patients, suggesting some genetic predisposition,[60] and (2) scoliosis in 15% of patients implies a diffuse abnormality in connective tissue development.

## CLINICAL PRESENTATION

The most frequent form of pectus carinatum is symmetric protrusion of the body of the sternum (gladiolus) and costal cartilages, termed chondrogladiolar protrusion (Fig. 62-10). An associated lateral depression of the ribs (runnels or Harrison grooves) is often present. It has been likened to a giant hand crushing the chest from each side.[113] Protrusion can also be asymmetric, limited to one side of the sternum, with the costal cartilages producing a keel-like protrusion (Fig. 62-11). Tenderness at the area of sternal prominence when lying prone is commonly described. Though some patients are asymptomatic, a minority of patients clearly report pain in the area of the protrusion and/or exercise limitation. A mixed deformity also occurs with components of both protrusion and depression. The sternum is often rotated posteriorly toward the depressed side. This variant is most frequently seen in conjunction with Poland syndrome.

The rarest form of pectus carinatum, chondromanubrial protrusion, is produced by protrusion of the manubrium and the superior costal cartilages, with a relative depression of the body of the sternum (Fig. 62-12). It is frequently associated with premature fusion of the sternal sutures and a broad comma-shaped or Z-shaped sternum. An increased incidence of congenital heart disease has been identified in these children.[114] Lees and Caldicott[115] identified anomalies of sternal fusion in 135 of 1915 children. Twenty percent of those with sternal fusion had congenital heart disease.

FIGURE 62-11 Twelve-year-old boy with asymmetric pectus carinatum has protrusion of the costal cartilages on only the right side, producing a keel-like deformity. (From Shamberger RC: Chest wall deformities. In Shields TW [ed]: General Thoracic Surgery, ed 5. Philadelphia, Lippincott Williams & Wilkins, 2000.)

## TREATMENT

Surgical repair of pectus carinatum has a colorful past that has been reviewed elsewhere.[60] In 1973, Welch and Vos[116] reported their approach to these deformities in 26 children. They stressed the need to preserve the perichondrial sheaths and to tailor the osteotomies to achieve the appropriate position of the sternum. A similar method was used by Pickard and colleagues.[117]

Fonkalsrud reported excellent results and minimal complications in a series of 260 patients over 37 years. All were

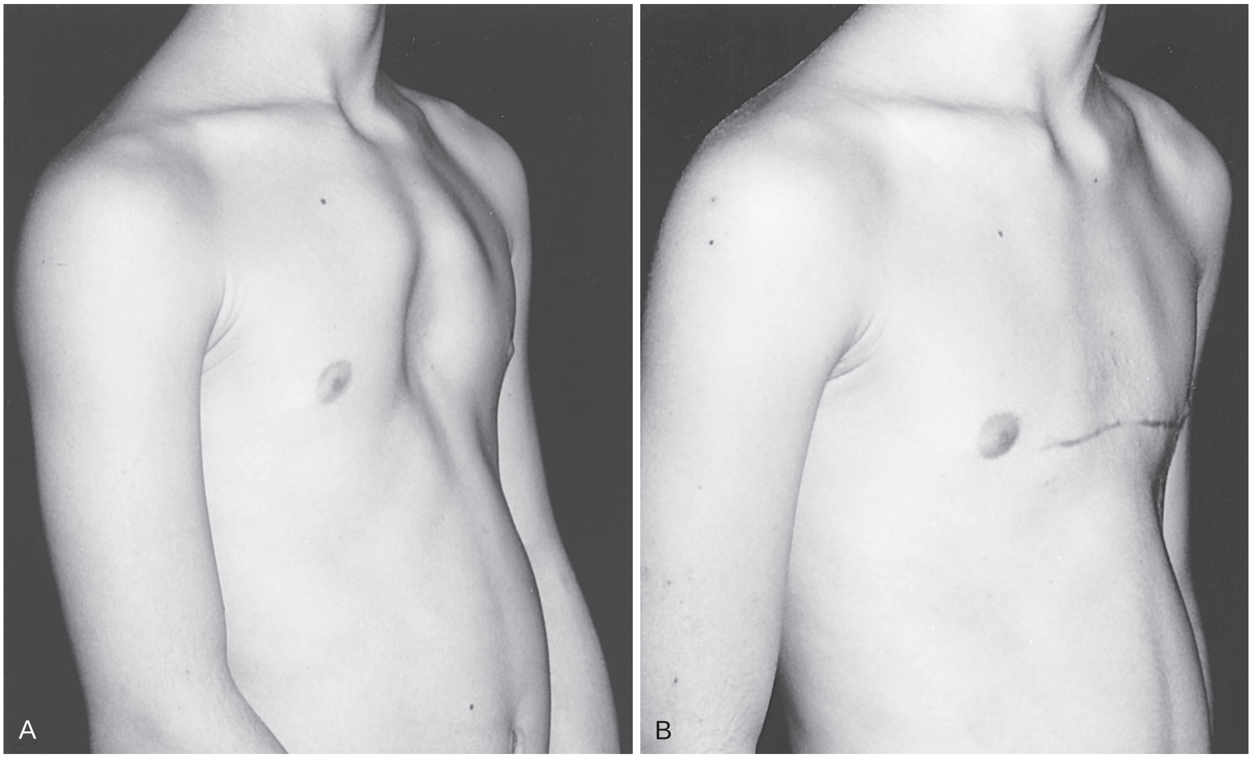

**FIGURE 62-12** **A,** Fifteen-year-old boy with chondromanubrial deformity. Note the posterior depression of the lower sternum accentuated by the anterior bowing of the second and third costal cartilages. **B,** After repair, the sternal contour is improved, and costal cartilages re-form in a more appropriate position.

symptomatic preoperative and had a cardiothoracic index by chest radiograph or CT scan of less than 2.[118]

Attempts to treat pectus carinatum by orthotic bracing have been reported, beginning in 1992 in Brazil. Evolution of bracing devices has led to increased success, and presently, several reports suggest that 65% to 80% of children will have resolution with brace treatment alone. Recently, efforts have focused on making the brace easy to conceal and comfortable to wear. Bracing strategies that work toward incremental correction over several months have met with better success than previous efforts. Brace treatment is best carried out in conjunction with physical therapists and/or physical medicine and rehabilitation physicians, who do most brace treatment in pediatric hospitals.[119–121] In teenagers, poor compliance with bracing programs can be addressed by peer pressure at a bracing clinic, along the lines of a spina bifida clinic.

## SURGICAL TECHNIQUE (OPEN PROCEDURE)

Initial exposure for repair of pectus carinatum is through a transverse incision identical to that for pectus excavatum repair, followed by mobilization of skin and pectoral muscle flaps. Many authors stress the need to remove all deformed or partially deformed cartilages, because with continued growth, mild deformities worsen and become apparent.[122,123] In the chondrogladiolar deformity, a single or, occasionally, a double osteotomy allows the posterior plate of the sternum to be fractured, returning the sternum to a normal position (Fig. 62-13, *A*). The wound is drained and closed in a fashion identical to that for pectus excavatum repair.

In the mixed deformity, the oblique position of the sternum must be corrected, as well as the position of the depressed and protruding costal cartilages. After subperichondrial resection of the abnormal costal cartilages is completed, a wedge-shaped osteotomy is created in the anterior sternal plate, with the broad portion of the wedge on the depressed side of the sternum (Fig. 62-13, *B*). Closure of the osteotomy both elevates and rotates the sternum into a corrected position. It is secured with sutures to close the osteotomy or with a strut.

With chondromanubrial and mixed deformities, management of the sternum requires special consideration. In the chondromanubrial form, the upper position of the sternum protrudes, and the lower body is angled toward the spine. In Ravitch's[66] first description of the repair of this deformity, he removed a wedge of the anterior plate of the sternum at its point of maximal protrusion and created a second osteotomy at the site of the second angle of the Z-shaped sternum. In our experience, the sternum has been comma shaped and truncated; so, a second osteotomy was not required (Fig. 62-13, *C*).[124] When the osteotomy is closed, both the posterior depression of the lower portion of the sternum and the anterior angulation of the manubrium are corrected as the manubrium rotates posteriorly on its attachment to the first costal cartilage.

## COMPLICATIONS

Complications of repair should be infrequent, including infection, pneumothorax, pneumonia, or wound separation. Blood transfusions are rarely required with the use of electrocautery. Results from correction are overwhelmingly

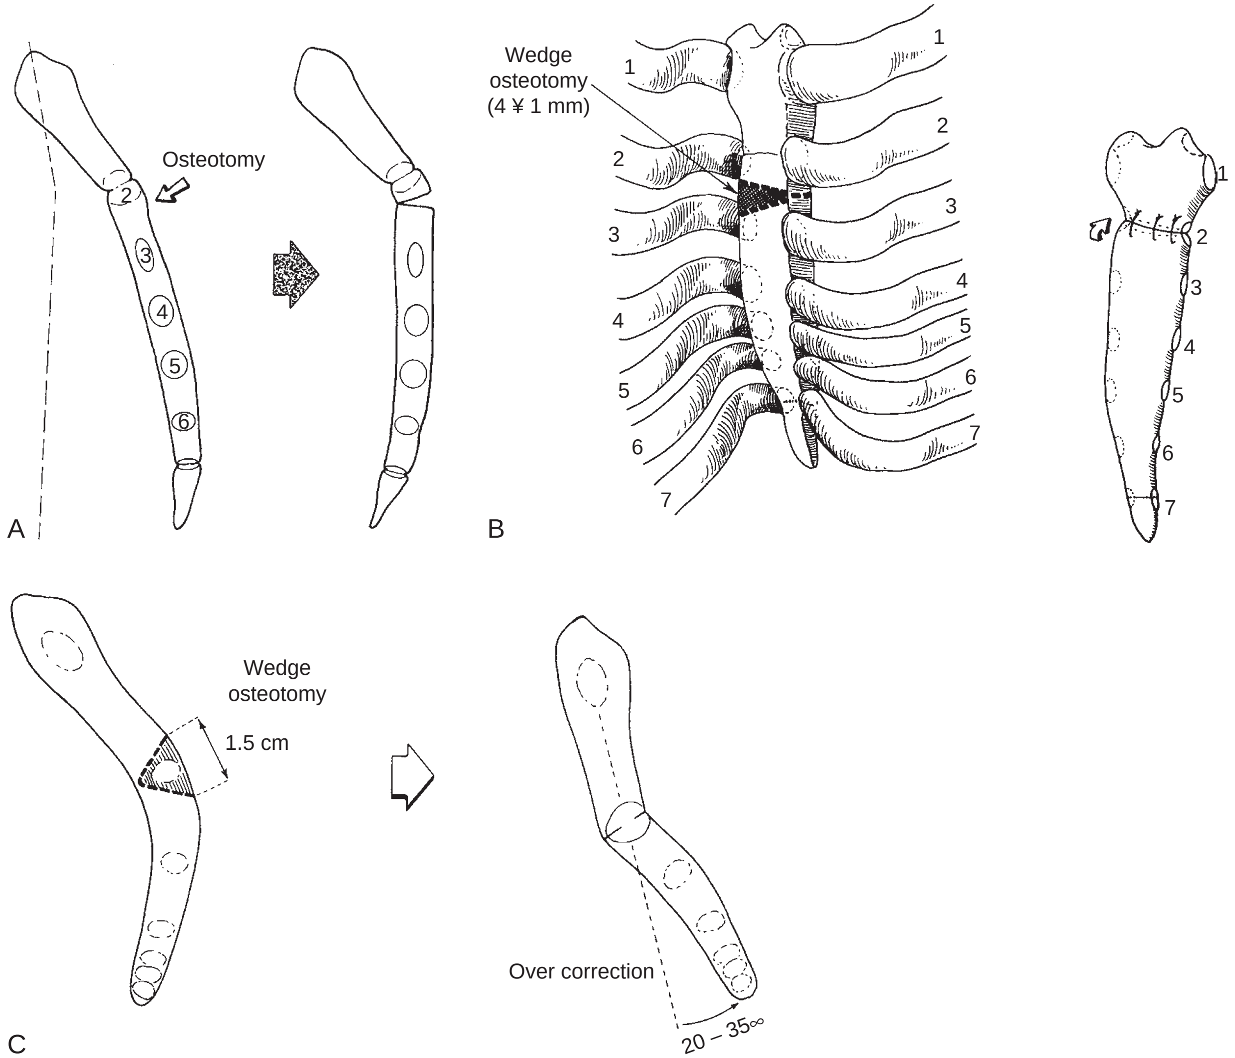

**FIGURE 62-13** **A,** Single or double osteotomy after resection of the costal cartilages allows posterior displacement of the sternum to an orthotopic position. **B,** Mixed pectus deformity is corrected by full and symmetric resection of the third to seventh costal cartilages, followed by transverse offset wedge-shaped sternal osteotomy. Closure of this defect permits both anterior displacement and rotation of the sternum. **C,** Chondromanubrial deformity is corrected with a broad, wedge-shaped sternal osteotomy placed through the anterior cortex at the obliterated sternomanubrial junction. Closure of the osteotomy after fracture of the posterior cortex achieves posterior displacement of the superior portion of the sternum, which is secured only by its attachment to the first rib. The lower portion of the sternum is overcorrected 20 to 35 degrees. (**B,** From Shamberger RC, Welch KJ: Surgical correction of pectus carinatum. J Pediatr Surg 1987;22:48-53. **C,** From Shamberger RC, Welch KJ: Surgical correction of chondromanubrial deformity [Currarino-Silverman syndrome]. J Pediatr Surg 1988;34:319-322.)

successful, and recurrence is rare. Incomplete correction of the deformity and repair at an early age before complete development of the deformity are the primary reasons for reoperation.[122,123]

## Surgical Technique, Minimally Invasive Procedures

Recently, Horacio Abramson of Buenos Aires, where there is a high incidence of pectus carinatum, has modified Nuss's operation for pectus excavatum to treat pectus carinatum.[125] In 2008, he described a series of 40 patients treated by passing a stainless steel bar anterior to the sternum subcutaneously/submuscularly and securing the bar to the ribs to hold the sternum in position.[126] Though still in evolution, this procedure appears likely to become a standard operative approach to treatment of pectus carinatum. In 2009, Kim and Odowu reported from Oakland the repair of the deformity by thoracoscopic cartilage resection, and the combination of these two approaches has met with early success at CHKD. Confirmation of broad applicability and long-term results are pending.[127]

## Poland Syndrome

The initial description of Poland syndrome appeared in the English literature in 1841,[128] although German and French cases had been described earlier.[100,129] Poland reported a case in which he performed an anatomic dissection while still a medical student. He described a constellation of anomalies,

including absence of the pectoralis major and minor muscles and syndactyly. Subsequent reports added other components of the syndrome, including absence of ribs, chest wall depression, athelia or amastia, absence of axillary hair, and limited subcutaneous fat. Thompson first summarized the full spectrum of anomalies in 1895.[100] Although described previously by others, this syndrome has been labeled Poland syndrome since 1962, when Clarkson[130] first applied this eponym to a group of patients.

## EMBRYOLOGY

Poland syndrome has a sporadic occurrence estimated at 1 in 30,000 to 32,000 live births; it is rarely familial.[131,132] Various causes have been suggested, including abnormal migration of the embryonic tissues forming the pectoral muscles, hypoplasia of the subclavian artery, and in utero injuries from attempted abortion, but none of these theories has been uniformly accepted.[133,134] Although some forms of syndactyly have been described as autosomal dominant traits, a similar pattern has not been demonstrated in patients with Poland syndrome, which is generally sporadic. Poland syndrome is associated with a second rare syndrome, Möbius syndrome, involving bilateral or unilateral facial palsy and abducens oculi palsy. Fontaine and Ovlaque[135] identified 19 such cases with these combined syndromes, but a unifying cause was lacking. Boaz and colleagues[136] reported an unusual association between Poland syndrome and childhood leukemia.

## CLINICAL PRESENTATION

Children demonstrate remarkable diversity in this syndrome (Fig. 62-14). The predominant defect varies, depending on the extent of involvement of the different components. By definition, all children with Poland syndrome have aplasia or hypoplasia of the sternocostal portion of the pectoralis major muscle and at least one other associated lesion. The degree of abnormality of the hand, breast, or chest wall can be quite variable. Thompson, in his early summary of this syndrome, found the pectoralis major muscle entirely absent in 20 cases and partially defective in 63; generally, the sternocostal component is the missing portion.[100] The pectoralis minor was described as absent in 53 cases and defective in many others. In no case was it described as normal. Children do not present with functional deficiency of the ipsilateral arm, however, because they compensate well for the missing pectoral muscles. Hand anomalies vary widely. In the report by Ireland and colleagues,[137] all their patients had syndactyly and a variable degree of brachydactyly, an obvious result of the authors' patient selection and referral patterns.[138] Al-Qattan has reported a recent classification of the hand anomalies occurring in Poland syndrome, recognizing the broad spectrum seen ranging from a perfectly normal hand or one with mild brachysyndactyly to those with severe loss of the central digits to the rarest and most severe cases with phocomelia-like deficiency.[138] In another series of 75 children with Poland syndrome, 50 had anomalies of the hand, and 37 had absence or hypoplasia of the breast or nipple.[139] In many, the nipple was lightly pigmented and higher on the chest than the normal contralateral nipple. There was no correlation between the severity of chest wall and hand anomalies. A broad range of thoracic deformities was seen in these children, ranging from a normal configuration of the ribs to aplasia of two to three ribs (Table 62-2; Fig. 62-15). Few children have a chest wall deformity so severe that it requires surgery.

CT scans have proved helpful in assessing the configuration of the chest wall and its need for reconstruction (Fig. 62-16).[15] CT scans can also evaluate the extent of muscular involvement. In one case, failure of a latissimus dorsi myocutaneous flap was attributed to unrecognized hypoplasia of the latissimus dorsi muscle.[140] All patients with absent ribs should be considered candidates for repair. The aplastic ribs are generally some combination of the second to the fifth, with the second being least frequently involved.[100] Only two cases have been published in which there was involvement of all the ribs inserting into the sternum below the first. Patients with a severe ipsilateral concave deformity of the chest wall should also be considered for repair.

## TREATMENT

Ravitch[67] and others have described reconstruction of aplastic ribs with autologous rib grafts. Use of the latissimus dorsi muscle to provide coverage for the ribs produces an improved appearance, but involves the possibility of functional loss when the pectoralis major muscle is also hypoplastic.[141–143] Use of the latissimus dorsi flap may be justified in females to optimize breast reconstruction, but its use in males—in whom arm strength is more important—is subject to debate, although it has been combined with implants in males to correct hypoplasia of the chest wall.[144] Haller and colleagues[145] and Urschel and colleagues,[146] in separate reports published in 1984, combined simultaneous latissimus dorsi muscle flaps with placement of rib grafts or Marlex mesh. The vital components of chest wall repair include correction of the abnormal position and rotation of the sternum, as well as replacement of the aplastic ribs. Haller and colleagues[147] described the frequent carinate deformity of the contralateral ribs, which require resection to optimize results. Resection also allows correction of the depression and rotation of the sternum. Hypoplasia of the ribs without localized depression is not surgically correctable (see Fig. 62-15, *A* to *C*).

## SURGICAL TECHNIQUE

Initial exposure of the chest wall is obtained through a transverse incision, as for pectus excavatum repair (Fig. 62-17, *A*). In patients requiring surgical correction, there is invariably severe depression of the involved side (occasionally with absent ribs) and rotation of the sternum, often producing a carinate protrusion on the contralateral side (Fig. 62-17, *B*). Caution must be used during this dissection when ribs are absent, because there is only a thin layer of attenuated pectoral fascia between the skin flaps and the endothoracic fascia (Fig. 62-17, *C*). Violation of this layer should be avoided to prevent entry into the thoracic cavity.

Subperichondrial resection of the costal cartilages is performed on both sides, removing the entire third, fourth, and fifth cartilages up to the costochondral junctions, which are preserved. Segments of the sixth and seventh costal cartilages are resected to the point where they flatten to join the costal arch. To correct the rotational deformity of the sternum and the depression of the involved ribs, a transverse wedge-shaped osteotomy is placed, as for the mixed pectus carinatum

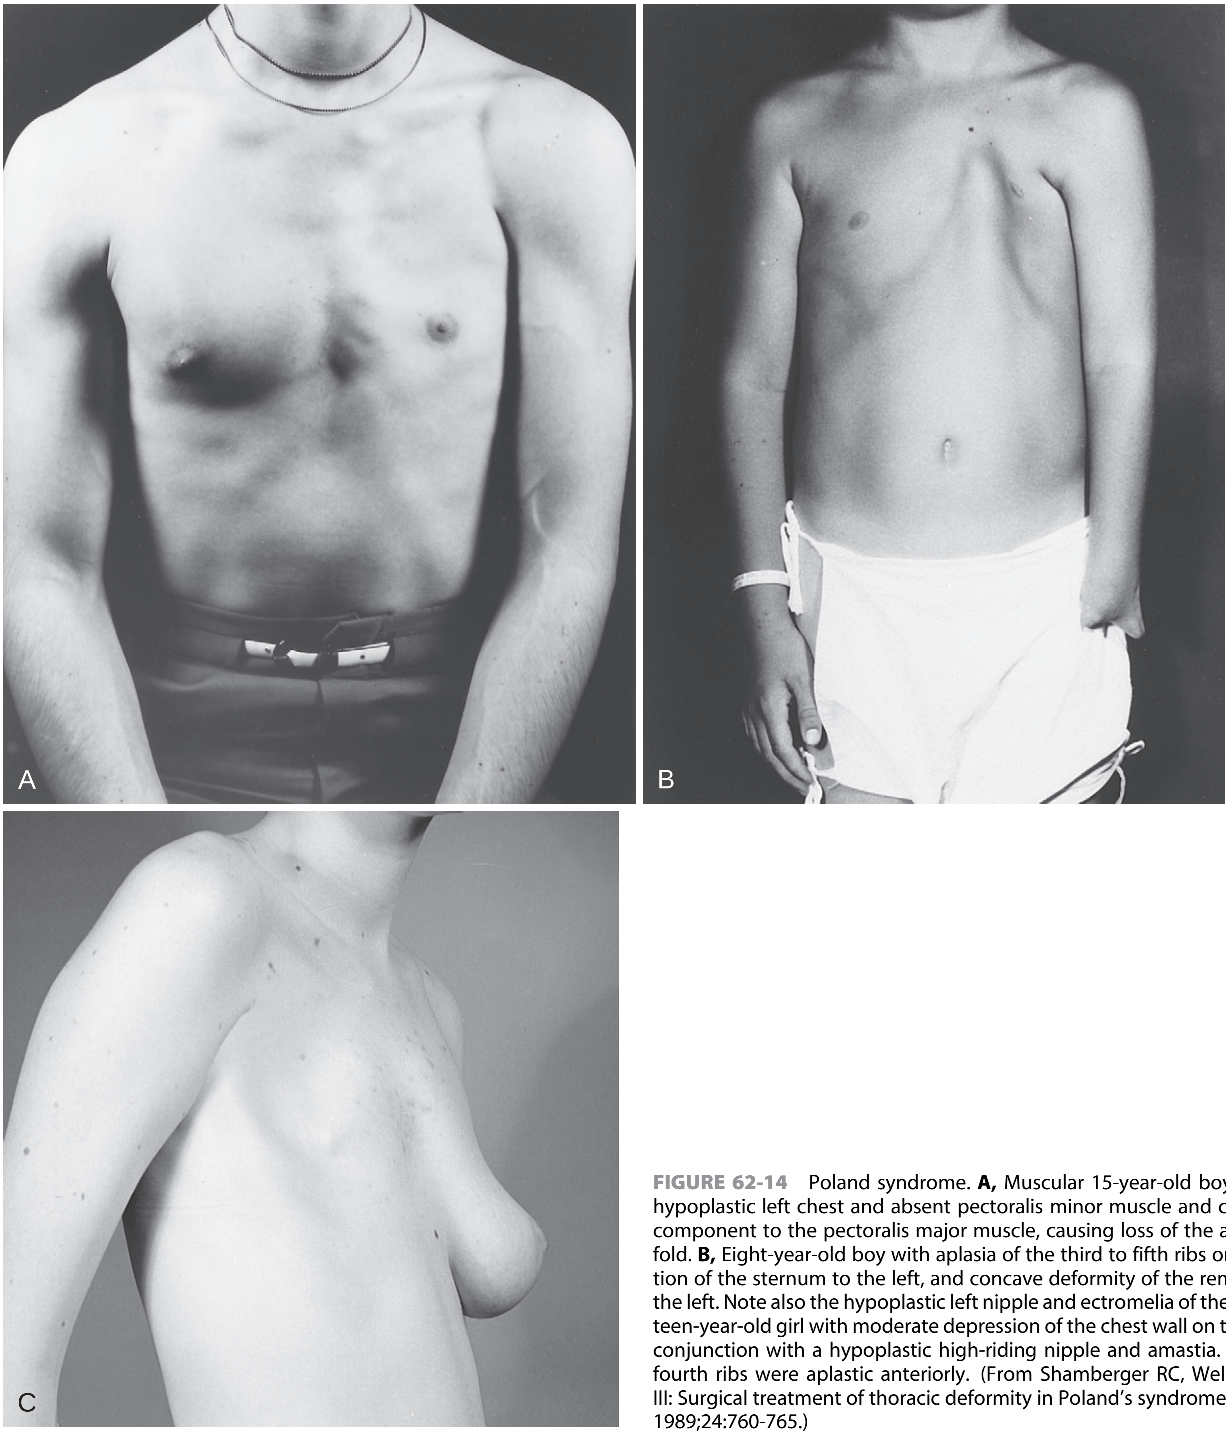

**FIGURE 62-14** Poland syndrome. **A,** Muscular 15-year-old boy with a mildly hypoplastic left chest and absent pectoralis minor muscle and costomanubrial component to the pectoralis major muscle, causing loss of the anterior axillary fold. **B,** Eight-year-old boy with aplasia of the third to fifth ribs on the left, rotation of the sternum to the left, and concave deformity of the remaining ribs on the left. Note also the hypoplastic left nipple and ectromelia of the hand. **C,** Fourteen-year-old girl with moderate depression of the chest wall on the right side in conjunction with a hypoplastic high-riding nipple and amastia. The second to fourth ribs were aplastic anteriorly. (From Shamberger RC, Welch KJ, Upton J III: Surgical treatment of thoracic deformity in Poland's syndrome. J Pediatr Surg 1989;24:760-765.)

deformity (Fig. 62-17, *D*). Closure of this osteotomy corrects both components of the abnormal sternal position. In patients with absence of the second, third, and fourth ribs, a rib graft is harvested from the contralateral fifth or sixth rib through the anterior incision used for the repair; the periosteum is left in situ to allow regeneration of the rib. A split rib graft is generally used to facilitate revascularization of the graft through the marrow cavity. This often achieves correction of the defect with only one harvested rib (Fig. 62-17, *E*). The graft is secured to notches created in the sternum before bringing the sternum anteriorly and to the involved ribs laterally with wire sutures placed through drill holes in the native rib and the graft. The rib grafts can be covered with a prosthetic mesh if further support is needed.

Breast reconstruction is required in most girls, but is best delayed until late puberty to optimize the match between the contralateral and reconstructed breasts. Implants are generally required, often in conjunction with a latissimus dorsi

**TABLE 62-2**

**Chest Wall Deformities in 75 Patients with Poland Syndrome**

| *Deformity* | *No. of Patients* |
|---|---|
| None | 41 |
| Hypoplasia of ribs without depression | 10 |
| Depression deformity of ribs | |
| Major | 11 |
| Minor | 5 |
| Aplasia of ribs | 8 |

flap. Customized implants have been used that correct both the hypoplasia of the chest wall and the absent breast tissue, but they have not been uniformly successful.[148–151]

### COMPLICATIONS AND OUTCOME

The patient, his or her parents, and the surgeon must enter into correction of this deformity with appropriate expectations. The components of the chest wall deformity must be well defined to identify the correctable factors. Diffuse hypoplasia of the ribs without depression is not correctable. Ipsilateral depression and contralateral protrusion with rotation of the sternum can generally be improved, as can aplasia of the ribs. The concavity below the clavicle created by the hypoplastic pectoralis major muscle is frequently bothersome in girls, because this area is apparent when wearing a bathing suit or gown. It can be partially corrected with rotation of the latissimus dorsi muscle flap at the time of breast reconstruction, but these flaps have been noted to atrophy with time.[144]

## Sternal Defects

Sternal defects are rare compared with pectus excavatum and pectus carinatum, yet they have received a great deal of attention in the medical literature. Indeed, documentation of their occurrence dates to the ancient cuneiform tablets that made up the Royal Library of Nineveh.[1]

Translations of those tablets reveal that the ancients believed that births with "the heart open, and that has no skin" predicted calamity. Dramatic presentations of such defects since that time, particularly involving the naked heart, have led to many isolated case reports in the modern medical literature, as well as several excellent reviews.

Weese provided the first anatomic classification of sternal defects in 1818, dividing them into ectopia cordis cum sterni fissura, ectopia suprathoracica, and ectopia subthoracica.[100] Breschet, in 1826, provided three comparable

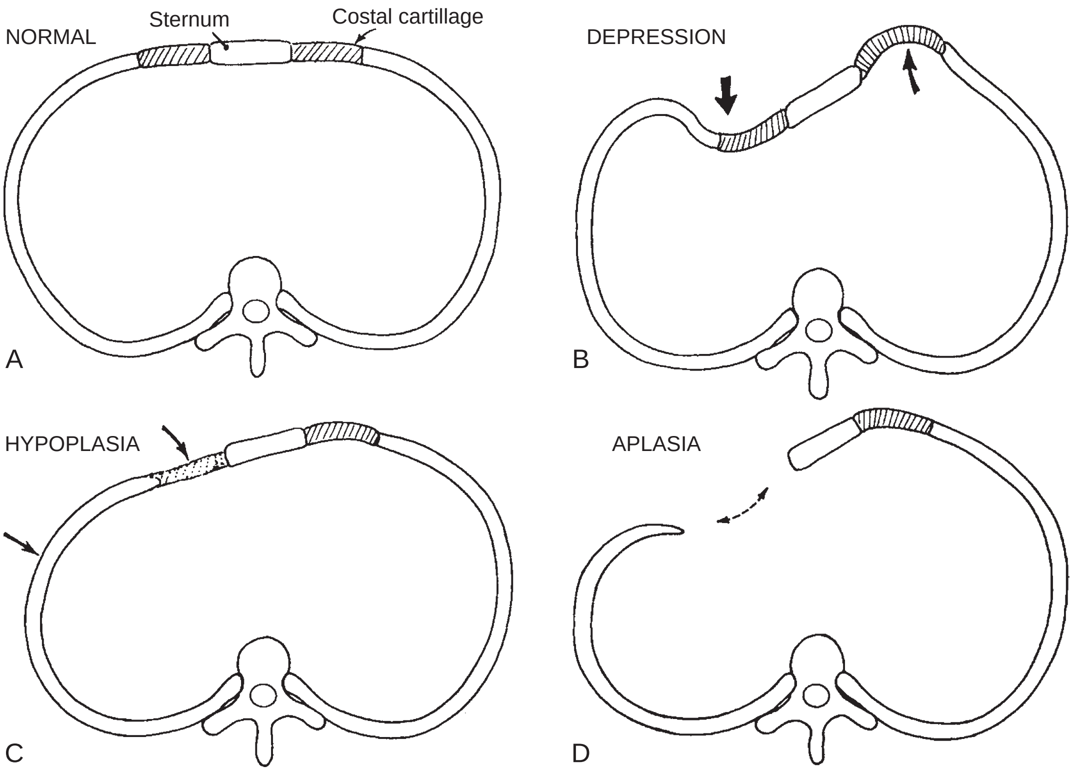

**FIGURE 62-15** Spectrum of rib cage abnormalities seen in Poland syndrome. **A,** Most frequently, the rib cage is normal, with only absent pectoral muscles. **B,** Depression of the involved side of the chest wall, with rotation and often depression of the sternum. A carinate protrusion of the contralateral side is frequently present. **C,** Hypoplasia of ribs on the involved side but without significant depression. This usually does not require surgical correction. **D,** Aplasia of one or more ribs is usually associated with depression of adjacent ribs on the involved side and rotation of the sternum. (From Shamberger RC, Welch KJ, Upton J III: Surgical treatment of thoracic deformity in Poland's syndrome. J Pediatr Surg 1989;24:760-765.)

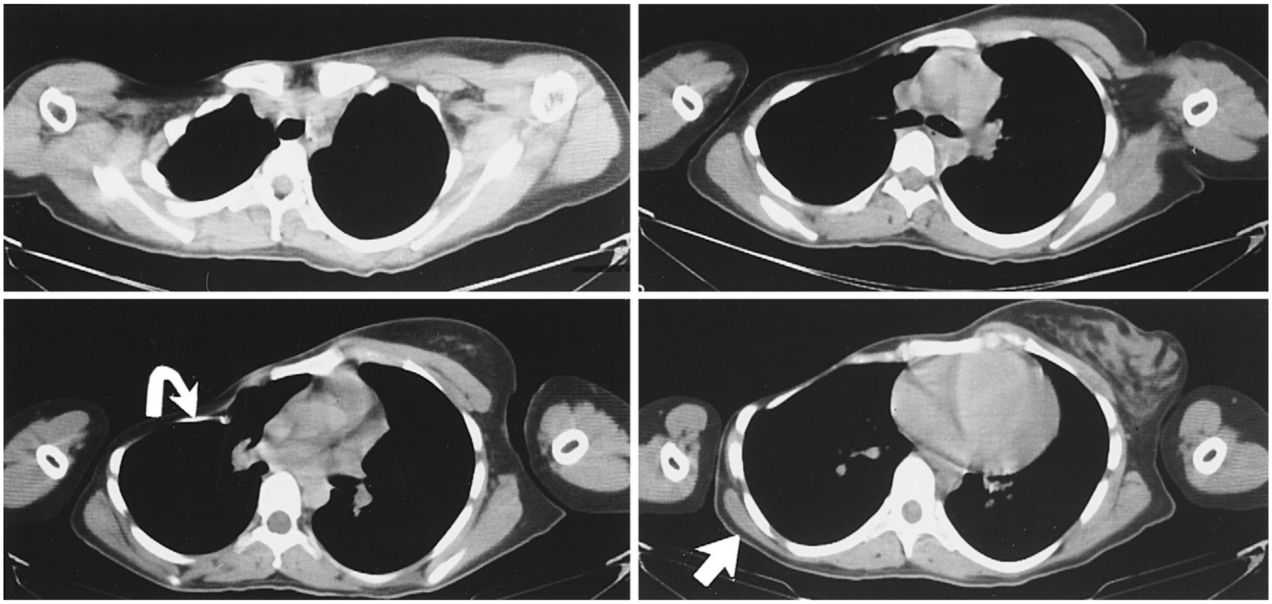

FIGURE 62-16 Computed tomography scan of the patient shown in Figure 62-14, *C*. Marked depression of the ribs is apparent (*curved arrow*), as well as aplasia of the ribs in the lower two frames. Hypoplasia of the latissimus dorsi muscle is also noted on the lower right frame (*straight arrow*). (From Shamberger RC, Welch KJ, Upton J III: Surgical treatment of thoracic deformity in Poland's syndrome. J Pediatr Surg 1989;24:760-765.)

divisions: ectopie thoracique du coeur, ectopie abdominale, and ectopie céphalique.[100] Roth, in 1939, divided these lesions into ectopia cordis thoracalis extrathoracica, ectopia cordis ventralis, and ectopia cordis suprathoracica (cervicalis); the first division was further subdivided into defects in the manubrium, defects in the body of the sternum, and ectopia cordis pectoralis sternoepigastrica.[100] Similarly, Shao-tsu[100] divided sternal defects into ectopia cordis cervicalis, with the heart in the neck; ectopia cordis thoracalis, with the heart outside the thorax and a sternal fissure; ectopia cordis thoracoabdominalis; and ectopia cordis abdominalis.

Despite these classifications, subsequent case reports often blurred the divisions and confused the field that had been so well defined by early authors. One sternal defect that was not accounted for in these classifications was the bifid or cleft sternum. In this deformity, the heart is in an orthotopic position in the thoracic cavity, but the sternum is cleft or only partially fused overlying the heart. Skin coverage is normal or with only a small superficial ulceration.

More than a century after these descriptions and classifications, Cantrell and Ravitch[152] summarized a group of patients with ectopia subthoracica or ectopia abdominale deformity, along with its associated defects of the diaphragm, pericardium, abdominal wall, and heart.

Subsequently, these patients were often referred to as having the Cantrell pentalogy, only adding to the confusion. A more recent report summarized the world literature and tabulated the associated anomalies that occur in these infants and children.[153] Review of this topic provides four basic types of sternal defects based on tissue coverage of the heart, with limited overlap between categories. Further divisions seem artificial and do not clarify the anatomy or have prognostic significance.

## THORACIC ECTOPIA CORDIS

Thoracic ectopia cordis consists of the ectopia cordis cum sterni fissura of Weese and the ectopie thoracique du coeur of Breschet. These lesions constitute the classical naked heart with no overlying somatic structures. The orientation of the apex of the heart is anterior and often superior (Fig. 62-18). Intrinsic cardiac anomalies are frequent, and associated lesions have been summarized.[153] Many case reports do not provide information on the intrinsic cardiac anatomy because of the striking external appearance of the heart. The sternum may be intact superiorly at the manubrium or entirely split; in rare cases, the heart may protrude through a defect in the central portion of the sternum. There is a severe lack of midline somatic tissues, and many attempts at primary closure have failed. Evaluation by CT has confirmed that the intrathoracic cavity is small in these infants.[154] Most successful repairs have not been achieved in true thoracic ectopia cordis but rather in thoracoabdominal ectopia cordis. Cutler and Wilens[155] first attempted repair in 1925 by skin flap coverage, but this failed because of cessation of cardiac function, presumably from pressure on the heart. In more than 29 attempts, only six survivors have been recorded.[156–162] The first successful repair of ectopia cordis was achieved by Koop in 1975, as reported by Saxena.[159] An infant with a normal heart had skin flap coverage at 5 hours of age, with inferior mobilization of the anterior attachments of the diaphragm. The sternal bands were 2 inches apart and could not be approximated primarily without cardiac compression and compromise. At 7 months of age, an acrylic resin of Dacron and Marlex mesh was inserted to widen the sternal cleft, with primary skin closure. Necrosis of the skin flaps complicated the postoperative course, and infection of the prosthetic material necessitated its removal. This child has survived to age 18 years and is reported to be entirely

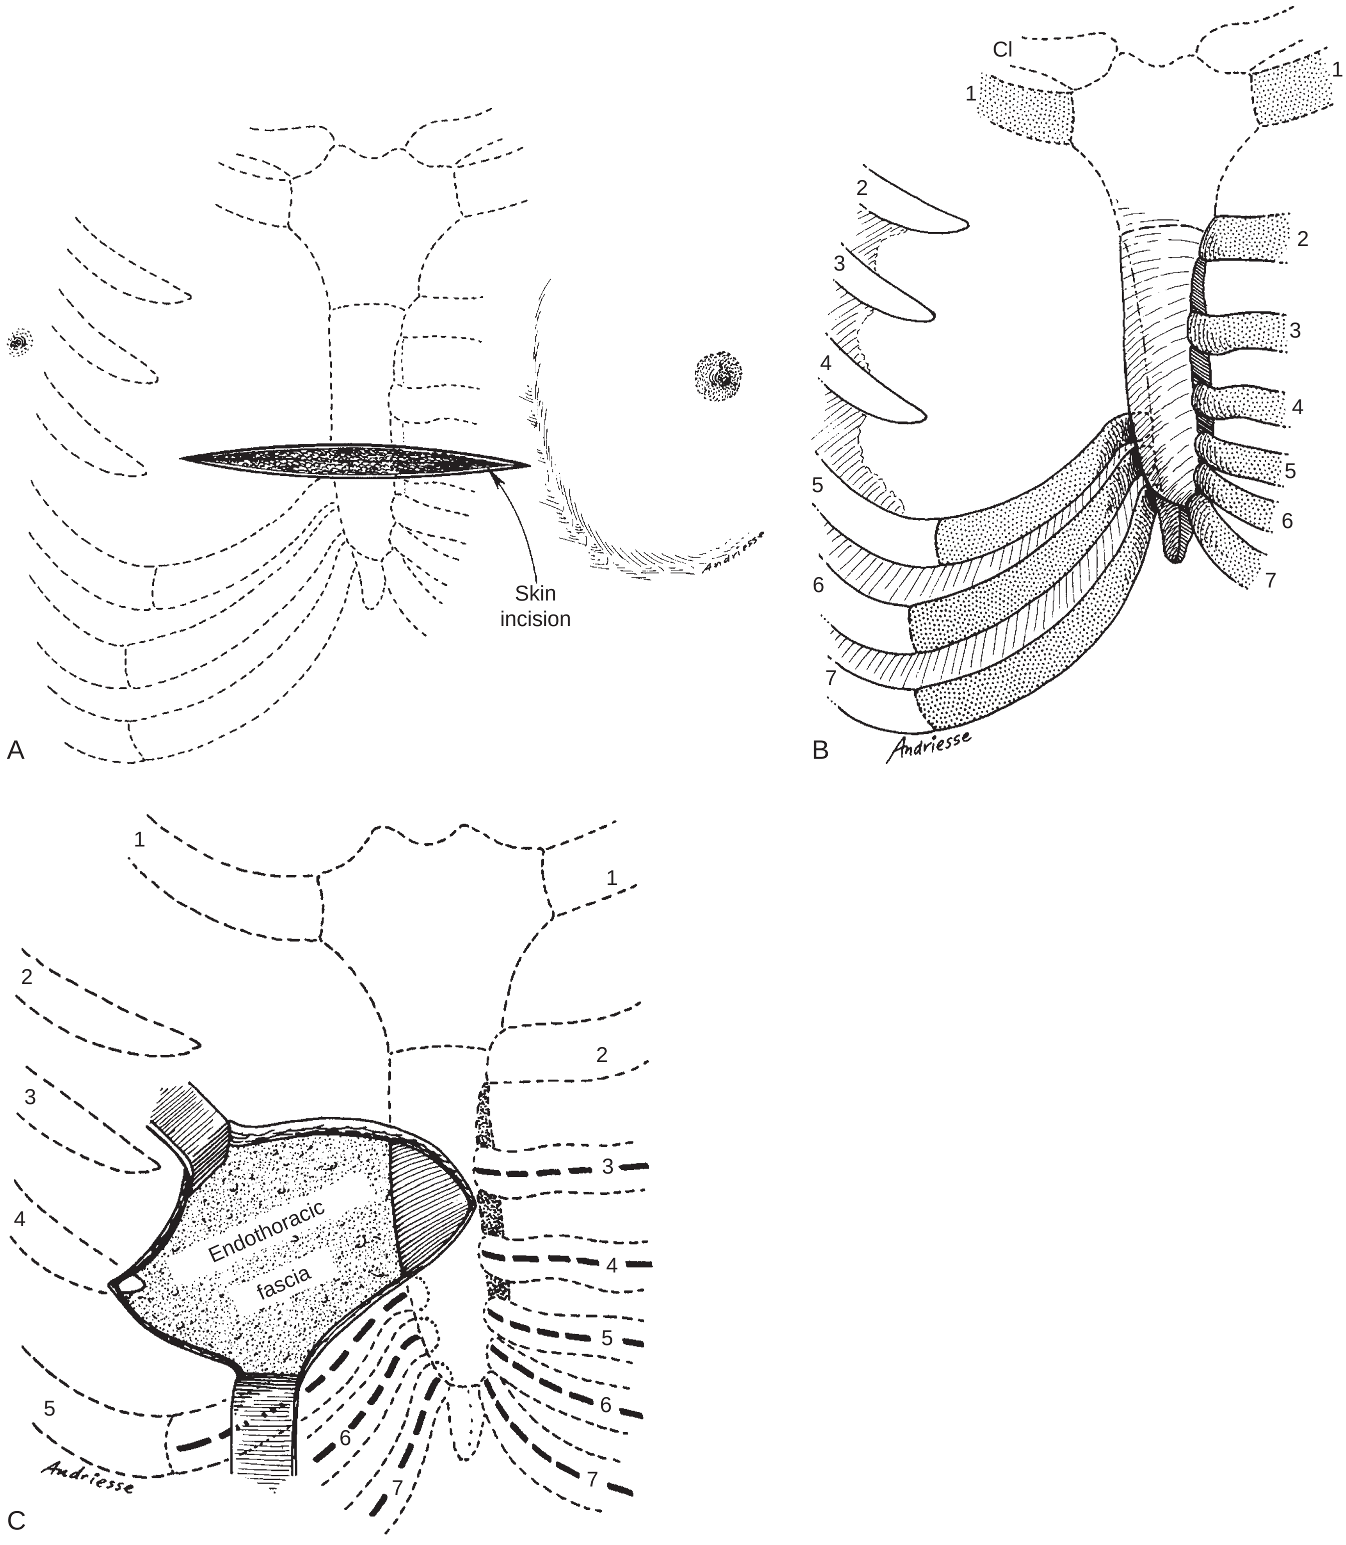

FIGURE 62-17 **A,** A transverse incision is placed below the nipple lines and, in females, in the inframammary crease. **B,** Schematic depiction of the deformity, with rotation of the sternum, depression of the cartilages on the involved side, and carinate protrusion on the contralateral side. **C,** In cases with aplasia of the ribs, the endothoracic fascia is encountered directly below the attenuated subcutaneous tissue and pectoral fascia. The pectoral muscle flap is elevated on the contralateral side and the pectoral fascia, if present, is elevated on the involved side. Subperichondrial resection of the costal cartilages is then carried out, as shown by the *dashed lines*. Rarely, this must be carried to the level of the second costal cartilage.

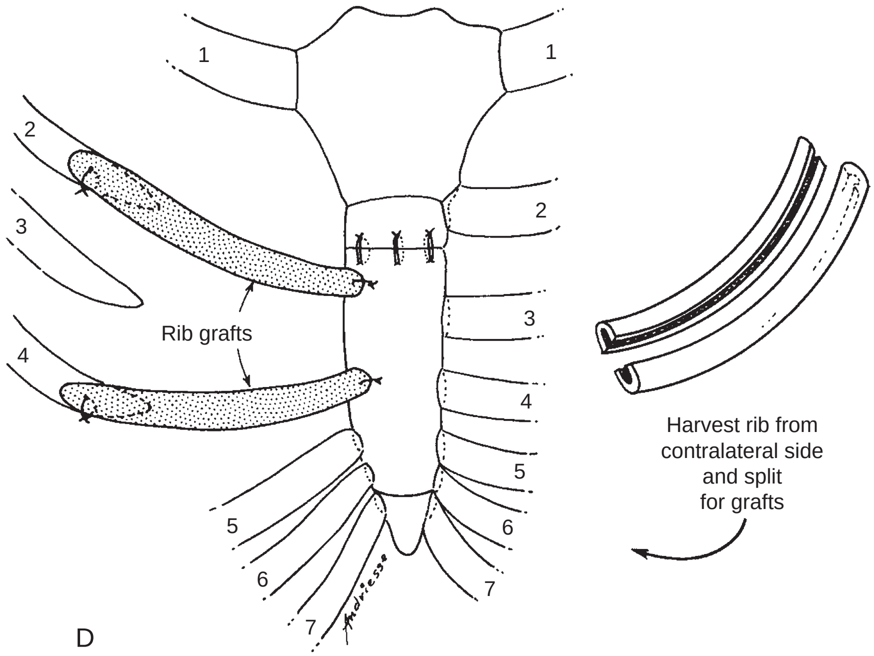
*Continued*



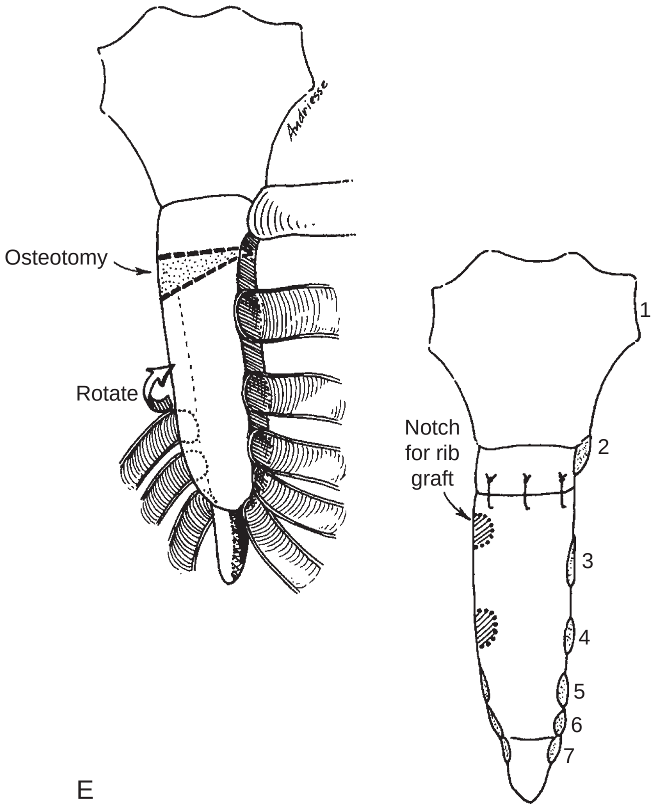


**FIGURE 62-17—CONT'D** **D,** A transverse offset wedge-shaped sternal osteotomy is created below the second costal cartilage. Closure of this defect with heavy silk sutures or by strut support corrects both the posterior displacement and the rotation of the sternum. **E,** In cases with rib aplasia, split rib grafts are harvested and secured medially with wire sutures into previously created sternal notches and with wire to the hypoplastic ribs laterally. Ribs are split as shown along their short axis to maintain maximal mechanical strength. (From Shamberger RC, Welch KJ, Upton J III: Surgical treatment of thoracic deformity in Poland's syndrome. J Pediatr Surg 1989;24:760-765.)

well. The case of Dobell and colleagues[156] is notable, because surgical correction was performed in two stages: skin flap coverage was provided as a newborn, and at 19 months of age, rib strut grafts were placed over the sternal defect and covered with pectoral muscle flaps. The pericardium was divided from its anterior attachments to the chest wall, allowing the heart to fall back partially into the thoracic cavity. The case of Williams, subsequently reported by Amato, was treated by moving

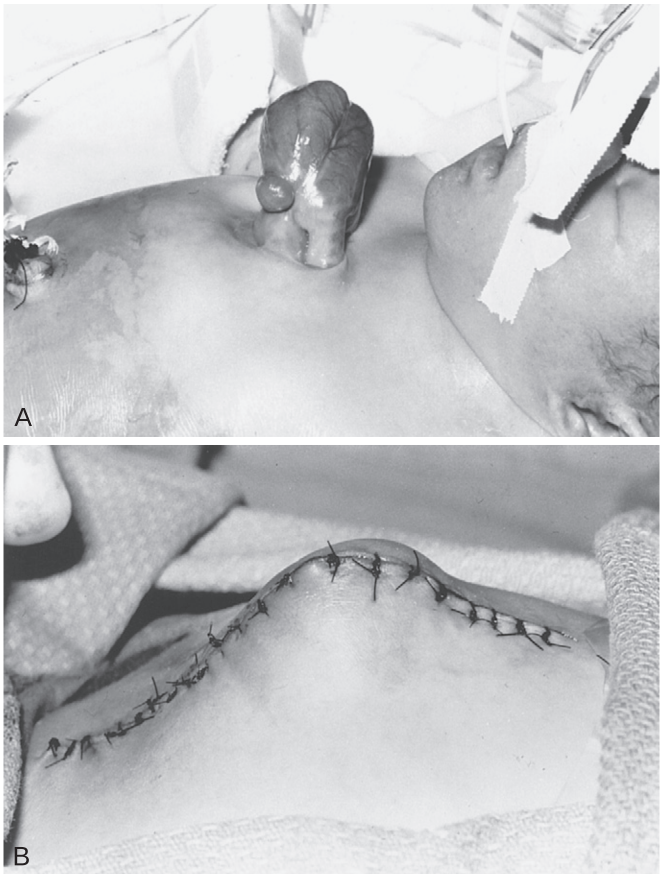

**FIGURE 62-18** **A,** Infant with thoracic ectopia cordis with no significant abdominal wall defect. **B,** Repair by skin flap coverage was achieved by extensive mobilization of the skin flaps laterally on the day of birth. Repair of the intracardiac defect—tetralogy of Fallot with long-gap pulmonary atresia—was achieved later through the skin flaps. (Courtesy Craig W. Lillehei, MD.)

the diaphragm inferiorly in three separate stages while the heart was covered with Silastic.[160] It was then ultimately covered by skin flaps. The child was lost to follow-up at 2½ years of age. Only Amato and colleagues[161] and Morales and colleagues[158] achieved complete soft tissue coverage in one stage. The unifying theme of successful management is the construction of a partial anterior chest cavity surrounding the heart and the avoidance of attempts to return the heart to an orthotopic location (see Fig. 62-12, *B*). Only one case, that of Lillehei and Mayer reported by Hornberger, survived with a significant intrinsic cardiac anomaly, tetralogy of Fallot with pulmonary atresia.[162] At 4 days of age, a left Blalock-Tausig shunt was performed, and the heart was covered with skin flaps. This was followed by a right Blalock-Tausig shunt and pulmonary arterioplasty at 20 months of age, and ultimately, at 2 years of age, a complete repair with an aortic homograft placed between the right ventricle and the pulmonary artery. The ventricular septal defect (VSD) was also closed at that time and the shunts removed. Of note, in the successful cases, intrinsic cardiac lesions and associated abdominal defects were absent, except for the final case and a muscular ventricular septal defect and a ventricular diverticulum in the case of Morales.[158] This characteristic, the absence of significant intrinsic cardiac anomalies, was what distinguished the successful cases from the failures in most cases, rather than any differences in surgical technique. In cases repaired with autologous tissue grafts (bone or cartilage) or synthetic materials, infection and extrusion of the graft invariably occur. Ultimate success can be achieved only with tissue coverage over the displaced heart that avoids posterior compression of the heart into an already limited thoracic space. This type of coverage may require the use of tissues from sites distant from the anterior chest wall or extensive mobilization of local tissues. The severe intracardiac defects associated with thoracic ectopia cordis also make achieving ultimate survival difficult. Regrettably, the only advancement in management of this lesion has been prenatal ultrasonographic identification, including definition of the intracardiac lesions and termination of the pregnancy if desired by the parents.[163]

Upper abdominal wall defects are also frequent in these patients, including upper abdominal omphalocele, diastasis recti, and rarely, eventration of the abdominal viscera. The presence of abdominal wall defects in conjunction with thoracic ectopia cordis should not, however, lead to the classification of these lesions as thoracoabdominal ectopia cordis; this term should be reserved for cases in which the heart is covered at birth.

## CERVICAL ECTOPIA CORDIS

Cervical ectopia cordis (ectopia suprathoracica of Weese and ectopie céphalique of Breschet) has historically been defined as a separate entity from thoracic ectopia cordis, based on the extent of superior displacement of the heart. Fusion between the apex of the heart and the mouth is often present, as are severe craniofacial anomalies. This lesion is relatively rare compared with thoracic ectopia cordis, but patients share the same dismal prognosis. In the summary of Shao-tsu, only five infants were classified with cervical ectopia cordis, whereas 121 infants had the thoracic variety.[100] No survivors or attempts at closure in this group of severely deformed infants have been reported.

## THORACOABDOMINAL ECTOPIA CORDIS

Thoracoabdominal ectopia cordis includes those lesions classified as ectopia subthoracica by Weese and ectopie abdominale by Breschet. It combines the rather artificial divisions of ectopia cordis thoracalis extrathoracica sternoepigastrica and ectopia cordis ventralis of Roth and the ectopia cordis thoracoabdominalis and ectopia cordis abdominalis of Shao-tsu. In this group, the heart is covered by a membrane of thin, often pigmented skin with an overlying, inferiorly cleft sternum (Fig. 62-19). The heart lacks the severe anterior rotation present in thoracic ectopia cordis. A 1798 report of this lesion by Wilson[157] clearly defined the associated somatic defects of the abdominal wall, diaphragm, and pericardium, as well as the intrinsic cardiac anomalies, more than 150 years before the reviews by Major[164] and Cantrell and Ravitch.[153] These patients almost invariably have associated abdominal wall defects (omphalocele, diastasis recti, or ventral hernia), along with anterior semilunar defects in the diaphragm and pericardium. Intrinsic cardiac lesions are frequently present in

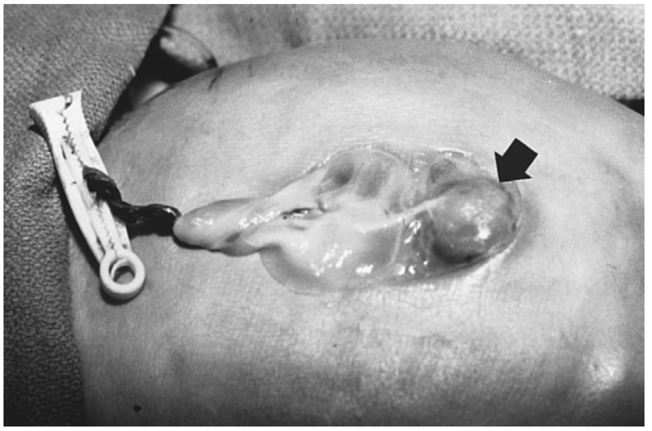

FIGURE 62-19 Infant with thoracoabdominal ectopia cordis, demonstrating a small abdominal wall defect covered by an omphalocele below the costal arch. The infant's head is to the right, and the heart (*arrow*) is visible just below the superior margin of the defect, covered by a thin membrane. Primary skin closure was achieved during the initial operation, with subsequent repair of the cardiac defect.

these patients and have been summarized.[153] The position of the heart varies; it may lie within the thoracic cavity, with only the diaphragmatic and pericardial defect below it, or it may reside entirely within the abdominal cavity, with the major vessels extending through the defect in the diaphragm. Diverticula of the left ventricle occur with surprising frequency in this anomaly. In many cases, the diverticulum protrudes through the diaphragmatic and pericardial defect into the abdominal cavity. Successful repair and long-term survival are more frequent in thoracoabdominal ectopia cordis than in thoracic ectopia cordis. Arndt[165] attempted the first repair in 1896, but return of the heart to the thoracic cavity resulted in death.

Wieting[166] performed the first successful surgical repair with primary closure of the diaphragm and abdominal wall fascia in 1912. Initial surgical intervention must address the skin defects overlying the heart and abdominal cavity. Primary excision of the omphalocele with skin closure is preferred to avoid infection and mediastinitis, although several cases have been managed successfully by local application of topical astringents, allowing secondary epithelialization to occur. Several early cases document the viability of individuals with thoracoabdominal ectopia cordis when there is intact skin coverage over an intra-abdominal heart.

Advances in pediatric cardiac surgery now allow correction of the intrinsic cardiac lesions that were often fatal in the past. An aggressive approach in these infants is appropriate. Closure of the abdominal wall defect or diastasis can be managed by either primary closure of the defect or prosthetic mesh closure. Primary closure is often difficult to achieve because of the wide distance between the two rectus muscles, which are attached superiorly to the splayed costal arches, limiting midline mobility.[167] The costal cartilages are divided laterally in one modification of closure, allowing them to rotate medially.[165] Complete repair of the intracardiac defect is best performed before placement of any prosthetic material over the heart. Once skin coverage is achieved, closure of this defect is important, primarily for mechanical protection of the heart. Fatal pulmonary hypoplasia has occurred in some infants with this anomaly.[153]

## CLEFT OR BIFID STERNUM

Cleft or bifid sternum is the fourth and least severe anomaly of the sternum. Infants in this group have an orthotopic heart, normal skin coverage, an intact pericardium, and a partially or completely cleft sternum (Fig. 62-20). Omphalocele is not associated with cleft sternum. The sternal defect, if partial, involves the upper sternum and manubrium, in contrast with the sternal defect in thoracic or thoracoabdominal ectopia cordis, in which partial defects involve primarily the lower sternum. Most cases are partially split (Table 62-3), with an intact xiphoid or lower third of the body of the sternum.

The bifid or cleft sternum is distinct from the other three categories of sternal defects, in that intrinsic cardiac defects are rare. Several distinct somatic associations are seen, including bandlike scars extending from the umbilicus to the inferior aspect of the sternal defect. Other children have superior scarlike extensions to the neck or mandible; rarely, a split mandible occurs (gnathoschisis). Fischer[77] reported an unexplained association with cervicofacial hemangiomas in 1879, and Ingelrans and Debeugny[166,168] later reported the occurrence of fatal postoperative hemorrhage from presumed hemangioma of the trachea after repair of a sternal defect.

In most cases, these infants' sternal defects are asymptomatic. Repair is performed to provide protective coverage for the heart. It may also improve respiratory mechanics, which are compromised by the paradoxical motion of the defect. Lannelongue,[157] in 1888, was allegedly the first to repair a cleft sternum, but his intervention was limited to excision of a small circular ulcer overlying the sternal defect. He created two relaxing incisions laterally, allowing primary closure of the skin, but ignored the underlying sternal separation. The first complete repair of a cleft sternum was accomplished by placing a cartilage graft from the costal arch over the defect.[169]

Maier and Bortone[170] achieved the first primary closure in 1949 in a 6-week-old infant. Subsequent methods have included bilateral oblique incisions through the costal cartilages to produce greater length and allow midline approximation of the sternal halves (sliding chondrotomies of Sabiston[171]; division of the cartilages laterally, swinging them medially to cover the defect (door-wing plasty of Meissner)[172]; rotation of the posterior sternal perichondrium to close the medial defect, followed by chondral grafts[173]; coverage with various autologous grafts (costal cartilage, rib, parietal skull); and coverage with prosthetic materials. Maier and Bortone[170] first stressed the importance of early repair in infancy, when the chest is most flexible, to achieve primary closure (Fig. 62-21). In most reported cases of primary repair, correction took place within the first 3 months of life (18 of 22 cases) and rarely after 1 year of age (2 cases).[153] In contrast, some form of chondrotomy was required in 22 patients, 8 of whom were older than 1 year. Often a wedge of cartilage must be excised from the point where the two sternal halves unite to allow approximation without tension.

FIGURE 62-20 Six-week-old infant with bifid sternum. Note the marked protrusion from the defect when crying (**A**) and depression of the defect with inhalation (**B**). Capillary hemangiomas are also visible on the lips.

**TABLE 62-3**
**Sternal Defects in 109 Patients with Cleft Sternum**

| *Defect* | *No. of Patients* |
|---|---|
| Upper cleft | 46 |
| Upper cleft to xiphoid | 33 |
| Complete cleft | 23 |
| Lower defect with manubrium or midsegment intact | 5 |
| Central defect with manubrium and xiphoid intact | 2 |

# Thoracic Deformities in Diffuse Skeletal Disorders

## ASPHYXIATING THORACIC DYSTROPHY: JEUNE SYNDROME

In 1954, Jeune and colleagues[174] described a newborn with a narrow, rigid chest and multiple cartilage anomalies. The patient died early in the perinatal period because of respiratory insufficiency.

Subsequent authors further characterized this form of osteochondrodystrophy, which has variable skeletal involvement. It is inherited in an autosomal recessive pattern and has now been associated with several genetic alterations.[175,176] Its most prominent feature is a narrow, bell-shaped thorax and protuberant abdomen. The thorax is narrow in both the transverse and the sagittal axes and has little respiratory motion because of the horizontal direction of the ribs (Fig. 62-22). The ribs are short and wide, and the splayed costochondral junctions barely reach the anterior axillary line. The costal cartilage is abundant and irregular, similar to a rachitic rosary. Microscopic examination of the costochondral junction reveals disordered, poorly progressing endochondral ossification resulting in decreased rib length.

Associated skeletal abnormalities that occur with this syndrome include short, stubby extremities with relatively short and wide bones. The clavicles are in a fixed and elevated position, and the pelvis is small and hypoplastic with square iliac bones.

This syndrome has variable expression and extent of pulmonary impairment. Although the initial cases reported resulted in neonatal deaths, subsequent reports document a wide range of survival in patients with this syndrome.[177,178] The pathologic findings at autopsy are variable, showing a spectrum of abnormal pulmonary development, which may

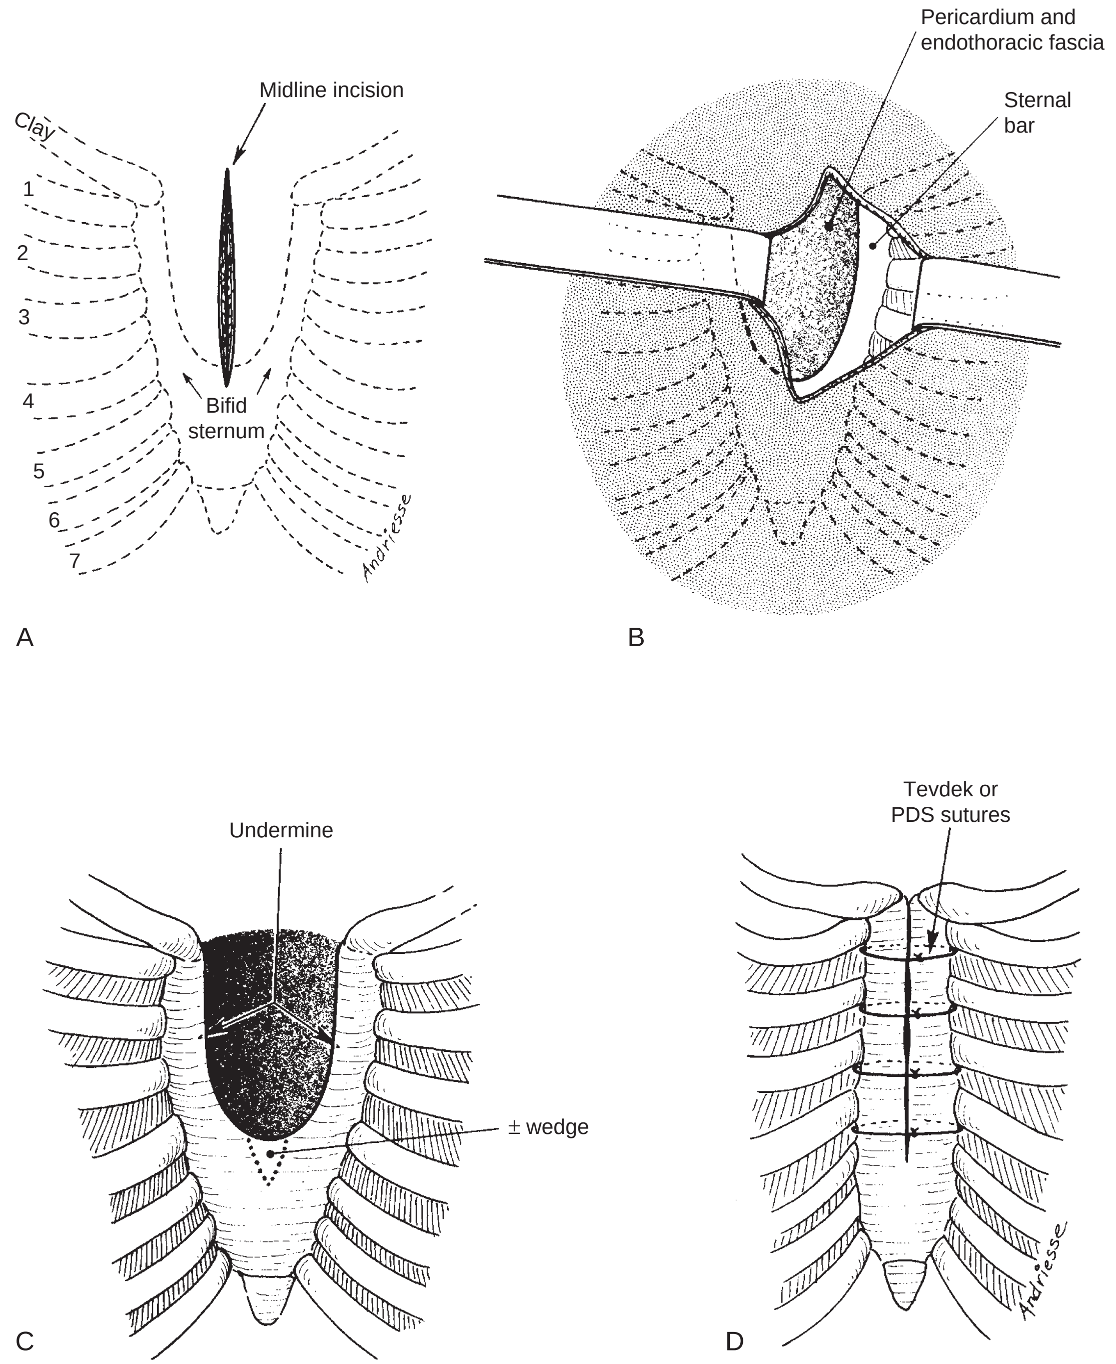

**FIGURE 62-21** **A,** Repair of bifid sternum is best performed through a longitudinal incision extending the length of the defect. **B,** Directly beneath the subcutaneous tissues, the sternal bars are encountered, with pectoral muscles present lateral to the bars. The endothoracic fascia and pericardium are just below these structures. **C,** The endothoracic fascia is mobilized off the sternal bars posteriorly with blunt dissection, to allow safe placement of the sutures. Approximation of the sternal bars may be facilitated by excising a wedge of cartilage inferiorly. Repair is best accomplished in the neonatal period, when there is greatest flexibility of the chest wall. **D,** Closure of the defect is achieved with nonabsorbable sutures. (From Shamberger RC, Welch KJ: Sternal defects. Pediatr Surg Int 1990;5:156-164.)

account for the variable survival. In most cases, however, bronchial development is normal, with fewer alveolar divisions, as described by Williams and colleagues[179] Surgical attempts to enlarge the thoracic cavity are generally unsuccessful and result in prolonged hospitalization and ultimate respiratory failure and death.

Initial attempts were made to divide the sternum with insertion of graft material to increase the diameter of the thoracic cavity. Subsequent reports describe an “expander” placed between the sternal halves.[180] Later, division of the costal cartilages laterally with overlapping of them to broaden the chest wall (lateral thoracic expansion) has been used as

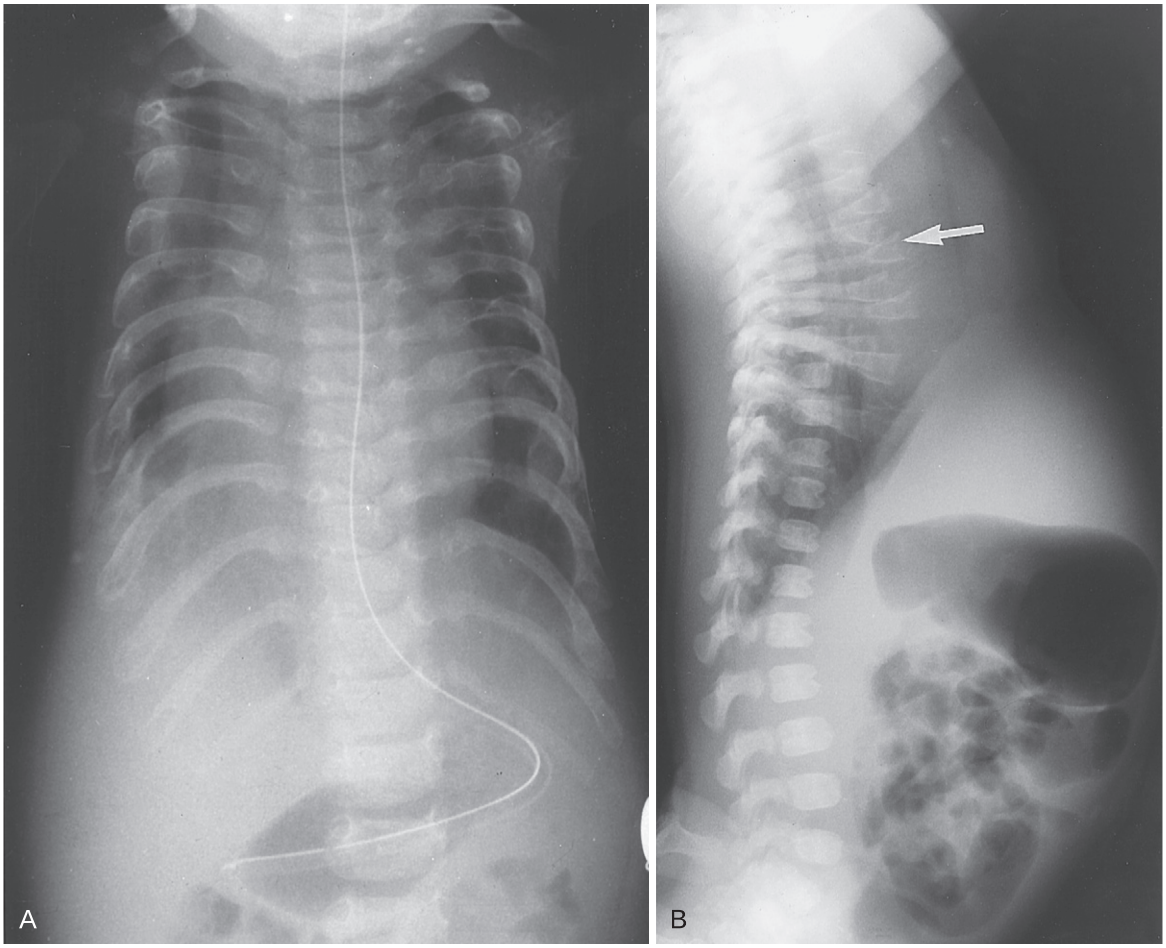

**FIGURE 62-22** **A,** Anteroposterior radiograph shows the short horizontal ribs and narrow chest of an infant with Jeune syndrome (asphyxiating thoracic dystrophy). **B,** Lateral radiograph demonstrates the short rib ends ending at the midaxillary line (*arrow*) and abnormal flaring at the costochondral junction. The infant died of progressive respiratory insufficiency at 1 month of age, and postmortem examination revealed alveolar hypoplasia. (From Shamberger RC: Chest wall deformities. In Shields TW [ed]: General Thoracic Surgery, ed 5. Philadelphia, Lippincott Williams & Wilkins, 2000.)

well, but both of these methods fail to provide progressive enlargement of the chest cavity as the infant grows.[181,182] More recently, use of the vertical expandable prosthetic titanium rib (VEPTR) has been reported in two children with Jeune syndrome.[183] A high-radius curvature device was used to distract the chest wall outward to increase the thoracic volume. The ribs were attached to the device using titanium wire so that the ribs could be distracted laterally. One child with Jeune syndrome, who had carbon dioxide retention, was improved after surgery. No information is available as to how these children have done long-term (Fig. 62-23).

## SPONDYLOTHORACIC DYSPLASIA: JARCHO-LEVIN SYNDROME

Spondylothoracic dysplasia is an autosomal recessive deformity described by Jarcho and Levin[184] in 1938 that is associated with multiple vertebral and rib malformations. Death often occurs in early infancy from respiratory failure and pneumonia. Patients have multiple alternating hemivertebrae that affect most, if not all, of the thoracic and lumbar spine. The vertebral ossification centers rarely cross the midline. Multiple posterior fusions of the ribs and remarkable shortening of the thoracic spine result in a crablike radiographic appearance of the chest (Fig. 62-24). One third of patients with this syndrome have associated malformations, including congenital heart disease and renal anomalies. Heilbronner and Renshaw[185] reported its occurrence primarily in Puerto Rican families. Bone formation is normal in these patients.

The thoracic deformity is secondary to the spinal anomaly, which results in close posterior approximation of the origin of the ribs. Most infants with this entity succumb before 15 months of age, and no surgical efforts have been proposed or attempted.[186]

## CEREBROCOSTOMANDIBULAR SYNDROME

The association of severe rib defects, micrognathia, and other anomalies was first described by Smith and colleagues[187] in 1966 and later by McNicholl and colleagues.[188] Infants with

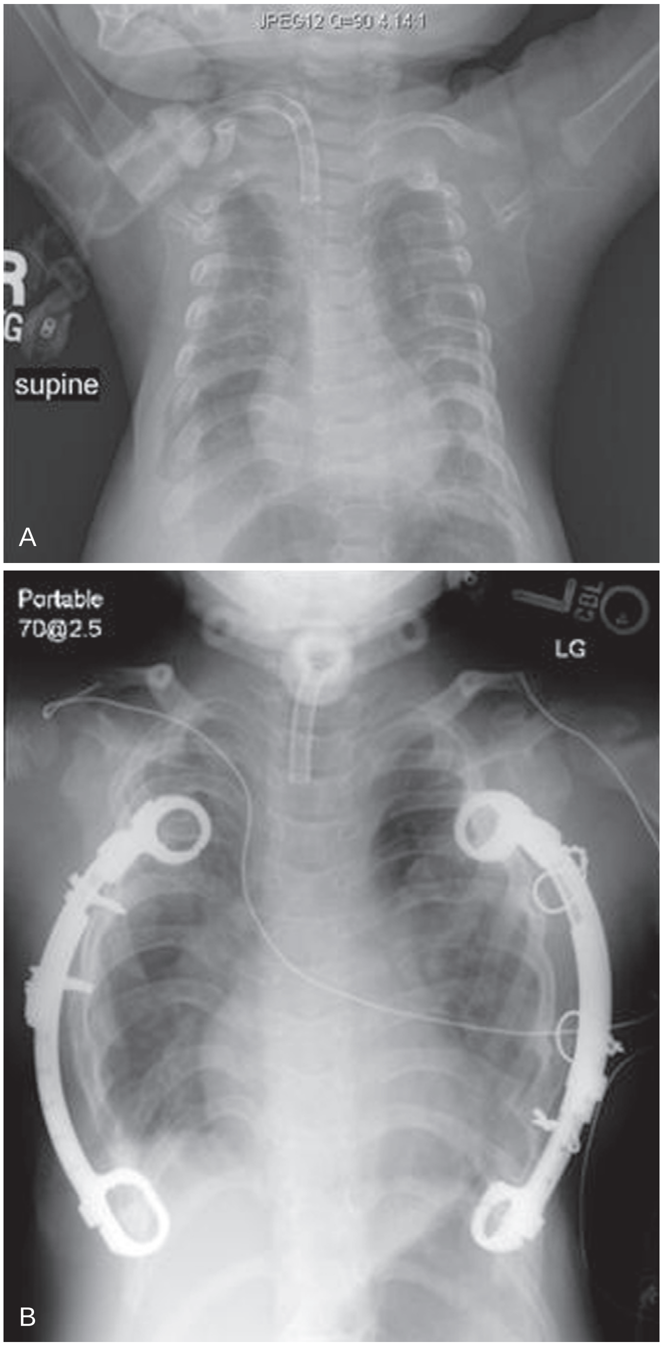

FIGURE 62-23 Vertical expandable prosthetic titanium rib device (VEPTR) in a patient with Jeune syndrome. Preoperative (**A**) and postoperative (**B**) radiographs of a child who required 24-hour ventilatory support before surgery and only nocturnal ventilation after repair. (Courtesy John H.T. Waldhausen, MD.)

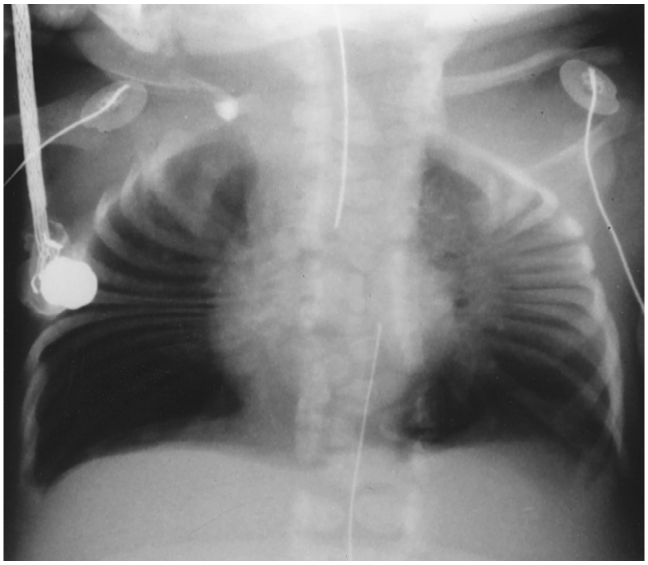

FIGURE 62-24 Chest radiograph of an infant with spondylothoracic dysplasia. Severe abnormality of the spine is apparent, with multiple alternating hemivertebrae and the crablike ribs. (From Shamberger RC: Chest wall deformities. In Shields TW [ed]: General Thoracic Surgery, ed 5. Philadelphia, Lippincott Williams & Wilkins, 2000.)

this constellation of anomalies have ossified ribs with an aplastic segment a short distance beyond the posterior rib angles. They also have micrognathia, abnormal tracheal cartilage, and defects of the soft and hard palates. Mild to moderate mental retardation occurs in 50% of infants surviving beyond the first year of life.[187] The extent of rib defects is variable, both in the number of involved ribs and in the extent of the defect, ranging from a narrow gap to a rudimentary rib. The third to seventh ribs are most frequently involved. The rib gap may contain fibrous tissue, skeletal muscle, or cartilage with variable calcification. The rib gaps produce a flail chest, and the prognosis for these infants is poor. Forty percent die from respiratory failure during the first year of life.[185] The underlying cause and the inheritance pattern are not known, and chromosomal studies are normal.

CHAPTER 63

# Congenital Diaphragmatic Hernia and Eventration

Charles J. H. Stolar and Peter W. Dillon

## History

The earliest English language description of the gross anatomy and pathophysiology associated with congenital diaphragmatic hernia (CDH) in a newborn was by McCauley, an associate of Hunter, as reported in the Proceedings of the Royal College of Physicans, 1754[1]:

> The child was born in the lying-in-hospital in Brownlow Street on the 24th of August, 1752: and was a fully grown boy, remarkably fat and fleshy. He was the fifth child of a healthy young woman who was well during her pregnancy. The child, when first born, started and shuddered; so that the nurse apprehended his going into fits. He breathed also with difficulty and it was some time before he could cry; which when he did, there was something peculiar in its note. He seemed to revive a little in about half an hour and breathed more freely: but soon relapsed and died before he was quite an hour and a half old. Being informed of these particulars by the mother, the matron, and the nurse, I was desirous of examining the body. . . .? I laid open the abdomen and found none of the intestines were contained in that cavity except part of the colon which was distended with meconium. Before I proceeded further with the dissection I sent to acquaint my ingenious friend, Dr. Hunter. We together dissected and examined this curious subject: and at the same time committed to writing the most remarkable appearances.
>
> When the sternum was raised, the stomach with the greatest part of the intestines, with the spleen, and part of the pancreas were found in the left cavity of the thorax; having been protruded through a discontinuation, or rather an aperture of the diaphragm, about an inch from the natural passage of the esophagus.
>
> From the extraordinary bulk of the parts contained in the left side of the thorax, the mediastinum, the heart, the esophagus, and the descending aorta were forced a considerable way to the right side of the thorax; because there was not the least mark of rupture or inflammation about the edges of the chasm: and because it is probable that the diminished size of the left lobes of the lungs, and the heart and mediastinum being pushed to the right side, were gradually affected by the bulk and increase of the viscera.
>
> As the esophagus was pushed to the right side by the stomach and the bowels, in the cavity of the thorax it kept the same course and pierced the diaphragm not in the usual place, but considerably further to the right side: and the aperture through which it passed was backwards and to the right side with respect to that for the vena cava.
>
> I have preserved the heart and lungs to show the disproportioned sizes of the lobes. And I have dried and prepared the diaphragm with its connections to the vertebrae and sternum to show the preternatural aperture through which the bowels passed into the thorax; as also the passage of the esophagus to the right side of the diaphragm. These preparations were at the same time shown to the Society.

Cooper,[2] in 1827, and Laennec,[3] in 1834, not only reported clinical descriptions and gross pathology of CDH but also suggested that laparotomy might be the proper approach for reduction and correction of the hernia. Bowditch,[4] in 1847, was the first to make the bedside diagnosis of CDH and further emphasized the clinical criteria for diagnosis. Although Bochdalek's understanding of the embryology was incorrect, this congenital defect continues to carry his name.[5] He speculated that the hernia resulted from a posterolateral rupture of the membrane separating the pleuroperitoneal canal into two cavities. He also incorrectly speculated that the best way to repair the defect was through the bed of the 12th rib. The record is not clear as to whether this was actually attempted. The earliest, although unsuccessful, efforts to repair CDHs were by Nauman,[6] in 1888, and O'Dwyer, in 1890.[7] The first reports of successful repairs were in an adult by Aue,[8] in 1901, and a child by Heidenhain,[9] in 1905.

The groundwork for treating CDH in the newborn period was laid by Hedblom,[10] whose review of the reported cases as of 1925 showed that 75% of 44 infants diagnosed in the newborn period died. He suggested that earlier intervention might improve survival. Successful repair of CDH remained rare until 1940, when Ladd and Gross[11] reported 9 of 16 patients surviving operative repair, the youngest being 40 hours old. It was not until 1946 that Gross[12] reported survival of the first infant younger than 24 hours old after operative repair of the defect. Until the 1980s, the standard of care remained immediate neonatal surgery followed by postoperative resuscitative therapy (Fig. 63-1).

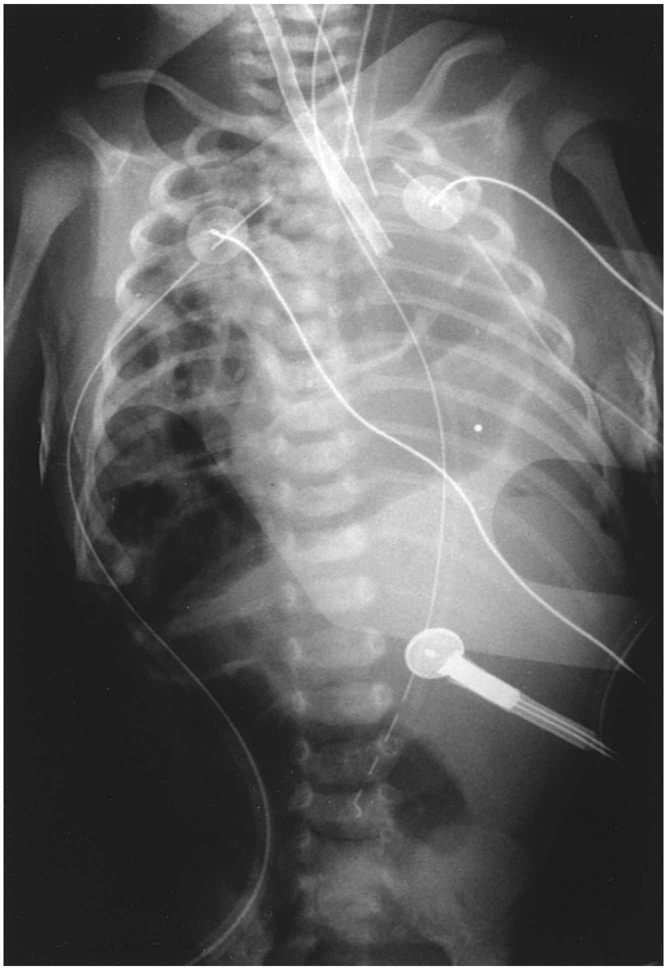

**FIGURE 63-1** Chest radiograph of an infant with a right-sided congenital diaphragmatic hernia demonstrating air-filled loops of intestine in the right hemithorax with contralateral displacement of the mediastinum. The infant has been cannulated for venoarterial extracorporeal membrane oxygenation.

## Epidemiology and Genetics

The reported incidence of CDH is estimated to be between 1 in 2000 to 5000 births. In the United States, approximately 1000 infants per year are affected with this condition, and in a recent study from Atlanta the birth prevalence was found to be 2.4 per 10,000 births.[17] The incidence in stillborns is less well documented. Approximately one third of infants with CDH are stillborn, but these deaths are usually the result of associated fatal congenital anomalies.[18–20] When stillborns are counted with live births, females appear to be more commonly afflicted than males.[13,21,22]

Defects are more common on the left side, with approximately 80% being left sided and 20% right sided. Bilateral CDH defects are rare and have a high incidence of associated anomalies.[103] Infants with isolated CDH are more likely to be premature, macrosomic, and male; and about one third of affected infants may have associated major defects.[24,25] Women who are thin or underweight for their height may have an increased risk of having an infant with an isolated CDH.[26] CDH is thought to represent a sporadic developmental anomaly, although a number of familial cases have been reported.[13,27–31] The expected recurrence risk in a first-degree relative has been estimated to be 1 in 45, or approximately 2%.[30] Structural chromosomal abnormalities have been identified in 9% to 34% of CDH infants and include trisomies, deletions, and translocations.[32] Specific chromosomes with deleted or translocated genes may be candidate loci for CDH development.[33,34] The combination of CDH and an abnormal karyotype has been associated with a poor outcome.[32,35,36]

The cause of CDH is unknown. As with other embryopathies, there is increasing evidence that CDH may be due to the exposure of genetically predisposed or susceptible individuals to environmental factors. Exposure to a number of pharmacologic agents and environmental hazards has been implicated in its development. These include insecticides and drugs, such as phenmetrazine, thalidomide, quinine, cadmium, lead, and nitrofen.[37–40] The clinical findings of vitamin A deficiency in CDH infants and the effects of vitamin A administration in nitrofen-induced pulmonary hypoplasia have strengthened the evolving hypothesis that alterations in retinoid-regulated target genes may be responsible for CDH development.[41]

## Associated Anomalies

Any newborn with a major congenital anomaly, including infants with CDH, has an increased incidence of an additional malformation compared with the general population. Although previously thought to be low, the incidence of associated malformations in infants with a CDH ranges from 10% to 50%.[42–46] Skeletal defects have been noted in as many as 32% of CDH infants and include limb reduction and costovertebral defects.[44,45,47] Cardiac anomalies have been found in 24% of infants.[48] Cardiac hypoplasia involving the left ventricle and often associated with hypoplasia of the aortic arch is frequently described and can be confused with hypoplastic heart syndromes. However, the clinical significance is limited. Most cardiovascular malformations involve the cardiac outflow tract, such as ventricular septal defects, tetralogy of Fallot, transposition of the great vessels, double outlet right ventricle, and aortic coarctation.[25,28,48–51] Anatomic anomalies of the tracheobronchial tree have been found in 18% of patients with CDH and include congenital tracheal stenosis, tracheal bronchus, and trifurcated trachea.[45] The incidence of associated malformations in stillborn infants with CDH is even higher. In one study, 100% of stillborn infants with CDH had associated lethal anomalies.[16,22] Abnormalities noted in this stillborn group were predominantly neural tube defects and included anencephaly, myelomeningocele, hydrocephalus, and encephaloceles. Even in infants who survive to birth but die shortly thereafter, neural tube defects were the most common malformations noted. Cardiac defects were the second most common group and included ventriculoseptal defects, vascular rings, and coarctation of the aorta.[51] Other midline developmental anomalies have also been reported and include esophageal atresia, omphalocele, and cleft palate. A number of syndromes have a CDH as a pathologic finding. These include trisomy 21, 18, and 13, and syndromes such as Frey, Beckwith-Wiedemann, Goldenhar, Coffin-Siris, Fryns, Meacham, and Kabuki.[23,35,50,53–55]

# Embryology

## DIAPHRAGMATIC DEVELOPMENT

The embryologic development of the diaphragm remains incompletely understood and involves multiple, complex cellular and tissue interactions. The fully developed diaphragm is derived from four distinct components: (1) the anterior central tendon forms from the septum transversum, (2) the dorsolateral portions form from the pleuroperitoneal membranes, (3) the dorsal crura evolve from the esophageal mesentery, and (4) the muscular portion of the diaphragm develops from the thoracic intercostal muscle groups. The precursors of diaphragmatic structure begin to form during the fourth week of gestation with the appearance of the peritoneal fold from the lateral mesenchymal tissue. At the same time, the septum transversum forms from the inferior portion of the pericardial cavity. The septum transversum serves to separate the thoracic from the abdominal cavities and eventually forms the central tendinous area of the fully developed diaphragm. It defines the rudimentary pleuroperitoneal canals and allows for the establishment of mesenchymal tissue within these canals that ultimately results in pulmonary parenchymal development.[56]

Closure of the pleuroperitoneal canals with the formation of a pleuroperitoneal membrane occurs during the eighth week of gestation. Several theories have been proposed to explain the formation of this membrane and the subsequent development of a diaphragmatic structure. Progressive growth of the pleuroperitoneal membrane has been one mechanism proposed for canal closure.[57–59] Other researchers have postulated that concurrent hepatic and adrenal organogenesis is crucial to this process.[7a,59,60,71] The involvement of a posthepatic mesenchymal plate in diaphragmatic formation has been proposed.[61]

The pleuroperitoneal folds extend from the lateral body wall and grow medially and ventrally until they fuse with the septum transversum and dorsal mesentery of the esophagus during gestational week 6. Complete closure of the canal takes place during week 8 of gestation. Anatomically, the right side closes before the left.[56] Muscularization of the diaphragm appears to develop from the innermost muscle layer of the thoracic cavity, although it has been proposed that the posthepatic mesenchymal plate is a possible source of muscular tissue.[60,61] Posterolaterally, at the junction of the lumbar and costal muscle groups, the fibrous lumbocostal trigone remains as a small remnant of the pleuroperitoneal membrane and relies on the fusion of the two muscle groups in the final stages of development for its strength. Delay or failure of muscular fusion leaves this area weak, perhaps predisposing to herniation. Bochdalek first described this area of the posterolateral diaphragm in 1848, and it is for this reason that the most common site for CDH bears his name.

## LUNG DEVELOPMENT

Fetal lung development is divided into five stages: embryonic, pseudoglandular, canalicular, saccular, and alveolar.[63] Embryonic lung development begins during the third week of gestation as a derivative of the foregut and is marked by the formation of a diverticulum off of the caudal end of the laryngotracheal groove.[64] The trachea and the two primary lung buds form from this diverticulum by the fourth week of gestation. At 6 weeks, these lung buds have further developed into defined lobar structures. The pseudoglandular phase of lung development takes place during the 7th to 16th weeks of gestation and involves airway differentiation. It is during this period that all bronchial airways develop. From the 16th to the 24th weeks of gestation, fetal lung development enters the canalicular phase of growth. During this period, airspace development occurs, as crude alveolar air sacs begin to take shape. Type 1 pneumocytes begin to differentiate, and the precursors of type 2 pneumocytes ultimately responsible for surfactant production begin to appear. Gas exchange becomes functionally possible at this stage.

Continued maturation of the crude alveolar airspaces takes place during the saccular phase of development that extends from 24 weeks' gestation to term. During this time period, there is continued remodeling of the airspace dimensions and a maturation of surfactant synthesis capabilities.[201] Mature, adult-like alveoli begin to appear shortly after birth.[66,67] Extensive alveolar maturation and multiplication then takes place from birth until approximately 8 years of age, with a 10-fold increase in the number of functioning alveoli.[68–71] Some investigators have proposed that alveolar formation may be completed by 2 years of age.[72]

Pulmonary vascular development follows the stages of airway and alveolar growth and can be divided into two anatomic units based on associated airway structure. The term acinus describes the functional unit of the lung that includes the respiratory bronchioli, alveolar ducts, and alveoli—all structures that evolve during or after the canalicular phase of lung development. Vascular development in this region proceeds concurrently with alveolar growth and multiplication. The preacinar structures include the trachea, major bronchi, and lobar bronchi up to the terminal bronchioles. Preacinar vascular development is completed by 16 weeks' gestational age.[73–76]

It is now recognized that pulmonary development is marked by a series of programmed events regulated by master genes, such as the homeobox genes, nuclear transcription factors, hormones, and growth factors. These processes involve genes regulating epithelial and endothelial interactions as well as temporal and spatial interactions of several hormones and growth factors. Early developmental transcription factors, such as hepatocyte nuclear factor-3β and thyroid transcription factor-1, regulate pulmonary development from the foregut mesenchyme. Additional stimuli of pulmonary development involve the transforming growth factor-β pathway, Sonic Hedgehog pathway, Notch-delta pathway, Wingless-Int pathway, and cytokine receptor pathways. Subsequent signal transduction control of organogenesis includes the apoptotic pathways, nuclear receptor pathways, and interleukin pathways. The angiopoietins and isoforms of vascular endothelial growth factor are involved in pulmonary angiogenesis and vascular development.[77,78] Hormones such as the glucocorticoids, thyroid hormone, and retinoic acid have been shown to regulate several of the crucial cellular interactions required for proper pulmonary organogenesis and differentiation.

Very little is known about the alterations in gene expression, growth factor interactions, and hormone levels associated with airway and vascular development in the hypoplastic CDH lung. A number of factors have been found to be elevated in CDH lung specimens, including epidermal

growth factor, transforming growth factor-α, vascular endothelial growth factor, insulin-like growth factor, tumor necrosis factor-α, angiopoietin-2, and glucocorticoid receptor gene expression.[41,77,79–83] Decreased expression of Sonic Hedgehog, heme-oxygenase-1, and endothelial nitric oxide synthase levels has been found in CDH specimens.[84–86] Abnormal levels of factors that contribute to the regulation of pulmonary vascular tone have also been reported. High plasma concentrations of endothelin-1, a powerful vasoconstrictor, have been found in association with increased expression of its pulmonary artery receptors in CDH infants.[87,88]

Advances in understanding potential mechanisms responsible for the alterations in pulmonary development associated with a congenital diaphragmatic hernia have been limited by the lack of a completely acceptable experimental animal model. Currently, three model systems exist for studying pulmonary maldevelopment: a surgical model of a diaphragmatic defect, a nitrofen model of pulmonary and diaphragmatic hypoplasia, and various gene knockout mice models of pulmonary hypoplasia.[89] Elegant models by de Lorimier and Harrison, in which diaphragmatic defects were surgically created in fetal sheep, showed that long-term compression of abdominal contents into the thoracic cavity resulted in pulmonary maldevelopment and lung hypoplasia.[90,91] The disadvantage of this surgical model is that the defect is created late in the time course of fetal development and may not address early developmental mechanisms. The nitrofen model of experimental CDH coincides with the theory that many developmental defects, including CDH, are embryopathies caused by toxin exposure. Nitrofen is an herbicide with known teratogenic effects. Its administration to pregnant mice results in offspring with pulmonary hypoplasia, diaphragmatic defects, reduced airway branching, excessive muscularization of pulmonary vessels, surfactant deficiency, and respiratory failure at birth. The pulmonary hypoplasia resulting from nitrofen administration has been associated with alterations in a number of growth factors and developmental pathways in embryonic mice.[92] Finally, investigations using specific knockout mice have contributed to the understanding of the role of various factors and pathways in pulmonary and diaphragmatic development.[89]

A number of physical factors may also affect pulmonary growth and development.[63] Adequate intrathoracic space is a prerequisite for normal pulmonary growth. Any intrathoracic or extrathoracic process that results in a decrease of the intrathoracic space and pulmonary parenchymal compression can lead to the development of structurally immature lungs.[90–96] Other physical factors important in lung growth include the maintenance of normal fetal lung liquid and amniotic fluid dynamics.[93,95,98,99,101]

## Pathology

Although the cause of CDH is uncertain, its consequences on pulmonary development and function are well documented. During the early development of the diaphragm, the midgut is herniated into the yolk sac. If closure of the pleuroperitoneal canal has not occurred by the time the midgut returns to the abdomen during gestational weeks 9 and 10, the abdominal viscera herniate through the lumbocostal trigone into the ipsilateral thoracic cavity. The resulting abnormal position of the bowel prevents its normal counterclockwise rotation and fixation. No hernia sac is present if the event occurs before complete closure of the pleuroperitoneal canal, but a nonmuscularized membrane forms a hernia sac in 10% to 15% of CDH patients.[100] Although some claim the herniation can occur late in gestation or be intermittently present as a dynamic process, in most cases the defect is established by gestational week 12.[100a] The subsequent postnatal problems relate to the effects of the herniated viscera on the developing heart and lungs.

The classical left-sided CDH features a 2.0- to 4.0-cm posterolateral defect in the diaphragm through which the abdominal viscera have been translocated into the hemithorax (Fig. 63-2). Herniated contents often include the left lobe of the liver, the spleen, and almost the entire gastrointestinal tract. The stomach is frequently in the chest, which results in some degree of obstruction at the gastroesophageal junction. This obstruction, in turn, causes dilation and ectasia of the esophagus. Occasionally, the kidney may be in the chest tethered by the renal vessels. In instances of a right-sided defect, the large right lobe of the liver can occupy much of the hemithorax in addition to other abdominal viscera. The hepatic veins may drain ectopically into the right atrium, and fibrous fusion between the liver and the lung has been reported. Both of these anatomic findings can significantly complicate attempted surgical repair of the diaphragmatic defect.[89,102]

The diaphragmatic defect usually features a completely open space between the chest and abdomen, although some infants have a membrane of parietal pleura and peritoneum acting as a hernia sac. This finding is to be distinguished from

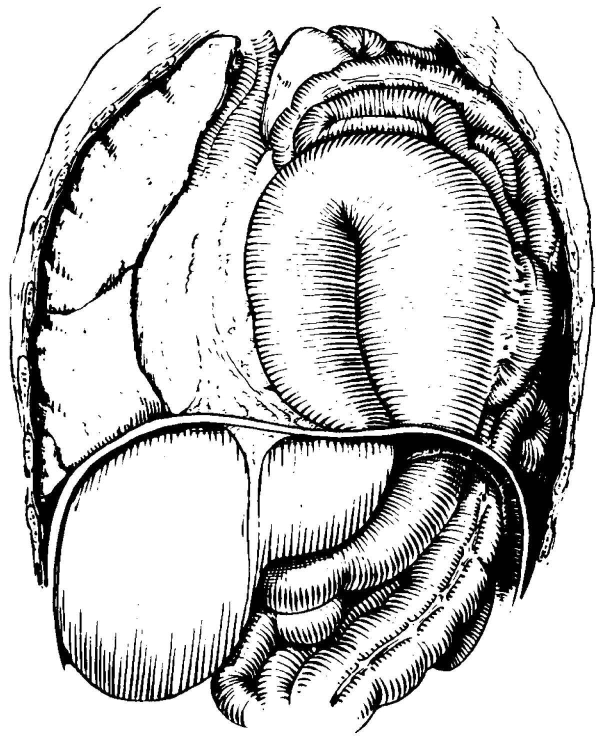

**FIGURE 63-2** Schematic illustration of a left congenital diaphragmatic hernia showing translocation of abdominal viscera through a posterolateral aperture into the chest. (From Spitz L, Coran AG [eds]: Rob & Smith's Pediatric Surgery. London, Chapman & Hall, 1996.)

an eventration of the diaphragm, which results from phrenic nerve or anterior horn cell degeneration. The muscle fibers of the diaphragm are usually present.

Bilateral CDH is an unusual occurrence and is almost always fatal because of bilateral lung growth arrest (Fig. 63-3).[103]

Unilateral visceral herniation affects both ipsilateral and contralateral pulmonary development, although hypoplasia is predictably more severe on the ipsilateral side. This is confirmed by an analysis of lung volumes and weights in human autopsy specimens and animal models.[90,96,104,105] Because the process of CDH herniation occurs at the time of bronchial subdivision, it is at this stage that lung development becomes compromised. Although all major bronchial buds are present in a CDH lung, the number of bronchial branches in the affected lung is greatly reduced. This finding was noted in both ipsilateral and contralateral pulmonary specimens.[104] Alveolar development is severely affected, and it has been reported that few normal alveoli exist in the lungs at term.[106] In addition, the changes in airway structure are quite variable. Infants requiring low ventilatory assistance during treatment had the same airway muscle mass as controls, whereas infants with prolonged ventilatory support had significantly greater muscle thickness throughout the conducting airways.[107]

The pulmonary vascular bed is distinctly abnormal in lungs from patients with CDH. A reduction in the total number of arterial branches in both the ipsilateral and the contralateral pulmonary parenchyma has been reported.[108,109] Structurally, significant adventitial and medial wall thickening has been noted in pulmonary arteries of all sizes in CDH lungs in association with abnormal muscularization of the small preacinar and intraacinar arterioles.[110–112] The physiologic consequence of this abnormal arterial muscularization may be an increased susceptibility to the development of fixed and intractable pulmonary hypertension. No significant changes in pulmonary venous structure have been identified resulting from CDH development. Increased adventitial thickness of pulmonary veins has been noted in CDH infants

FIGURE 63-3 Operative photograph of a left congenital diaphragmatic hernia created in a fetal lamb. The posterolateral defect can be seen looking from the abdomen into the chest. (From Spitz L, Coran AG [eds]: Rob & Smith's Pediatric Surgery. London, Chapman & Hall, 1996.)

but appears to be postnatally derived, perhaps as a result of treatment or secondary to the pathology of pulmonary hypertension.[28,113]

Pulmonary blood flow accounts for only 7% of cardiac output during normal fetal development, and pulmonary vascular resistance remains high. The fetus preferentially shunts oxygenated blood from the placenta through the foramen ovale and ductus arteriosus in a right-to-left direction into the systemic circulation. At birth, a number of hemodynamic changes take place that dramatically alter this circulatory profile. With the institution of breathing, pulmonary vascular resistance falls, as does pulmonary artery pressure allowing for an increase in pulmonary blood flow. Systemic vascular resistance and left atrial pressure rise, causing the foramen ovale to close. Increased arterial oxygen tension induces spontaneous closure of the ductus arteriosus. Transition from a fetal to an adult-type circulatory pattern is accomplished. Persistent fetal circulation may develop if this process is interrupted. After birth and interruption of placental circulatory support, persistently elevated pulmonary vascular resistance results in increased pulmonary artery pressures and decreased pulmonary vascular blood flow. The increased vascular resistance results in right-to-left shunting of blood at either the atrial or the ductal levels with the delivery of unsaturated blood into the systemic circulation. As the blood flow in the shunt increases, the oxygen saturation in the systemic circulation falls and the mixed venous blood returning to the right side of the heart becomes progressively desaturated. The resulting hypoxia further increases pulmonary vascular resistance and compromises pulmonary blood flow while increasing the right-to-left shunt flow. Severe and progressive respiratory failure ensues.

Factors that contribute to the persistence of high pulmonary vascular resistance in CDH lungs are thought to be the structural changes in decreased total arteriolar cross-sectional area in the involved lungs and the increased muscularization of the arterial structures that are present. In the postnatal period, there is failure of the normal arterial remodeling process, further maintaining the abnormal vascular resistance that may be only partly reversed by treatment interventions.[114] Additional exacerbations of pulmonary vascular resistance may be induced by the known stimulators of pulmonary hypertension, including hypoxia, acidosis, hypothermia, and stress.[115] Alterations in the levels of various prostaglandins, leukotrienes, catecholamines, and the renin-angiotensin system have been implicated as mediators of this complex process.[116–118] It can only be surmised at this time whether there is an exaggerated response to these stimuli by the abnormal vascular structures of CDH lungs.[113]

## DIAGNOSIS

The diagnosis of a CDH is often made on a prenatal ultrasound (US) examination and is accurate in 40% to 90% of cases.[119,119a] Although considerable variation in detection rates have been reported, the mean gestational age at discovery is 24 weeks and has been reported as early as 11 weeks.[120] The US may be obtained for routine obstetric care or because of suspicion concerning the presence of polyhydramnios. Polyhydramnios has been reported present in up to 80% of pregnancies with associated CDH.[99a] The mechanism of polyhydramnios is thought to be due to kinking of the gastroesophageal junction

by translocation of the stomach into the thorax with resultant foregut obstruction. The US diagnosis of a CDH is most often suggested by observing the stomach in the fetal thorax at the same cross-sectional level as the heart (Fig. 63-4). Additional US findings suggestive of a CDH include the absence of the stomach in the abdomen and the presence of the liver or other solid viscera in the thorax. The stomach may be small because of interference with fetal swallowing. If the diaphragmatic defect is on the right side, the liver can tamponade the hernia site and obscure the diagnosis. The diagnosis of CDH may be missed because intermittent herniation of abdominal viscera into the thoracic cavity has been reported.[99a] Furthermore, when the stomach is in a normal abdominal position, herniated small bowel loops are not easily distinguishable from lung parenchyma. The misinterpretation of the fetal US scan can be caused by other diagnoses, such as esophageal atresia and cystic lung anomalies. Functional information concerning fetal breathing can be obtained by duplex Doppler examination of amniotic flow at the fetal nares at the time of fetal US. A fetal tidal volume/minute ventilation can be determined that may have a bearing on prognosis.[121]

In addition to diagnosis, prenatal US may also be of benefit in predicting outcome by using quantitative techniques to estimate the severity of pulmonary hypoplasia of the fetal CDH lung. Three-dimensional estimation of the fetal lung volume, calculation of the right lung area to thoracic area ratio, and calculation of the lung to thoracic circumference ratio are three different measurements that may correlate with neonatal outcome,[122–125] but the lung-to-head ratio has been the most widely used prognostic indicator.[126] US can be limited by the poor acoustic contrast between fetal lung and herniated viscera, position of the fetus, and operator experience. As a result, prenatal magnetic resonance imaging (MRI) evaluation is being used with increasing frequency when obstetric sonography has detected a complex fetal anomaly and is ideally suited for fetuses with a diaphragmatic hernia.[127–129] MRI can readily determine liver position in relation to the diaphragm and detect herniated liver into either hemithorax. It may also be used to more accurately assess lung volume and perhaps correlation with outcome.[130–132]

After birth, the spectrum of respiratory symptoms in an infant with a CDH is determined by the degree of pulmonary hypoplasia and reactive pulmonary hypertension. The most severely affected infants develop respiratory distress at birth, whereas a majority demonstrate respiratory symptoms within the first 24 hours of life. Classically, these infants have a scaphoid abdomen and an asymmetric distended chest. The chest may become more distended as swallowed air passes into the stomach and intestines. Gastrointestinal distention further compresses pulmonary parenchyma and affects ventilatory characteristics. It may lead to additional mediastinal compression with impairment of the contralateral lung. Because of the small size of the neonate's chest, breath sounds may or may not be present on the side of the defect. Mediastinal compression with shift into the contralateral thorax may cause deviation of the trachea away from the side of the hernia and also result in obstruction to venous return with the hemodynamic consequences of hypotension and inadequate peripheral perfusion. The signs of respiratory distress may include cyanosis, gasping, sternal retractions, and poor respiratory effort. In babies with a left CDH, heart sounds will be heard best over the right chest; "dextrocardia" accompanied by respiratory distress is a CDH until proven otherwise.

The diagnosis of a CDH can be confirmed by a plain chest radiograph that demonstrates loops of intestine in the chest. The location of the gastric bubble should also be noted, and its position can be confirmed by placement of an orogastric tube. Rarely, a contrast study of the upper gastrointestinal tract is required. The chest radiograph shows angulation of the mediastinum and a shifting of the cardiac silhouette into the contralateral thorax. Although minimal aeration of the ipsilateral parenchyma may be noted, chest radiographs are unreliable for estimating the degree of pulmonary hypoplasia.[58,133–135]

Once the diagnosis of a CDH is confirmed, additional radiographic and US examinations should be carried out to search for associated anomalies. Echocardiography and both renal and cranial US scans should be obtained.

Although most CDHs present in the first 24 hours of life, 10% to 20% of the infants with this defect present later.[136,137] These latter infants present with recurrent mild respiratory

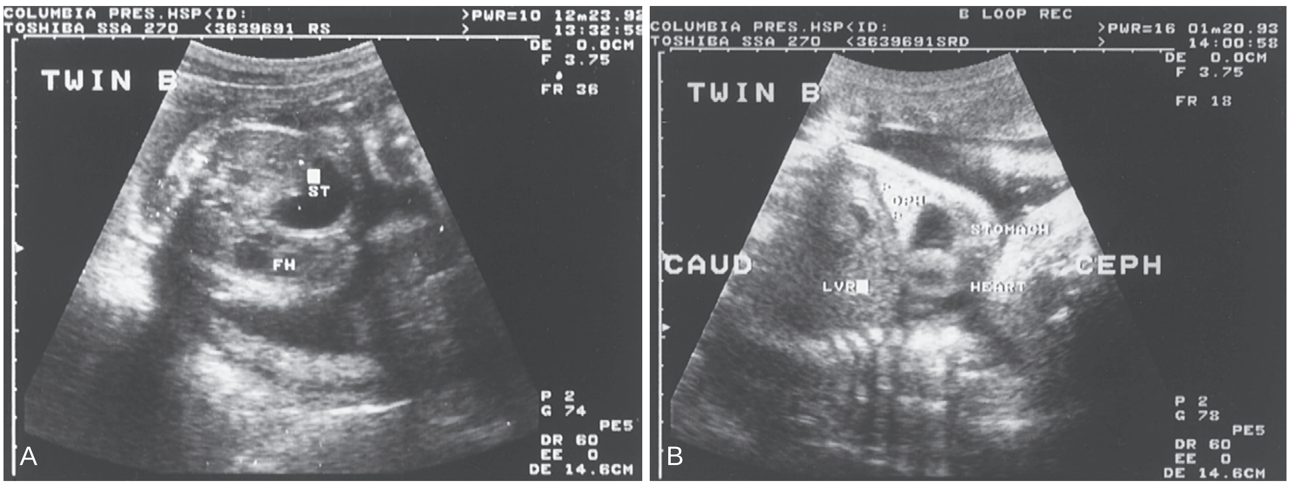

**FIGURE 63-4** **A,** Ultrasound examination of a 28-week gestation fetus (twin B) in cross section demonstrating the fetal heart (FH) and stomach (ST) in the same plane. **B,** Ultrasound examination of the same fetus but in a sagittal plane, demonstrating relationship of the stomach, liver, and heart.

illnesses, chronic pulmonary disease, pneumonia, effusion, empyema, or gastric volvulus. Occasionally, neonatal streptococcal pneumonia may mask a delayed-onset right CDH.[138]

# Differential Diagnosis

The diagnosis of a CDH can be confused with a number of other congenital thoracic conditions, including eventration of the diaphragm, anterior diaphragmatic hernia of Morgagni, congenital esophageal hiatal hernia, congenital cystic disease of the lung, and primary agenesis of the lung. Diaphragmatic eventration has many causes but is seen in the newborn with birth trauma or Werdnig-Hoffmann disease. The eventrated diaphragm can rise as high as the third intercostal space and have the same physiologic consequences as CDH. It can also be completely asymptomatic. The diagnosis is made by fluoroscopy or real-time US with the demonstration of paradoxic movement of the diaphragm. MRI is also useful in determining diaphragmatic structure. Morgagni hernias occur at the hiatus for the internal mammary arteries and are much less common than Bochdalek hernias. Most are diagnosed incidentally on plain radiographs, but some Morgagni hernias can present as a gastrointestinal crisis because of incarceration or volvulus of the colon or small bowel and require immediate operative intervention.

# Prognostic Factors

The search to determine clinically relevant prognostic factors that predict the outcome of infants with CDH has been frustratingly complex, contradictory, and for the most part unsuccessful. Many studies have attempted to examine both anatomic and physiologic parameters that relate to survival, but each has been hampered by its retrospective analysis in the presence of the continuing evolution of new therapies.[139,139a] Whereas consideration of multiple factors may influence one's clinical impression regarding the survival potential of an infant with CDH, such an impression cannot be derived from one measurement alone.

## ANATOMIC FACTORS

With the ability to establish the diagnosis of CDH in utero as a result of the increased use of prenatal US, studies suggested that the antenatal diagnosis of a CDH before 24 weeks' gestational age was associated with a high mortality. Others have shown that antenatal diagnosis, regardless of timing, of an isolated CDH without other associated anomalies is not an indicator of outcome,[140] but more recent reports confirm that antenatal diagnosis is associated with a worse prognosis. A CDH associated with another significant anomaly still has a dismal prognosis. If a CDH is not detected by prenatal US but is subsequently diagnosed after birth, survival rates may be excellent.[122] The Canadian Pediatric Surgery Network (CAPSNet) collected 347 CDH cases between May 2005 and May 2010 (www.capsnetwork.org/resources/annual report 2010); of the 269 patients admitted alive to a pediatric center and with a completed record, 68% had a prenatal diagnosis, with a 74% survival, while the 32% without a prenatal diagnosis had a 96% survival (this drops to 86% when the babies who died in transport are included). Preselection bias prior to transport was not reported.

Antenatal diagnosis and antenatal referral to a full-service children's facility, especially those with maternal/fetal–medicine/lying-in services, has removed much of the postnatal/pretransfer bias and selection. It was also reported that the presence of polyhydramnios was indicative of poor survival.[141] A number of studies, however, have refuted this observation and have shown that the presence of polyhydramnios has no predictive value on the eventual outcome of an infant with CDH.[142,143] The anatomic position of the liver has not been consistently shown to be a reliable predictor of mortality in CDH.[120,126,131,144–146] Nevertheless, there are reports suggesting the presence of liver herniation may be predictive of the need for extracorporeal membrane oxygenation (ECMO) as well as a requirement for prosthetic patch repair for diaphragmatic repair.[15,126,147]

The position of the stomach has been proposed as a prognostic indicator by a number of investigators. Survival rates of infants with CDH with the stomach properly located below the diaphragm at the time of diagnosis have been reported to be as high as 100% but is only 30% when the stomach had herniated into the chest.[148,149] Other studies have shown no predictive value of such positioning.[150] The side of the diaphragmatic defect may be somewhat predictive of outcome. It has been reported that patients with right-sided defects have a worse prognosis than those with left-sided defects.[14,151] A recent study reported no differences in outcomes between the two sides.[152] However, right-sided defects may not become evident in the newborn period and may present with very mild respiratory symptoms at a later age.[153]

A number of different imaging parameters have been reported in an attempt to predict the presence of pulmonary hypoplasia and serve as a prognostic indicator of survival. These include measurements of the fetal thorax and lung, fetal breathing movements, and various calculated blood flow measurements within the pulmonary arteries.[154] The lung–head ratio (LHR) has been the most extensively studied. The LHR is measured using ultrasonography and is the ratio of the area of the contralateral lung (opposite the hernia defect) to the fetal head circumference. The lung area is calculated from perpendicular transverse measurements determined at the plane of the four-chamber view of the fetal heart. This measurement has been suggested to predict prognosis and guide management.[126,155,156] However, there is no consensus as to what value of LHR should serve as a determinant of prognosis or when during gestation that measurement should be made.[157] Because LHR has been proposed to determine the timing of experimental fetal intervention, most studies report LHR measurements before 32 weeks' gestational age.[158] Current data indicate that the strength of association with survival is strongest for those fetuses with LHR greater than 1.0 compared with LHR less than 1.0.[159] A recent report by Aspelund and colleagues of a single-institution experience of all inborn CDH infants managed with a consistent treatment algorithm had significant statistical power to support an LHR less than 0.85 as reliably predicting 100% mortality.[160]

Because LHR changes with gestational age, use of the *observed-to-expected* LHR (O/E-LHR) has been reported.[158,161] A severe left CDH has been characterized by an O/E-LHR of less than 25%.

Prenatal magnetic resonance imaging is being investigated extensively as a method for improving prognostic predictive capability by more accurately determining lung volumes in CDH patients.[162] Measured indices include lung to head ratio as well as relative and absolute fetal lung volumes. The prognostic accuracy appears to be slightly better than sonographic determinations.[146] Signal intensity analysis of fetal lung tissue as part of MRI imaging studies may be a future application of this modality, although a recent report found that lung volumes was a better predictor.[162,163]

The sophisticated analysis of cardiopulmonary structure and function in either the prenatal or postnatal period may also be of prognostic importance.[142,164–166] A number of indices have been reported, including the calculation of the cardioventricular index (left ventricle/right ventricle), the cardiovascular index (Ao/PA), pulmonary artery diameters, the McGoon index (MGI), and pulmonary artery index (PAI).[166–170] The McGoon and pulmonary artery indices are determined shortly after birth by the following formula:

$$\begin{aligned} \text{MGI} &= (\text{RPA diameter} + \text{LPA diameter})/\\ &\quad\ \text{Descending aorta diameter}\\ \text{PAI} &= (\text{RPA area} + \text{LPA area})/\text{BSA} \end{aligned}$$

(RPA and LPA = right and left pulmonary artery, respectively; BSA = body surface area)

MGI scores less than 1.31 have been found to be highly predictive of mortality, while the same has been found for PAI scores less than 90. An analysis of left ventricular mass combined with the simultaneous determination of fractional shortening has also been used to predict outcome, with an index of 1.2 associated with nonsurvival.[171] Advanced echocardiographic measurements with interesting clinical promise include the determination of lung tissue perfusion with the analysis of fractional moving blood volume (FMBV) and the use of pulsed Doppler measurements in the proximal branch of the pulmonary artery to determine the pulsatility index (PI) and the peak end-diastolic reversed flow (PEDRF).[172–174] These measurements may have increasing importance in the search for suitable prenatal predictors of survivability in the setting of fetal therapy.[175]

## PHYSIOLOGIC PARAMETERS

Unfortunately, there are few physiologic parameters that can be measured in the neonate to assess pulmonary function other than $PO_2$, $PCO_2$, and pH. Thus arterial blood gas analysis has been the cornerstone for attempting to establish clinical predictive criteria. Early studies showed differences in pH and $PCO_2$ between survivors and nonsurvivors in response to therapeutic interventions available at that time.[176–178] Infants with a low $PCO_2$ and a $PO_2$ that was initially normal or improved with mechanical ventilation had an excellent outcome, whereas those infants who had high $PCO_2$ levels unresponsive to mechanical ventilation did poorly. These authors noted the importance of measuring both preductal and postductal blood gases to assess the degree of right-to-left shunting. The report by Stolar and colleagues[179] advocated *preductal* oximetry values in the setting of maximal conventional care to identify potential ECMO candidates. In the absence of preductal $SaO_2$ greater than 90%, overwhelming pulmonary hypoplasia was inferred, and ECMO was not offered. This represented less than 5% of all patients, for which there was 100% mortality.

Since these initial reports, investigators have derived a number of formulas using various blood gas components to predict outcome. The most basic concept is the alveolar–arterial oxygen gradient ($AaDO_2$). It is calculated by the formula

$$AaDO_2 = [\{(713 \times FiO_2) - PaCO_2\}/0.8] - PaO_2$$

Although initially used to determine entry criteria for ECMO, its use has been superseded by the development of other indices.

Using blood gas analysis and $PCO_2$ levels in combination with ventilatory data, parameters were determined to predict outcome in CDH infants managed with conventional ventilatory techniques.[110,180–182] To do this, a ventilatory index (VI) was calculated:

$$VI = RR \times (PIP - PEEP)$$

(PEEP = positive end-respiratory pressure; PIP = peak inspiratory pressure; RR = respiratory rate)

When the $PCO_2$ could be reduced to less than 40 mm Hg with a ventilatory index less than 1000, all patients survived. A modified ventilatory index (MVI) was calculated by using peak inspiratory pressure rather than mean airway pressure (MAP):

$$MVI = (RR \times PIP \times PaCO_2)/1000$$

In infants with an MVI less than 40, the survival rate was 96% using conventional therapy. All infants died if the MVI was greater than 80.[183]

The most commonly used calculation is the oxygenation index (OI). It is calculated by the formula

$$OI = (MAP \times FiO_2 \times 100/PaO_2)$$

This formula should be calculated using the *preductal* $PaO_2$, because the postductal one varies tremendously with the amount of shunting.

A 1994 report showed that with conventional ventilatory therapy, an OI less than 6 had a survival rate of 98%, whereas an OI greater than 17.5 had no survivors.[183] The predictive powers of these factors with such therapies as ECMO, high-frequency oscillation (HFO), surfactant, and nitric oxide (NO) have not been determined. Simple preoperative lung function measurements are difficult to obtain but may be of some interest.[184]

In summary, efforts to reliably predict mortality for the fetus or live-born infant with isolated CDH have been fraught with uncertainty. Although a calculated LHR less than 0.85 (or an observed/expected LHR less than 20% to 25%) may have high predictability for mortality, better understanding of prognosis awaits functional evaluation of the fetus. This might include tidal amniotic fluid breathing/lung volumes or response to maternal hyperoxia. Postnatal use of the McGoon index, also because of its functional nature, holds promise.[184a] In the absence of substantiated, reproducible information regarding prognosis, treatment continues to be guided by best clinical judgment.

## PULMONARY FUNCTION TESTS

The analysis of preoperative and postoperative pulmonary function tests has been reported to have predictive value in identifying infants who might require ECMO therapy as well as identifying survivors.[184] Initial studies of respiratory

function in infants with CDH uncovered the detrimental changes in compliance measurements resulting from surgical repair and helped support the hypothesis of medical stabilization and delayed surgical intervention.[185–187] Using the treatment strategies of delayed surgical repair and ECMO, when necessary, infants did not require ECMO when their initial preoperative compliance measurement was greater than 0.25 mL/cm $H_2O$/kg and initial tidal volume was greater than 3.5 mL/kg. An improvement in the tidal volume of 4 mL/kg after repair correlated with survival.[188]

Studies have indicated that preoperative measurement of functional residual capacity may predict fatal pulmonary hypoplasia.[184] In addition, serial measurements of total pulmonary compliance have been found useful in predicting outcome in high-risk infants.[189]

Although no single parameter has proven sufficient as a prognostic factor in managing CDH infants, recent multicenter studies have shown that significant independent predictors of total mortality include prenatal diagnosis, birth weight, low 1- and 5-minute Apgar scores, score for neonatal acute physiology (SNAP-II), and right-sided defect.[139,190–192]

# Treatment

Success in the management of CDH has improved dramatically from 1929 when Greenwald and Steiner[27] wrote, "For the patient in whom the hernia makes its appearance at birth, little or nothing can be done from a surgical standpoint." A number of innovative treatment strategies have been used, although consistent impact on overall survival is still difficult to obtain.

## PRENATAL CARE

The diagnosis of a CDH is being made with increasing frequency by prenatal US examination. This study may be initiated when a discrepancy between size and dates is noted. The prenatal diagnosis of CDH should be complemented by a careful search for other congenital anomalies, particularly those affecting the cardiovascular and nervous systems. Evaluation of fetal karyotype should be accomplished by amniocentesis or chorionic villus or fetal blood sampling. Currently, the standard of care is to support the fetus and mother while bringing them to delivery as close as possible to term. The advantage of prenatal diagnosis is in being able to properly prepare and inform the parents about possible treatments and outcomes. The fetus and mother should be referred to an appropriate tertiary perinatal center where the full array of respiratory care strategies, including NO, oscillating ventilators, and ECMO are immediately available. Anything less may potentially compromise the best possible outcome.[143] Spontaneous vaginal delivery is preferred, unless obstetric issues supervene. The mere diagnosis of a CDH is not an indication for elective cesarean section.

At this time, fetal intervention with attempted in utero correction of the defect is investigational and highly experimental.[105,193–195] In North America, trials of fetal tracheal occlusion for CDH in an effort to promote antenatal lung growth have been abandoned, because they did not show improved survival rates versus contemporary conventional treatments.[193,196] Tracheal occlusion resulted in lung enlargement but did not reverse the pathologic process associated with pulmonary hypoplasia. The selection criteria for the severity of pulmonary hypoplasia to enter the fetal treatment trials has also been questioned.[93,94,193,197–199] The North American trial used an LHR less than 1.4 as entry criterion; the Eurofetus trials have advocated LHR less than 1.0 as entry criterion. Fetoscopic tracheal occlusion trials are ongoing in Europe, with over 200 cases reported,[198] and there are plans for an international prospective randomized trial involving North American centers that participate in NAFTNet (the North American Fetal Treatment Network).

Although prenatal corticosteroids are used to enhance lung development in premature infants, the role of antenatal corticosteroid therapy in CDH patients remains undetermined. The rationale for such therapy to induce pulmonary maturation in a hypoplastic lung is based on animal studies and isolated case reports.[200–203] Balanced against these observations is the growing evidence from premature infant studies that such drugs may also have adverse perinatal and long-term effects.[204,205] The true potential of this therapy in improving CDH outcomes awaits the results of a randomized prospective study.

## PREOPERATIVE CARE

### Resuscitation

After the birth of the infant and confirmation of the diagnosis of CDH, all efforts should be made to stabilize the cardiorespiratory system while inducing minimal iatrogenic injury from therapeutic interventions. It is essential to consider that the CDH is a physiologic emergency and not a surgical emergency. The respiratory distress associated with a CDH in the newborn results from a combination of two factors previously discussed: uncorrectable pulmonary hypoplasia and potentially reversible pulmonary hypertension. The balance between these two factors determines the response to therapy and ultimately the outcome. Clinically, both are manifested by an increase in pulmonary vascular resistance and elevated pulmonary artery pressures, right-to-left shunting at the ductal and foramen levels, and progressive hypoxemia. Because there are no proven therapies to promote pulmonary growth at this time, therapeutic interventions are aimed at governing pulmonary vascular tone.

Resuscitation begins with endotracheal intubation and nasogastric tube insertion. Ventilation by mask and Ambu bag is contraindicated to avoid distention of the stomach and intestines that may be in the thoracic cavity. Arterial and venous access should be acquired through the umbilicus. If the umbilical venous catheter can be passed across the liver into the right atrium, it can be useful for monitoring central venous pressures as well as obtaining mixed venous blood gas samples. Although the umbilical artery is excellent for monitoring systemic blood pressure and obtaining postductal arterial blood gas specimens, additional information can be obtained by monitoring arterial oxygen saturation in a preductal position either with a right radial arterial catheter or a transcutaneous saturation probe. An important part of the treatment algorithm is an attempted estimation as to whether the infant has enough lung capacity for meaningful gas exchange.

It is important to consider this fact before exposing an infant and family to heroic treatment strategies.

As in any neonatal resuscitation, meticulous attention must be paid to maintaining proper temperature regulation, glucose homeostasis, and volume status in the neonate in an effort to maintain adequate oxygen delivery. Any stressful stimulus can further exacerbate already elevated pulmonary pressures and lead to increased shunt flow and further systemic desaturation. Infants should be properly sedated, and any combination of agents, including midazolam, fentanyl, or morphine, can be used. Muscle paralysis is strongly discouraged because of its untoward consequences on ventilatory mechanics and potential morbidity. Infants not “cooperating” with ventilator strategies generally need attention to their discomfort, not muscle paralysis. Systemic hypotension and inadequate tissue perfusion may be observed and reversed with intravenous fluid administration, including crystalloid, blood products, and colloid. Cardiotonic drugs, such as dopamine or dobutamine, may be required. Because of the unstable pulmonary vascular tone and the compromised alveoli, excessive intravenous hydration should be avoided, because it may lead to pulmonary edema, loss of compliance, and further impairment of gas exchange.

Metabolic acid-base disturbances are usually related to hypoperfusion and should be corrected by fluid management or bicarbonate administration. Metabolic acidosis can be reversed with bicarbonate administration if ventilation can be appropriately managed. Severe hypercapnia ($P_{CO_2}$ > 70 mm Hg) should be managed by changing ventilator strategy.

There is no need for a chest tube in the absence of an active air leak, pneumothorax, or hemothorax.[206,207]

## Ventilation

The type of mechanical ventilator needed for the infant with a CDH is a matter of personal and institutional preference. Most infants can be successfully managed with a simple pressure-cycle ventilator, using a combination of high rates (100 breaths per minute) and modest peak airway pressures (18 to 22 cm $H_2O$ and no PEEP) or lower rates (20 to 40 breaths per minute) and higher pressures (22 to 35 cm $H_2O$, 3 to 5 cm PEEP). The goal of such ventilatory support is to maintain minute ventilation while obtaining a preductal $P_{O_2}$ greater than 60 mm Hg ($Sa_{O_2}$ 90% to 100%) with a corresponding $P_{CO_2}$ of less than 60 mm Hg. pH and $P_{CO_2}$ levels have been shown to be important in modifying pulmonary vascular tone.[307b] The successful clinical manipulation of these parameters in therapeutic interventions in neonates with persistent pulmonary hypertension represents an initial treatment strategy. It is now clear, however, that the extremes of hyperventilation with induced alkalosis should be avoided because such therapy compounds the pulmonary problems with serious iatrogenic injury.[208] A respiratory strategy based on permissive hypercapnia and spontaneous respiration has proven to be quite successful.[206] If conventional mechanical ventilatory techniques cannot reverse the hypoxemia or hypercarbia, high-frequency techniques using an oscillating ventilator may be required. This technique may be effective in removing carbon dioxide and temporarily stabilizing an infant in severe respiratory distress. When such techniques have been used as initial therapy, survival results have been quite good.[137,209,210]

## Pharmacology

A broad spectrum of drugs and antihypertensive agents has been used in attempts to modify the pulmonary vascular resistance in infants with CDH and respiratory failure. Experience has been extrapolated from clinical trials of infants with persistent pulmonary hypertension of the newborn (PPHN) and other forms of neonatal respiratory failure.

In the past, agents such as tolazoline,[211,212] which exerts its effects through α-receptor blockade, had been used to lower pulmonary vascular resistance in the face of hypoxemia and respiratory failure.[212,213] Its efficacy in CDH infants was marginal. Other drugs, such as nitroprusside, isoproterenol, nitroglycerin, and captopril, have not been effective.[214] The administration of various prostaglandin derivatives, including prostaglandin $D_2$ ($PGD_2$), prostaglandin $E_1$ ($PGE_1$), and prostacyclin, and of the cyclooxygenase inhibitor indomethacin has also been disappointing.[115,215]

New management strategies for treating persistent pulmonary hypertension now undergoing clinical evaluation include various calcium channel blockers, prostacyclin derivatives, endothelin receptor antagonists, and phosphodiesterase-5 inhibitors such as sildenafil.[216,217]

## Surfactant

Animal models have demonstrated that experimentally induced CDH lungs are surfactant deficient,[218] but such results have not been replicated in human studies. Early reports in infants with CDH demonstrated alterations in surfactant levels and composition.[219,220] However, recent studies have indicated that the surfactant pool in infants with CDH is no different than control patients, even in infants requiring ECMO support.[221–224] There may be alterations in synthetic and metabolic kinetics for individual components.[221] In terms of improving respiratory function and outcomes, clinical and experimental investigations with surfactant administration have been mixed.[224–228] A multicenter review of surfactant administration in CDH patients showed no overall benefit to its use and demonstrated a lower survival rate in preterm infants compared with full-term infants.[229] At this time, there are no clinical data to support the administration of surfactant in the management of CDH infants.

## Nitric Oxide

NO is a potent mediator of vasodilatation and was originally identified as endothelial-derived relaxing factor.[230] Because it is a highly diffusible gas that is rapidly inactivated by binding to hemoglobin, it is particularly suited for administration to the pulmonary vasculature with mechanical ventilatory techniques. In clinical studies, NO was effective in improving oxygen saturation levels in neonates with respiratory failure due to PPHN.[231,232] In an animal model of PPHN, NO decreased pulmonary artery pressures and increased arterial oxygen saturation without discernable side effects.[233] Unfortunately, its effects in CDH infants with respiratory failure have been mixed.[86,231,234–238] There are no data to show that NO administration improves survival or decreases the requirement for ECMO.[239] The variable physiologic response to NO in these infants may be related to the method of its administration.[228,240] NO administered through a nasal cannula has been used for the treatment of late pulmonary hypertension following extubation.[231] The exact role of NO in the treatment

of pulmonary hypertension and respiratory failure in CDH infants has not been defined despite its widespread use.

## SURGICAL MANAGEMENT

### Timing of Surgical Repair

Historically, CDH was considered a surgical emergency. Infants were rushed to the operating room as soon as possible after birth in the belief that reduction of the abdominal contents from the chest would relieve the compression of the lungs. Frequently, after a brief postoperative honeymoon period marked by adequate gas exchange, progressive deterioration in the infant's respiratory status ensued with elevated pulmonary vascular resistance, right-to-left shunting, hypoxemia, and ultimately death resulting from respiratory failure.

As management techniques for neonatal respiratory failure evolved, a period of medical stabilization and delayed surgical repair, in an attempt to improve the overall condition of the infant with CDH, was proposed.[117,180,241–249] At the same time, there was increasing evidence of the potential detrimental effects of early surgical repair on respiratory function.[250] Since then, multiple single-institution studies have reported improved survival rates with delayed surgery as part of their treatment protocols, whereas others have found no changes in overall outcome. Importantly, no study has shown a decrease in survival rates with this technique. Although delayed surgical repair is now widely practiced, there is no statistical evidence that supports this approach over immediate repair at this time.[251]

The optimal timing of operative repair when using a strategy of delayed repair also remains undetermined. The period of preoperative stabilization has varied from several days to several weeks.[186,253–255] Some authors have reported waiting until the infant is successfully weaning off mechanical ventilation and requiring low ventilator settings. Others follow the severity of pulmonary hypertension with serial echocardiographic examinations and wait until the hypertension has abated or at least stabilized.[256–258]

### Operative Repair

Most surgeons approach the defect through a subcostal incision, although the repair can be done through a thoracotomy incision as well. For rare cases in which reduction of the herniated contents is difficult because of an abnormally shaped liver or spleen, a combined approach can be used.[259] Both thoracoscopic and laparoscopic techniques have been used to repair these defects.[260–265a] Although thoracoscopic repairs have application in stable CDH patients[266] and can be accomplished with primary or prosthetic material closure, a recent report by Gander and colleagues[261] suggests thoracoscopic repair is associated with an unacceptably high recurrence rate within 1 year after repair.

After division of the abdominal wall muscles and entrance into the abdominal cavity, the viscera are gently reduced from the defect and completely eviscerated for adequate visualization. The spleen on the left side and the liver on the right are usually the last organs to be mobilized from the chest cavity (Fig. 63-5, *A* and *B*). Mobilization can be difficult and must be done without injury to either organ. On the right side, the kidney and adrenal gland may be found in the chest as well. Abnormal drainage of the hepatic veins on either side may complicate mobilization of the liver.

Once the abdominal contents are reduced, the defect in the diaphragm in the posterolateral position can be examined. In 20% of patients, a hernia sac formed by parietal pleura and peritoneum is present and must be excised to minimize chances of recurrence.[16] Usually, there is an anterior rim of diaphragm of varying size. The posterior rim of diaphragm must be searched for in the retroperitoneal tissue, because it may be rolled up like a window shade by the peritoneum. The peritoneum must be opened over this fold and the diaphragmatic tissue mobilized. When tissue is adequate, a primary repair with interrupted nonabsorbable suture material can be performed (Fig. 63-5, *C*). In some cases, the posterior rim of tissue may disappear along the lateral chest wall. If enough diaphragmatic tissue exists anteriorly, it can be sutured directly to the body wall with sutures placed around the ribs.

If the defect is too large to be closed in a primary fashion, a number of reconstructive techniques have been described using various nearby structures, such as prerenal fascia, rib structures, and various abdominal wall muscle flaps.[267–272] If there is any chance that ECMO support might be required in the management of the infant, however, the use of complex reconstructive techniques requiring extensive tissue dissection is contraindicated because of the risk of bleeding. The use of prosthetic material to complete the diaphragmatic closure has gained widespread acceptance (Fig. 63-5, *D*). A floppy, tension-free diaphragmatic repair can be accomplished, which may lessen the degree of intra-abdominal pressure when closing the abdominal wall.[273] In addition to the risk of infection, the major drawback to using a prosthetic patch closure is the risk of dislodgment and subsequent reherniation.[274] This complication may be lessened by using a cone-shaped patch.[275] Complications of prosthetic patch repair occur in approximately 10% to almost 50% of cases. Patients who develop a recurrent hernia present with bowel obstruction or respiratory distress or may be asymptomatic.[276,277] Recently, the split abdominal wall muscle flap repair was shown to be safe to use on ECMO and was associated with only one recurrence in 23 patients, with a mean follow-up of 4.8 years.[278]

With the loss of intra-abdominal domain, abdominal wall closure may not be possible at all or may result in unacceptable intra-abdominal pressure (i.e., abdominal compartment syndrome), even after extensively stretching the abdominal wall. In these situations, simple closure of the skin can be accomplished with repair of the resultant ventral wall defect some months later. If the skin cannot be closed successfully, temporary closure using prosthetic material, such as a silo, can be used. Biologic closure should then be obtained as soon as safely possible in the postoperative period. Drainage of the chest cavity on the repaired side with a tube thoracostomy is not indicated except for active bleeding or uncontrolled air leak. It has been proposed that such a tube with even a small degree of negative suction may add to the barotrauma and pulmonary hypertension imposed by mechanical ventilation on a hypoplastic lung.[254,279] Additional surgical procedures at the time of the repair, such as correction of the nonrotation as well as appendectomy, are not indicated and should be avoided if ECMO is to be considered.

The repair of recurrent defects can present a formidable surgical challenge. Since the most common organ involved in

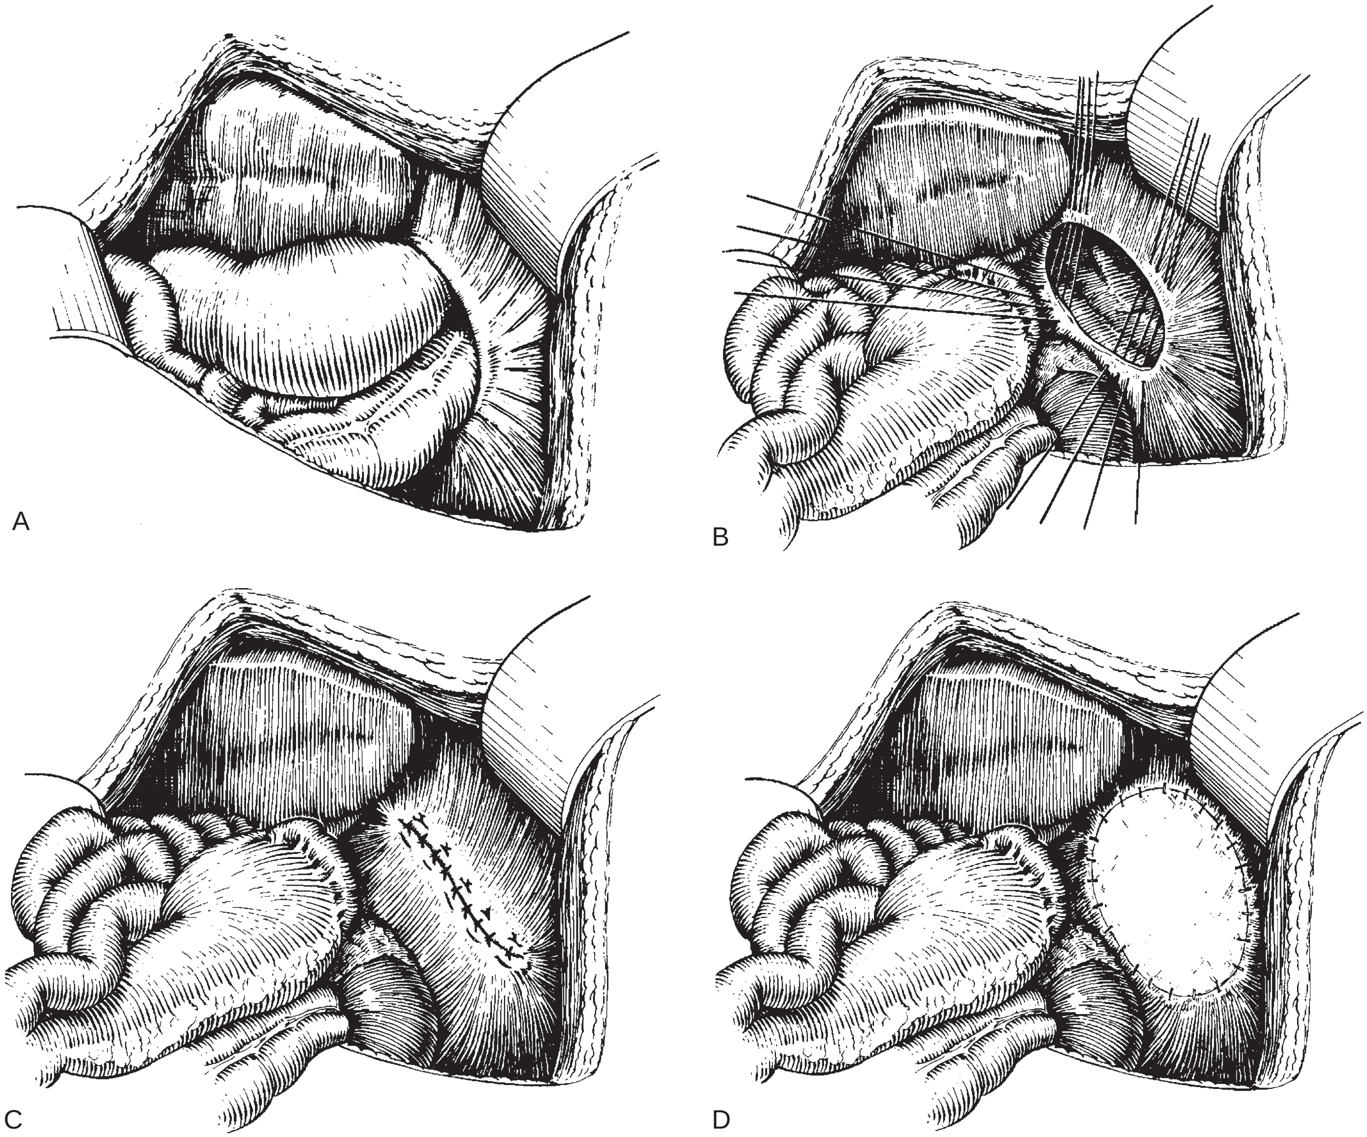

**FIGURE 63-5** **A,** Schematic drawing of an unreduced left congenital diaphragmatic hernia as seen from the abdomen. **B,** The same hernia but now reduced, demonstrating that the spleen is usually the last organ to be reduced from the chest cavity. Sutures have been placed for a primary repair. **C,** Completed primary repair of a left congenital diaphragmatic hernia. **D,** Repaired left congenital diaphragmatic hernia using prosthetic material. (From Spitz L, Coran AG [eds]: Rob & Smith's Pediatric Surgery. London, Chapman & Hall, 1996.)

recurrent herniation is either the small or large bowel, intestinal adhesions to the disrupted diaphragm or intrathoracic organs may compromise attempted closure. Repair is most commonly approached through the abdomen but can be accomplished through a thoracotomy as well. If adequate diaphragmatic tissue is present, then primary reapproximation should be attempted. Otherwise, different techniques for prosthetic material insertion have been tried [269,276,280] Because most recurrent CDH occur after initial patch repair and often well away from the neonatal period, once the baby is more stable, repair using a latissimus dorsi muscle flap through a thoracic approach may provide the best means to prevent further recurrence.[281]

## Anesthesia

To avoid the stresses of transport and sudden changes in ventilation parameters imposed by a trip to the operating room, a number of centers have adopted the policy of performing surgical repair of CDH infants in the neonatal intensive care unit. This change in location allows for the lowest degree of disruption in the neonate's environment. Anesthesia is achieved by intravenous narcotic and muscle relaxant techniques. With intravenous anesthetics, the infant ventilator can be used continuously rather than a conventional anesthesia machine.

## Postoperative Management

Postoperative management should continue the trends and goals established before the operative procedure. Ventilator support should be tailored to keep preductal $Sa_{O_2}$ greater than 90% and $P_{CO_2}$ less than 60 mm Hg.[282] Echocardiograms should be obtained routinely to assess pulmonary hypertension, shunt flow, and ventricular performance. Therapeutic interventions discussed previously may be used if respiratory decompensation develops. Weaning from ventilator support should be slow and deliberate as tolerated by the infant.

Meticulous attention to fluid status must be maintained, particularly in the immediate postoperative period. As a result of surgical intervention, these infants are often hypovolemic and frequently require extra volume administration over time.

## EXTRACORPOREAL MEMBRANE OXYGENATION

Even with recent advances in treatment strategies, overwhelming respiratory failure requiring ECMO support occurs in 10% to 20% of CDH infants.[206,283–285] Initially, infants were placed on ECMO after developing respiratory failure following the immediate repair of the diaphragmatic defect. With the evolution of delayed surgical repair, ECMO is now considered a part of the preoperative stabilization process.

Clinical criteria for determining ECMO use in infants with CDH have been based on factors predictive of at least an 80% mortality rate with mechanical ventilation.[214] A number of parameters have been proposed, including the calculation of the oxygenation index (OI) and the alveolar–arterial oxygen difference $AaDo_2$. For CDH patients, the most common reason for the initiation of ECMO was an OI of 40 or greater, and it is often considered for an OI as low as 25.[283] Generally accepted criteria for initiating ECMO support for neonatal respiratory failure based on $AaDo_2$ criteria include a value of 610 or greater despite 8 hours of maximal medical management. It must be realized that such criteria continue to be institution specific and that no calculations can replace clinical judgment and frequent bedside assessment. Failure to improve in the setting of severe pulmonary hypertension and progressive hypoxemia despite maximum medical intervention remains a valid qualifying criterion for ECMO support.

Controversy still exists as to whether ECMO support should be offered to all infants with CDH and respiratory failure.[32,140,286,287] The issue of severe pulmonary hypoplasia incompatible with life must be kept in mind when ECMO is being considered. This intervention is successful when used to support an infant with a reversible process of pulmonary hypertension. However, it is not a treatment for those infants with irreversible hypoplasia. Differentiating these infants on clinical parameters can be quite difficult. A newborn with a CDH who is unable to reach a preductal oxygen saturation level of at least 90% or a markedly elevated $Pco_2$ level unresponsive to any type of ventilatory intervention during the pre-ECMO course has a high likelihood of having irreversible hypoplasia.[179,289] On the other hand, others have proposed that all infants should be ECMO candidates. Ultimately the decision to use ECMO is a clinical decision. If the infant's tissue oxygen requirements are not being met, as manifest by end-organ failure, despite best conventional care, ECMO is a reasonable consideration.

Although widely accepted as a treatment for the respiratory failure associated with CDH, the impact of ECMO on improving overall survival continues to be debated. Over the past decade, a number of studies have demonstrated improved survival rates in CDH infants with ECMO as part of the treatment strategy.[283,290,291] However, other institutions have either not noted any improvements resulting from ECMO or have been able to manage their infants without it with equivalent success.[137,248,292,293,301] Overall survival rates of infants treated with ECMO vary from 34% to 87% and are clearly dependent on a number of variables, including gestational age and birth weight, respiratory function, and the degree of pulmonary development and associated pulmonary hypertension.[219,256,292,294] The impact of barotrauma and oxygen toxicity from overly aggressive respiratory care strategies on outcome cannot be overemphasized. As conventional treatment strategies continue to improve, ECMO use and concomitant survival rates following ECMO may decrease.

A number of surgical issues are relevant in the management of CDH infants while on ECMO. Both venovenous and venoarterial techniques have been reported to be equally effective in supporting patients while on bypass.[284,295] With venovenous bypass, severe right-sided heart failure can be managed temporarily with a $PGE_1$ infusion to keep the ductus open until the pulmonary hypertension resolves or by converting to venoarterial support. The timing of the surgical repair of the defect in relation to ECMO support remains variable. As a result of the acceptance of delayed surgical repair as a treatment strategy, more than 90% of CDH infants requiring ECMO support are placed on bypass before undergoing surgical repair.[242] Surgical repair of the defect while on ECMO can then be accomplished but has been associated with hemorrhagic complications in 60% of the patients.[244,296] Survival rates after surgery on ECMO have varied from 43% to 80%.[287,297,298] To minimize the risk of hemorrhagic complications, a number of techniques have been proposed, including the use of heparin-bonded ECMO circuits, performance of the surgical repair just before expected decannulation, and aggressive management of the anticoagulant status of the infant, including the use of antifibrinolytic therapy. Because of the coagulation problems, less than 20% of infants are reportedly repaired while on ECMO.[299] The majority undergo repair after the completion of ECMO. This delayed operative approach, sometimes not occurring until several days after decannulation, has been extremely successful, with survival rates of almost 80% and higher.[258,284,300] However, there are currently no available studies comparing either pathway.

## OUTCOME

Survival rates for infants born with a CDH vary from approximately 60% to 90% because of the use of more physiologic treatment strategies, including "gentle ventilation" techniques, high-frequency ventilation, cardiovascular pharmacologic support, and ECMO.* With the gradual improvement in survival rates over the past 2 decades, there is a greater appreciation for issues related to the long-term development of CDH survivors and the frequency of associated morbidities, as a greater number of physiologically compromised infants are surviving beyond the neonatal period. It is now recognized that CDH survivors are at significant risk for chronic neurologic, developmental, gastrointestinal, nutritional, pulmonary, musculoskeletal, and other disorders. Late deaths have been reported in approximately 10% of initial survivors, mainly because of the consequences of persistent pulmonary hypertension or iatrogenic complications.[19,39,306,307] The requirement for coordinated long-term follow-up and care of these patients has become evident from studies carried out over the past decade.[303,307a,308]

Pulmonary issues are the most common long-term problems in the postnatal period and include chronic lung disease or bronchopulmonary dysplasia, reactive airway disease,

*References 191, 206, 211, 241, 287, 301–305.

pulmonary hypertension, and pneumonia. Pulmonary developmental studies have shown that alveolar multiplication continues for several years after birth. However, a normal number is never achieved in CDH hypoplastic lungs. Over time, the alveoli in both lung fields may become emphysematous, as the contralateral lung may herniate across the mediastinum on chest radiographs. Gradual remodeling of the pulmonary vascular bed occurs. However, vascular growth may not match alveolar growth.[309,310] Pulmonary function testing remains the most useful test, because ventilation-perfusion studies have been associated with conflicting reports on pulmonary growth.[311]

Immediately following surgical repair of the hernia and for the first 6 months of life, abnormalities in pulmonary function values have been reported in such measurements as functional residual capacity (FRC), compliance (C), airway resistance (R), and maximum expiratory flow rate at FRC.[151,312,313] Significant improvements in lung function become evident during the first year of life, with only mild abnormalities in subsequent tests noted after 2 years of age, indicating that lung function does improve over time. These improvements in lung function parameters, such as compliance and airway resistance, correlate with the growth of the infant, and any compromise of the nutritional status of a CDH infant should raise concern about lung growth and development.[19] Chronic lung disease has been reported in CDH survivors, particularly in those requiring ECMO support.[314,315] Whether this finding is related to the pathology of the disease or has been induced iatrogenically resulting from techniques of ventilation is unclear.[250] Treatment strategies for these patients have included the use of supplemental oxygen, bronchodilator therapy, corticosteroids, diuretics, and appropriate immunizations. Prolonged ventilator support and tracheostomy may be required in a small percentage of patients.[316]

In long-term studies of pulmonary function in survivors, many adolescents and adults have been found to have nearly normal exercise capacity and cardiorespiratory response to exertion.[151,315,317–321] Abnormalities in such parameters as forced expiratory volume in 1 second ($FEV_1$), forced vital capacity (FVC), and maximum midexpiratory flow and peak expiratory flow rates indicate that obstructive and restrictive ventilatory impairments are present in up to 50% of survivors.[311,318,320,322] The functional consequences of these flow abnormalities are reportedly minimal.

The risk of pneumonia in CDH survivors, particularly in infancy and early childhood, is significant and has been reported in up to 35% of patients by the age of 12. Viral bronchiolitis, particularly with respiratory syncytial virus (RSV), is a concern in the first 3 years of life.[151,323]

Although it is known that patients with congenital heart disease and CDH have a poor prognosis, the long-term consequences of structural cardiac abnormalities in survivors are unknown. Although the frequency of cardiovascular malformations ranges from 11% to 17% and includes major structural defects, such as atrial and ventricular defects, conotruncal defects, and left ventricular outflow tract obstructive defects, the risk of death in these patients can be as high as 3 times that for patients with CDH alone.[48,324] Prolonged elevation in pulmonary artery pressure, whether it results from pulmonary hypoplasia, bronchopulmonary dysplasia, or structural cardiac disease, impacts survival, and late deaths have been associated with persistent pulmonary hypertension. Pulmonary artery pressures determined by echocardiography normalize in approximately 50% of all patients with CDH by 3 weeks of age but can remain elevated for months in up to one third of surviving infants.[256,307,325]

A high incidence of neurodevelopmental abnormalities have been detected in CDH survivors. Developmental delay has been reported in a number of surviving infants as well as abnormalities in motor and cognitive skills.[314,326] Both motor and language problems are evident within the first 3 years of life, and infants with motor problems detected at age 1 year were more likely to have abnormal postnatal neuroimaging studies.[327–329] Progressive sensorineural hearing loss has been demonstrated in up to 50% or more of CDH survivors with no discernable etiology. Its onset appears to be within the first 2 years of life, but late onset deficits in patients with previously normal audiology tests have been reported.[62,330] It is a progressive abnormality and requires frequent audiology follow-up. Aggressive use of aminoglycoside antibiotics and furosemide diuretics may be part of the etiology. Other neurologic findings reported in CDH survivors include visual disturbances, seizures, and abnormal computed tomography (CT) and MRI studies.[314,331] Most studies have implicated ECMO as a factor in these neurologic problems, but infants treated without ECMO are also at risk.[332–334]

CDH survivors have a high incidence of gastrointestinal conditions, of which gastroesophageal reflux is the most significant (Fig. 63-6).[52,314,335,336] The condition may occur in as many as 80% of patients after CDH repair and in 60% of long-term survivors.[337] Infants requiring patch closure of the defect, having an intrathoracic position of the stomach at the time of repair, or requiring ECMO support are at higher risk for developing symptomatic reflux.[52,336a–338] Antireflux surgery for severe disease is required in 15% to 35% of cases. Nutritional and growth-related problems have been found in a significant number of survivors.[92,339,340] Aggressive nutritional management using gastrostomy feedings may be required.[303]

A number of skeletal disorders have been reported, including chest wall deformities and scoliosis.[341,342] Chest wall

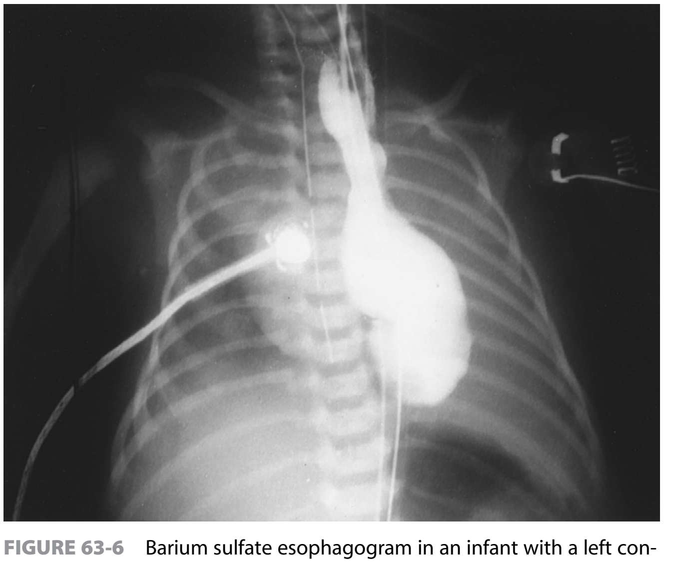

**FIGURE 63-6** Barium sulfate esophagogram in an infant with a left congenital diaphragmatic hernia demonstrating a dilated, ectatic esophagus. The stomach was oriented vertically and emptied slowly.

deformities have been associated with patch repair of the defect. Most defects are minor, and treatment of these problems has included initial attempts at bracing followed by surgical correction if progressive.

Recurrent diaphragmatic hernia and small bowel obstruction are the dominant surgical challenges following initial repair. Recurrent hernias may occur in up to 50% of infants undergoing patch repair of the defect and in 10% of primary repairs, and they tend to occur in the first 4 years of life.[342–344] A small bowel obstruction may occur in a small percentage of patients and may be related to adhesions, reherniation, or, rarely, a volvulus. Chylothorax can also occur after both primary and patch closure and may require surgical intervention if conservative management is unsuccessful.[65]

There is a growing realization that infants with a right-sided diaphragmatic defect may present with management challenges and outcomes different from those with left-sided defects. Herniation of the liver into the right chest can be a surgical challenge in diaphragmatic repair, and cases of hepatopulmonary fusion have been reported.[345–347] Infants with right-sided defects may have a higher requirement for patch repair of the diaphragm as well as for ECMO support.[348,349]

Over the last decade, it has become clear that CDH survivors present many complex management challenges and require lifelong medical surveillance and follow-up. Comprehensive multispecialty clinics that provide specialty physician and support services, along with evidence-based guidelines, are important in advancing the care of these patients.[307a,342]

## FUTURE THERAPIES

Despite the advancements that have been made in treating infants with CDH, it still represents a frustrating and complex clinical problem. As the striking variance in survival rates attests, no currently used therapeutic intervention or management strategy has emerged for widespread successful application. Even with the increasing success of current treatment strategies, such as permissive hypercapnia, delayed operative repair, antihypertensive pharmacology, and advanced ventilatory techniques, a cohort of infants refractory to these interventions continue to be candidates for novel treatments.

Fetal intervention in the management of CDH remains highly controversial. The concept of fetal surgical intervention evolved from the experimental observations in lambs that the reduction of compressive forces on the lung resulted in continued pulmonary growth and development.[91,98,101,194,350] With the development of fetal surgical techniques, initial studies attempted direct surgical repair of the defect with reduction of the herniated contents.[351,352] When no clinical advantage in survival was demonstrated, this approach was terminated. Experimental evidence for the important role of lung fluid dynamics in fetal lung development[101,353–355] has subsequently triggered interest in the role of tracheal occlusion (TO) as a fetal intervention to promote in utero lung growth.[175,356–359] The clinical technique has evolved from the open or fetoscopic placement of extraluminal clips on the trachea to the insertion of an endoluminal device with either a foam plug or detachable balloon. Experimentally, lung growth was further enhanced using intraalveolar fetal albumin administration.[360] Although TO has been shown in some studies to induce changes in pulmonary morphology, pathologic changes, such as a decrease in type II (surfactant-producing) pneumocytes, have also been noted.[356,361–365] Improvement in physiologic lung function was seen in some studies but not in others.[252,310,358,366] Local effects on tracheal structure have included tracheomegaly.[367,368] Although this intervention in the prenatal management of fetuses with CDH has been reported in several institutional studies,[197–199] there are no randomized trials in the North American setting demonstrating a clinical benefit in improving postnatal survival in a cohort of CDH fetuses with agreed upon prohibitive mortality.[193,196,352] The role of tracheal occlusion in the treatment of CDH remains experimental and unproven. Continued evolution in the techniques of this procedure as well as bona fide, randomized clinical trials will continue to generate interest and perhaps validation of this intervention.

Liquid ventilation techniques have been attempted in CDH infants while on ECMO (Fig. 63-7).[369,370] After perfluorocarbon administration, significant increases were reported in $Pa{O_2}$ levels and in static total pulmonary compliance measurements accompanied by a fall in $Pa{CO_2}$ levels. No adverse side effects were noted. Extensive studies are required to examine this newest form of ventilation before its efficacy can be judged.

Based on the observations of fetal lung growth induced by tracheal occlusion, inducement of postnatal lung growth with static distention has also been investigated. During the course of the liquid ventilation experiments, pulmonary distention as a result of perfluorocarbon administration was observed. Its use as a potential treatment to induce postnatal lung growth in CDH patients was then reported.[371–373] Preliminary studies have shown significant radiographic enlargement of the lung and improved gas exchange. Animal studies have supported the concept of accelerated postnatal lung growth using perfluorocarbon distension.[374] Further study of this potential intervention is required.

Lung transplantation has also been used anecdotally in the surgical treatment of CDH.[375,376] Both unilateral and bilateral

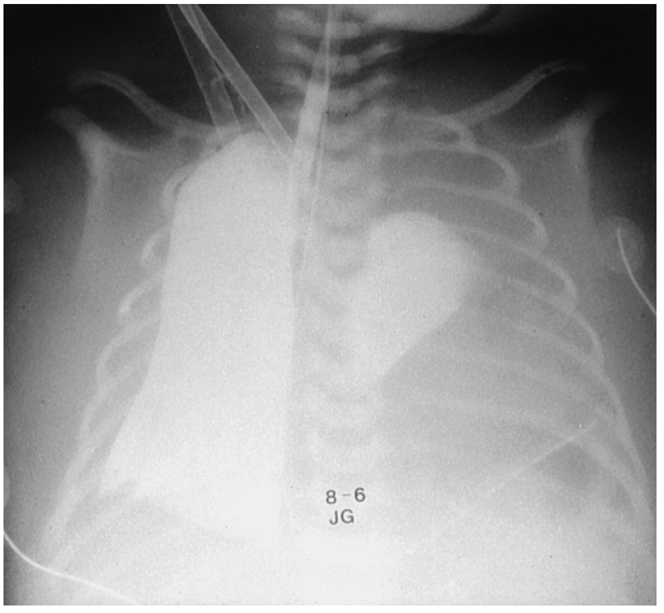

FIGURE 63-7 Chest radiograph of a left congenital diaphragmatic hernia being supported with extracorporeal membrane oxygenation. The lungs have been opacified with perflubron for liquid ventilation. The pulmonary hypoplasia can be appreciated. (Courtesy R. B. Hirschl, MD.)

transplants have been attempted. Currently, not enough experience exists to recommend this form of treatment.

The potential role of pharmacologic augmentation of pulmonary growth and development is currently being investigated. The combined administration of thyrotropin-releasing hormone and glucocorticoid therapy has been studied in a chemically induced rat model of CDH, with positive effects on lung growth.[24,377] It is also known that a number of growth factors are crucial to normal pulmonary development. It has been proposed that perhaps selected administration of one or several of these pharmacologic agents or growth factors may be able to reverse the pulmonary hypoplasia of CDH.[60,377] Continued experimental work using the nitrofen model of CDH may uncover new candidates to promote lung growth and development either prenatally or after birth.

Finally, given the current wide-ranging survival rates at various institutions, an in-depth study and evaluation of current management techniques and outcomes must be made. The efforts of the CDH Study Group, Extracorporeal Life Support Organization (ELSO),[378] and the Canadian Pediatric Surgery Network to interpret very heterogeneous data are an encouraging beginning. Such studies might result in the refinement and consolidation of current practices into a universally effective treatment strategy.

# Foramen of Morgagni Hernia

The diaphragmatic hernia of Morgagni is located anteromedially on either side of the junction of the septum transversum and the anterior thoracic wall. The defect occurs through the embryologic space of Larrey. Occasionally, bilateral Morgagni hernias communicate in the midline, constituting a large anterior diaphragmatic defect extending all the way across the midline from right to left. Typically, a sac is present, and herniation of the colon or small bowel is usually discovered to the right or left of the midline. Morgagni hernias account for less than 2% of diaphragmatic defects. Although this defect may be observed in neonates, it usually presents more commonly in older children or adults. Associated anomalies may be present and include malrotation, cardiac defects, and trisomy 21.[379,379a] An anterior midline deficiency in the diaphragm, with or without the other elements of the pentalogy of Cantrell, with free pericardial and peritoneal communication may allow herniation of intestine into the pericardium. The hernia is often discovered incidentally as a mass or air–fluid level on a chest radiograph. A barium enema or a CT scan may confirm the diagnosis.

Operative correction is easily performed through an upper transverse abdominal incision. The diaphragm is sutured to the underside of the posterior rectus sheath at the costal margin after reduction of the hernia and resection of the sac. Laparoscopic and thoracoscopic techniques have also been used to repair this defect, but the laparoscopic approach is generally favored.[380–384]

# Eventration of the Diaphragm

Eventration of the diaphragm may be either congenital or acquired. The congenital form may be indistinguishable from a diaphragmatic hernia with a sac, and symptoms may be similar for the most severe forms, while small localized eventrations are usually discovered incidentally on chest radiographs. A lateral chest radiograph is essential to the evaluation of eventration, especially on the right side. A modest posteromedial eventration that looks much more significant on an anteroposterior view is unlikely to benefit from surgical intervention. The acquired lesion is due to paralysis of the phrenic nerve, which may occur from injury during repair of congenital heart defects or through brachial plexus injury at birth (Erb palsy).[385] In these cases, the diaphragmatic muscle is usually present in its normal distribution, but it is attenuated and inactive.

There may be no symptoms whatsoever, even in the presence of a large eventration, although the findings may range from wheezing, frequent respiratory infections, and exercise intolerance to extreme respiratory distress. Diagnosis is usually made on fluoroscopy of the chest or with ultrasound examination. In such cases, the diaphragm moves paradoxically with respiratory motion. This paradoxic movement may be so marked that it results in severe compromise of gas exchange. Although pneumoperitoneum was used frequently in the past as a diagnostic modality, CT or MRI is used more often today. A right diaphragmatic eventration may be difficult to differentiate from a CDH, because the liver may block the defect; sometimes thoracoscopy is required for diagnosis.

A small eventration may be left untreated. Repair is indicated when a large functional deficit in the function of the ipsilateral lung on ventilation/perfusion studies is found in an apparently asymptomatic patient. In such cases, the compressed lung will not grow well. Repair may be performed either through the abdomen or the chest, but, in most cases, a low thoracotomy is recommended, because this approach allows identification and preservation of phrenic nerve fibers in case the damaged nerve recovers. A thoracic approach is especially preferred for right diaphragmatic eventration, because the liver would make an abdominal approach more difficult. Through this approach, the diaphragm is best plicated with nonabsorbable interrupted 2-0 sutures. A radial or peripheral incision may also be made in the diaphragm and the edges overlapped and sutured. It is important to reef up and overlap the diaphragm so that it is taut—overcorrecting it somewhat, because invariably, the muscle will stretch and the eventration will recur if this is not done. Although phrenic nerve injury may spontaneously recover, diaphragmatic plication for acquired eventration is frequently necessary to wean infants from ventilatory support. Plication can also be accomplished by either a laparoscopic or thoracoscopic approach. This operation does not preclude normal diaphragmatic function, should phrenic nerve function return.

CHAPTER 64

# Cysts of the Lungs and Mediastinum

N. Scott Adzick and Diana L. Farmer

Familiarity with normal variations and potential pathologic abnormalities in the lung and mediastinum is necessary, because questions frequently arise on evaluation of chest radiographs. The possibility of infection, respiratory difficulty, and airway obstruction from space-occupying lesions makes mandatory the expeditious evaluation and treatment of children with a mediastinal or pulmonary cystic mass. The prognosis of mediastinal and lung cysts in most children is good.

## Embryology

Mediastinal and lung cysts are developmental in origin. Embryologic development pertinent to mediastinal masses is mostly related to the foregut and the thymus. The foregut is first recognizable as an epithelial-lined tube late in the third postconceptual week, by which time the respiratory groove (tracheal bud) is visible. Septation of the esophagus and the trachea occurs over the ensuing 2 weeks by a process of cephalocaudal growth of both structures, lateral infolding of the foregut, and caudocranial septation of the trachea and esophagus. During this interval, there is proliferation of foregut epithelium that almost completely obliterates the esophageal lumen before subsequent tubularization. Differentiation of both esophageal and tracheal epithelium is recognizable in the fourth week. The process is largely completed by day 32 to 34. It is presumed that incomplete tubularization after the epithelial proliferative phase results in foregut duplication cysts.[1]

The thymus develops as paired primordia from the ventral third pharyngeal pouch. During the seventh postconceptual week, the primordia elongate caudad and ventromedially to their normal position anterior to the aortic arch. At that time, the two thymic lobes attach to each other by connective tissue but not parenchyma. Initially, thymic primordia contain a thymopharyngeal duct, which is obliterated after complete descent. Incomplete descent may result in solid or cystic masses in the neck. Lack of obliteration of the thymopharyngeal duct results in congenital cysts of the thymus.[2]

Prenatal lung development is described in Chapter 63. A mixed lung lesion consisting of a combination of bronchogenic cyst, bronchopulmonary sequestration, and congenital cystic adenomatoid malformation suggests a common embryologic link for these malformations, but the precise embryologic causes are unknown.[3]

## Cystic Lung Lesions

### DIAGNOSIS AND TREATMENT

The true incidence of cystic lung lesions is unknown, because there are no population-based studies in the literature. Congenital cystic adenomatoid malformation was first described as a distinct pathologic entity by Chin and Tang in 1949.[4] Before then, congenital cystic adenomatoid malformation was grouped under the general diagnosis of congenital cystic lung disease, along with bronchopulmonary sequestration, congenital lobar emphysema, and bronchogenic cyst.

Prenatal diagnosis provides insight into the in utero evolution of fetal lung lesions, such as congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration (BPS), and congenital lobar emphysema. Serial sonographic study of fetuses with lung lesions has helped define the natural history of these lesions, determine the pathophysiologic features that affect clinical outcome, and formulate management based on prognosis.[5–10] A decade ago, we reported a series of more than 175 prenatally diagnosed cases from the Children's Hospital of Philadelphia and the University of California, San Francisco, and our clinical experience over the last 15 years at the Center for Fetal Diagnosis and Treatment at the Children's Hospital of Philadelphia now extends to more than 700 cases. We found that the overall prognosis depends on the size of the lung mass and the secondary physiologic derangement: A large mass causes mediastinal shift, hypoplasia of normal lung tissue, polyhydramnios, and cardiovascular compromise, leading to fetal hydrops and death (Fig. 64-1).[11]

Huge fetal lung lesions have reproducible pathophysiologic effects on the developing fetus. Esophageal compression by the thoracic mass causes interference with fetal swallowing of amniotic fluid and results in polyhydramnios. Polyhydramnios is a common obstetric indication for ultrasonography; so, a prenatal diagnostic marker exists for many large fetal lung tumors. Support for this concept comes from the absence of fluid in the fetal stomach in some of these cases and the

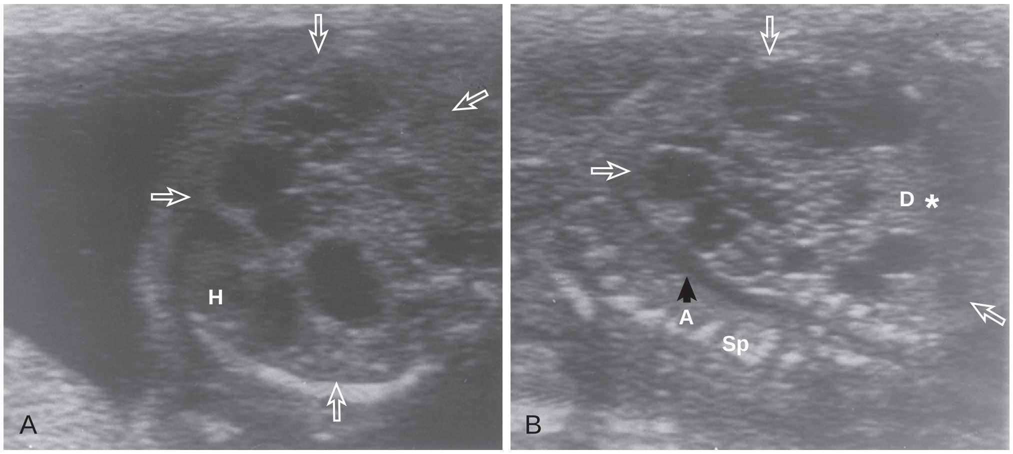

**FIGURE 64-1** **A,** Transverse ultrasonographic scan of the fetal thorax at 22 weeks' gestation. A large multicystic mass in the left hemithorax (*open arrows*) displaces the mediastinum to the right. H, Heart. **B,** Sagittal ultrasonographic scan of the fetal thorax and abdomen shows a mixed cystic/echogenic mass (*open arrows*) of the left hemithorax that flattens the left hemidiaphragm (*D*)*. A, Aorta; Sp, spine. This lesion grew and resulted in fetal hydrops. Fetal surgical resection of the affected lobe was performed successfully at 23 weeks' gestation, delivery occurred at 35 weeks' gestation, and the infant survived.

alleviation of polyhydramnios after effective fetal treatment.[11] The hydrops is secondary to vena caval obstruction and cardiac compression from large tumors, causing an extreme mediastinal shift. Like CCAMs, a fetal BPS can also cause fetal hydrops, either from the mass effect or from a tension hydrothorax that is the result of fluid or lymph secretion from the BPS.[11] Hydrops is a harbinger of fetal or neonatal demise and manifests as fetal ascites, pleural and pericardial effusions, and skin and scalp edema. Although there is some association of both polyhydramnios and hydrops with fetal lung lesions, experience indicates that either can occur independently of the other.

Smaller thoracic lesions can cause respiratory distress in the newborn period, and the smallest masses may be asymptomatic until later in childhood when infection, pneumothorax, or malignant degeneration may occur. Large fetal lung tumors may regress in size on serial prenatal sonography illustrating that improvement can occur during fetal life.[12–14] In particular, many noncystic BPSs dramatically decrease in size before birth and may not need treatment after birth.[11] However, fetal lung lesions that seem to disappear on prenatal ultrasonography and are not seen on neonatal chest radiograph still require evaluation by chest computed tomography (CT) scan, which will frequently detect a lesion.[15]

Recently, fetal CCAM volume has been determined by sonographic measurement using the formula for a prolate ellipse (length × height × width × 0.52). A CCAM volume ratio (CVR) is obtained by dividing the CCAM volume by head circumference to correct for fetal size. A CVR greater than 1.6 is predictive of increased risk of hydrops, with 80% of these CCAM fetuses developing hydrops. The CVR may be useful in selecting fetuses at risk for hydrops and thus needing close ultrasound observation and possible fetal intervention.[16] Serial CVR measurements have shown that CCAM growth usually reaches a plateau by 28 weeks' gestation. For fetuses at less than 28 weeks' gestation, the recommendation is twice-weekly ultrasound surveillance if the CVR is greater than 1.6 and initial weekly surveillance for fetuses with smaller CVR values.

The finding that fetuses with hydrops are at very high risk for fetal or neonatal demise led to the performance of either fetal surgical resection of the massively enlarged pulmonary lobe (fetal lobectomy) for cystic/solid lesions or thoracoamniotic shunting for lesions with a dominant cyst.[11,17,18] It is possible that administration of a short course of maternal betamethasone may impair CCAM growth in some cases and lead to amelioration of hydrops; so, we recommend this therapy for fetal CCAM cases with a CVR greater than 1.4.[19] Lesions with associated hydrops that are diagnosed late in gestation may benefit from resection using an ex utero intrapartum therapy (EXIT) approach.[20] The fetus with a lung mass but without hydrops has an excellent chance for survival with maternal transport, planned delivery, and neonatal evaluation and surgery.

Neonates with respiratory compromise resulting from a cystic lung lesion require prompt surgical resection, usually by lobectomy. In the most severe cases, ventilatory support with high-frequency ventilation or extracorporeal membrane oxygenation may be required. In asymptomatic neonates with a cystic lung lesion, we believe that elective resection is warranted because of the risks of infection and occult malignant transformation.[21] Malignancies consist mainly of pulmonary blastoma and rhabdomyosarcoma in infants and young children and bronchioloalveolar carcinoma in older children and adults.[22–26] After confirmation of CCAM location by postnatal chest computed tomography with intravenous contrast, we recommend elective resection at 1 month of age or older. An experienced pediatric surgeon can safely perform a thoracotomy and lobectomy in infants with minimal risk of morbidity,[27] and experience with thoracoscopic resection has been growing.[28] Early resection also maximizes compensatory lung growth; long-term follow-up has shown normal pulmonary function.[29,21] In contrast, we have usually followed patients with a tiny, asymptomatic, noncystic extralobar bronchopulmonary sequestration if we are confident of the diagnosis based on postnatal imaging studies. We do not favor the approach of catheterization and embolization for the treatment of larger bronchopulmonary sequestration lesions but instead opt for surgical resection.

## CONGENITAL CYSTIC ADENOMATOID MALFORMATION

CCAM is characterized by an "adenomatoid" increase of terminal respiratory bronchioles that form cysts of various sizes. Grossly, a CCAM is a discrete, intrapulmonary mass that contains cysts ranging in diameter from less than 1.0 mm to more than 10.0 cm. Histologically, CCAM is distinguished from other lesions and normal lung by (1) polypoid projections of the mucosa, (2) an increase in smooth muscle and elastic tissue within cyst walls, (3) an absence of cartilage (except that found in "entrapped" normal bronchi), (4) the presence of mucus-secreting cells, and (5) the absence of inflammation.[30] Although the tissue within these malformations does not function in normal gas exchange, there are connections with the tracheobronchial tree, as evidenced by air trapping that can develop during postnatal resuscitative efforts. Cha has identified two histologic patterns of fetal CCAM: pseudoglandular and canalicular.[31] Stocker defined three types of CCAM (types I to III) based primarily on cyst size,[30,32] but this categorization has little clinical relevance. Prenatally diagnosed CCAMs are divided into two categories based on gross anatomy and ultrasound findings.[5] Macrocystic lesions contain single or multiple cysts that are 5.0 mm in diameter or larger on prenatal ultrasonography, whereas microcystic lesions appear as a solid echogenic mass on sonography.

The overall prognosis for prenatally diagnosed lesions depends primarily on the size of the CCAM rather than on the lesion type, and the underlying growth characteristics are likely to be important. Resected large fetal CCAM specimens demonstrate increased cell proliferation and markedly decreased apoptosis compared with gestational-age-matched normal fetal lung tissue.[33] Examination of factors that enhance cell proliferation or down-regulate apoptosis in CCAM may provide further insights into the pathogenesis of this tumor and may suggest new therapeutic approaches. Fetal CCAMs that grew rapidly, progressed to hydrops, and required in utero resection showed increased platelet-derived growth factor *(PDGF)* gene expression and PDGF protein production compared with either normal fetal lung or term CCAM specimens.[34] Flake's group showed that transuterine ultrasound-guided microinjections of adenoviral vector encoding the *RFGF10* transgene leads to fibroblast growth factor (FGF)10 overexpression and consequent CCAM lesions in fetal rat lung. Remarkably, FGF10 overexpression in the proximal tracheobronchial tree during the pseudoglandular stage of rat lung development resulted in large cysts, whereas FGF10 overexpression in the distal lung parenchyma during the canalicular stage resulted in small cysts, and the lesions showed the pathologic spectrum of human CCAM. These findings support a role for FGF10 in the induction of human-like CCAMs.[35]

CCAM usually arises from one lobe of the lung, with the lower lobes being the most common site. Bilateral lung involvement is rare. CCAM lesions have an equal left- and right-sided incidence. For those children who are not diagnosed as a fetus or newborn, the usual clinical presentation is with infection in the CCAM area, probably because of failure of clearance of environmental bacterial pathogens. Other presentations include pneumothorax, reactive airway disease, and failure to thrive. There is no gender predominance. Associated anomalies in our experience are very uncommon.

## BRONCHOPULMONARY SEQUESTRATION

A BPS is a mass of nonfunctioning lung tissue that is supplied by an anomalous systemic artery and does not have a bronchial connection to the native tracheobronchial tree. There are two forms of sequestration: extralobar and intralobar. Extralobar sequestrations are completely separate from the normal lung and are surrounded by a separate pleural covering, whereas intralobar sequestrations are incorporated into the normal surrounding lung. An extralobar sequestration may reside in the chest, within the diaphragm, or in a subdiaphragmatic location. Intralobar and extralobar sequestrations can occur simultaneously. An entire lung can be sequestered, and bilateral sequestrations have been reported but are very rare.[36,37] Because of the foregut derivation, communication between the esophagus or the stomach and a BPS may occur and, if suspected, should be delineated preoperatively by upper gastrointestinal series.[38] Arterial blood supply to the BPS can arise from below or above the diaphragm, and venous drainage can be to either the pulmonary or the systemic venous circulation. The anomalous blood supply can result in high-output cardiac failure because of substantial arteriovenous shunting through the BPS[39] or bleeding with massive hemoptysis or hemothorax.[40]

On prenatal ultrasonography, a BPS appears as a well-defined echodense, homogeneous mass. Detection by color-flow Doppler of a systemic artery or arteries from the aorta to the fetal lung lesion is a pathognomonic feature of fetal BPS (Fig. 64-2).[41] However, if this Doppler finding is not detected, then an echodense microcystic CCAM and a BPS can have an identical prenatal sonographic appearance. Ultrafast fetal magnetic resonance imaging (MRI) may help differentiate CCAM from BPS.[42] Furthermore, there are prenatally diagnosed lung masses that display clinicopathologic features of

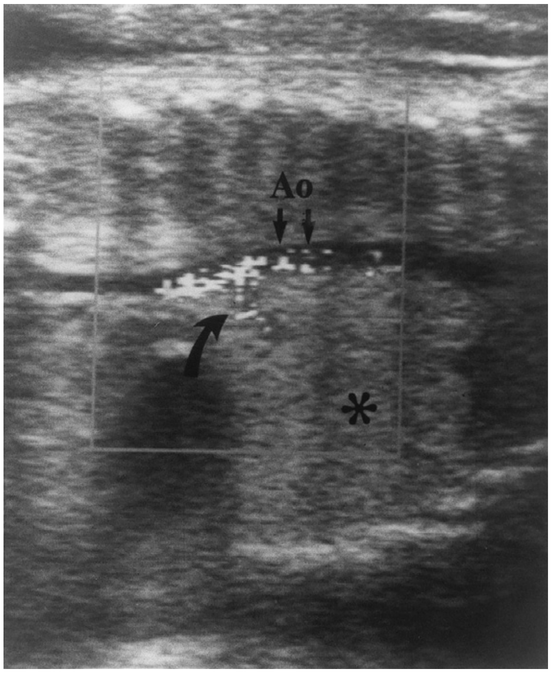

**FIGURE 64-2** By Doppler studies, a systemic artery (*curved arrow*) from the descending aorta (*Ao*) supplies the mass (*), consistent with the prenatal diagnosis of pulmonary sequestration.

both CCAM and sequestration-hybrid lesions, which suggests a shared embryologic basis for some of these lung masses.[43–45] The ability to differentiate intralobar and extralobar sequestration before birth is limited unless an extralobar sequestration is highlighted by a pleural effusion or is located in the abdomen (usually close to the left adrenal gland). There are no diagnostic hallmarks for the specific prenatal diagnosis of an intralobar sequestration.

Extralobar BPS has a predominance in males (3:1), is more common on the left side, and can be associated with conditions such as congenital diaphragmatic hernia, vertebral deformities, and congenital heart disease. Approximately 5% of neonates with a congenital diaphragmatic hernia will have an extralobar BPS, which is usually an incidental intraoperative finding. An isolated, tiny noncystic extralobar BPS rarely requires treatment. An intralobar BPS is most commonly seen in the medial basal or posterior basal segments of the lower lobes, left side more frequent than the right side. Upper lobe involvement is present in only 10% to 15% of cases. For those cases that are not prenatally diagnosed, the usual postnatal presentation of an intralobar BPS is recurrent pneumonia and even abscess formation within the BPS; thus resection (usually by lobectomy) is warranted. It is mandatory to identify and ligate the feeding systemic arterial vessel(s), which usually is found within the inferior pulmonary ligament.

## CONGENITAL LOBAR EMPHYSEMA

Several causes for congenital lobar emphysema (CLE) have been described,[46] but the fundamental mechanism is that the affected bronchus allows passage of air on inspiration but only limited expulsion of air on expiration leading to lobar overexpansion. Air trapping in the emphysematous lobe may be the result of (1) dysplastic bronchial cartilages creating a ball-valve effect or a complete bronchial atresia[47,48]; (2) endobronchial obstruction from inspissated mucus[49] or extensive mucosal proliferation and infolding[50]; (3) extrinsic compression of the bronchi from aberrant cardiopulmonary vasculature or enlarged cardiac chambers[51]; and (4) diffuse bronchial abnormalities that may or may not be related to infection.[52] Careful preoperative bronchoscopy may help delineate an intrinsic obstructive lesion.[47] The most common site of involvement for CLE is the left upper lobe (40% to 50%), followed by the right middle lobe (30% to 40%), right upper lobe (20%), lower lobes (1%), and multiple sites for the remainder.

Barotrauma associated with the treatment of bronchopulmonary dysplasia in preterm infants can result in acquired emphysema in which multiple areas of hyperinflation may be present.[53] Because of endotracheal tube positioning, right lower lobe involvement is common in these cases, which helps to differentiate acquired from congenital disease. Polyalveolosis, or the polyalveolar lobe first described by Hislop and Reid, has been found in some cases of congenital lobar emphysema.[54] The total alveolar number is increased several-fold in this condition, but the airways and arteries are normal for age in number, size, and structure. The polyalveolar lobe becomes overinflated and hyperlucent on chest radiography because of impaired air exchange in the affected lobe. Because clinical presentation and imaging cannot differentiate between true CLE and polyalveolar lobe, the term "congenital lobar overinflation" has been used to include both entities.[55]

Congenital lobar emphysema can be distinguished prenatally from other cystic lung lesions on ultrasonography by increased echogenicity and reflectivity compared with a microcystic CCAM, and the absence of systemic arterial blood supply compared with a BPS.[56,57] Progressive enlargement of these lesions prior to 28 weeks' gestation may be due to fetal lung fluid trapping in the lobe, analogous to the air trapping seen postnatally. Late in gestation, lobar emphysema may regress in size and echogenicity, rendering it indistinguishable from adjacent normal fetal lung.[57] Postnatal assessment is important because of the risk of postnatal air trapping in the emphysematous lobe. At the time of birth, the affected lobe may be radiopaque on chest radiography because of delayed clearance of fetal lung fluid. Prenatally diagnosed mainstem bronchial atresia results in massive lung enlargement, hydrops, and fetal death; ultrafast fetal MRI demonstrates that the entire lung is involved and that there are dilated bronchi distal to the mainstem atresia.[58] Congenital lobar emphysema is diagnosed at birth in about 25% of cases and by age 1 month in about 50%. The diagnosis is sporadic after 6 months of age. The earlier the onset of symptoms, the more likely the progression of lobar emphysema and the need for resection. Nevertheless, some infants have very mild symptoms that do not progress, and the emphysematous lobe remains stable and does not encroach on adjacent lung; so, resection is not required in these cases.[59] Besides chest radiography and CT (Fig. 64-3), a ventilation-perfusion scan can demonstrate delayed uptake and washout of the xenon radioisotope from the affected lobe and little blood flow through it. If the presentation is respiratory distress and pulmonary lobar hyperinflation, then the mainstay of management is resection of the emphysematous lobe. Positive-pressure ventilation may result in abrupt exaggerated air trapping in the lobe, with sudden cardiopulmonary decompensation; so, it is important for the surgeon to be present during anesthetic induction in the event that urgent thoracotomy is needed. At operation, the

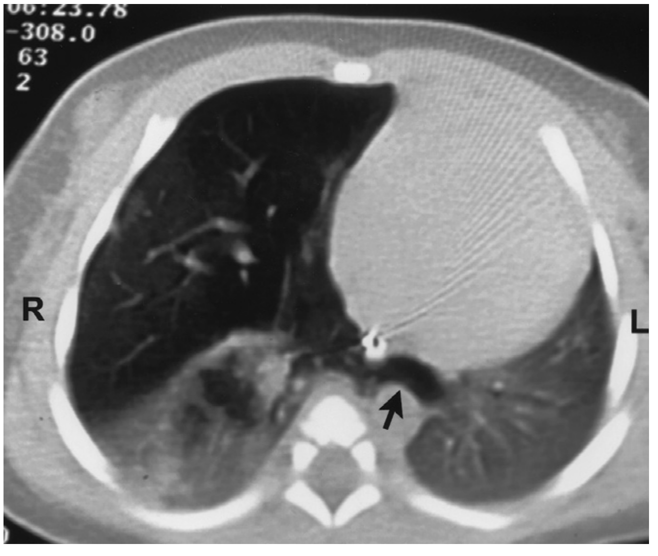

**FIGURE 64-3** Chest computed tomography (CT) scan from a neonate with congenital lobar emphysema involving the right middle lobe. There are dilated airspaces in the right middle lobe with compressive atelectasis of the right lower lobe. The mediastinum is shifted to the left, and a portion of the emphysematous lobe herniates across the midline posterior to the heart (*arrow*).

affected lobe will characteristically "pop out" through the thoracotomy wound. High-frequency ventilation,[60] selective bronchial intubation,[61] and endoscopic decompression of the emphysematous lobe[62] may be useful adjuncts in the preoperative management of patients with respiratory distress. Long-term pulmonary growth and function after lobectomy for congenital lobar emphysema is excellent.[63]

# Cystic Mediastinal Lesions

## CLINICAL FEATURES

The clinical manifestations of mediastinal lesions are the result of mass effects and are influenced by the location of the lesion within the chest. Many are asymptomatic, although the most important symptom of anterior and middle mediastinal masses is respiratory distress, particularly in infants when noisy, stridorous breathing or cyanosis while feeding is observed.[64] In older children, cough, chest pain, dyspnea, orthopnea, or, rarely, hemoptysis occurs.[65] Respiratory distress may be life threatening in all age groups.[66–69] Rapid onset of respiratory distress or symptoms of superior vena caval obstruction suggest lymphoma.[64,70] Although rare, infected teratomas have been reported to rupture into the bronchus, pleura, pulmonary artery, and pericardium.[65,71,72] Posterior mediastinal masses can be quite large and yet asymptomatic, often discovered incidentally on a chest radiograph taken for other indications. Less frequently, pain or symptoms of spinal cord compression lead to recognition.[73,74]

Reports from individual institutions regarding mediastinal masses may be biased by selection. If more recent series are compared with those published before 1967 (Table 64-1), an increase in malignancy, particularly of lymphomas and neuroblastoma, is evident.[64,70,72,74–79] Such is the case in a single large institutional series from Walter Reed Army

Hospital[80] in which a retrospective review compared the 60-year experience before and after 1970. The best estimate of prevalence of mediastinal masses is provided by a retrospective pathology study of mediastinal masses from Victoria in Australia, which had an estimated pediatric population of 900,000. In that series, 50% of mediastinal masses were lymphomas, followed by 20% of neurogenic origin, 8% foregut duplication cysts, and 6% teratomas.[81] This prevalence is similar to U.S. series (see Table 64-1).

## ANATOMIC CONSIDERATIONS

A clear understanding of the anatomic subdivisions of the mediastinum is useful in differential diagnosis and selection of diagnostic studies. The mediastinum is the central thoracic space bounded laterally by the right and left parietal pleura, anteriorly by the sternum, posteriorly by the vertebral bodies to include the transverse processes, superiorly by the thoracic inlet, and inferiorly by the diaphragm. Although several classifications for subdividing the mediastinum exist, the classical anatomic description is used here.[82] The value of any system of anatomic subdivision is to provide insight into the contents of that region, which simplifies differential diagnosis.

The superior mediastinum is delimited by the thoracic inlet superiorly and the plane between the sternomanubrial junction and the inferior limit of the fourth thoracic vertebra inferiorly. The lateral boundaries are the parietal pleurae. Normal anatomic contents of this subdivision are the thymus, other lymphatic structures, and mesenchymal derivatives, including vasculature, diffusely found throughout the entire mediastinum.

The anterior mediastinum is the zone posterior to the sternum, anterior to the pericardium, superior to the diaphragm, and inferior to the plane through the sternomanubrial junction. This space normally contains mesenchymal derivatives, fat, and connective tissue.

The middle mediastinum is delimited by the pericardium and origins of the great vessels. Therefore its normal contents are the pericardium, heart, great vessels, lymphatics, and mesenchymal derivatives.

The posterior mediastinum is outlined by the pericardium and great vessels anteriorly, the vertebral column posteriorly, and, as in each of the prior subdivisions, the parietal pleurae laterally. Its contents include the trachea and main bronchi, esophagus, widely distributed lymphatic structures, sympathetic nervous ganglia, descending aorta, azygous venous system, and thoracic duct.

Large masses or diffuse processes may transgress multiple subdivisions. An additional caveat to aid in differential diagnosis is age. With the exception of posterior mediastinal neuroblastoma, mediastinal masses in young children are most likely to be developmental in origin. Mediastinal masses that are not cystic will also be mentioned.

## DIAGNOSIS AND TREATMENT

Recognition of cystic mediastinal masses may first occur on fetal ultrasonography.[83–85] The fetus who develops progressive nonimmune hydrops, cardiac failure, or mediastinal shift with compression of developing lung tissue may benefit from in utero decompression or resection of a cystic mediastinal lesion.[86]

For cystic mediastinal masses, the initial postnatal diagnostic study should be anteroposterior and lateral chest radiographs. A presumptive diagnosis can often be made based on the location of the lesion on the plain radiograph. CT has now largely replaced endoscopy and esophagograms as part of the preoperative evaluation. Several studies comparing contrast medium-enhanced CT with MRI suggest that CT is superior, given its ability to define calcification within a mass.[87,88] MRI is useful if spinal involvement is in question or if vascular lesions are being considered. An esophagogram reveals the characteristic extrinsic mass effect of a foregut duplication cyst, but CT is probably the most useful study for this diagnosis. Echocardiography has value in defining the rare intrapericardial teratoma in the neonate with an enlarged pericardial silhouette[89] and can detect congenital heart disease if present.

The goal of the preoperative diagnostic workup is to help define the optimal surgical approach. When the nature of a mediastinal mass is uncertain or if the potential of malignancy exists, a preoperative serum sample should be drawn for determination of alpha fetoprotein or beta-human chorionic gonadotropin levels, particularly in the case of anterior mediastinal tumors. Similarly, urinary catecholamine catabolites should be obtained in suspect posterior mediastinal masses.

Surgical resection at the time of diagnosis is the preferred treatment of most benign mediastinal cysts and tumors. When indicated, thoracoscopic resection or biopsy can be performed with adequate results and minimal morbidity.[90,91] Large anterior mediastinal masses are best approached through median sternotomy, and middle and posterior mediastinal masses are best approached through posterolateral thoracotomy.

# Anterior and Superior Mediastinum

The anterior and superior mediastinum contains the thymus, great vessels, and a network of lymphatic structures, as well as connective and adipose tissue. Lymphomas are the most common tumors, followed by teratomas, germ cell tumors, cystic lymphangiomas, and thymic lesions (Fig. 64-4). Anterior mediastinal masses in infants are usually either a teratoma or a thymic enlargement.

Foremost in evaluation of masses of the anterior mediastinum is assessment of the risk of malignancy. Malignant disease, such as lymphoma, generally presents in the older child, is often associated with systemic symptoms and adenopathy elsewhere, and is frequently associated with symptoms of airway compromise. When possible, the diagnosis should be sought from nonmediastinal sources, such as bone marrow, pleural fluid, or other nodal tissues, thus avoiding a general anesthetic.[77,79] If a diagnosis is still lacking in the presence of airway compromise, corticosteroid administration reduces the risk of open biopsy yet does not affect diagnostic accuracy. Lymphomas are discussed in Chapter 38.

## THYMUS

Thymic cysts are seen in the anterior mediastinum and the neck (Figs. 64-5 and 64-6). They are usually asymptomatic but can become infected or hemorrhagic or produce

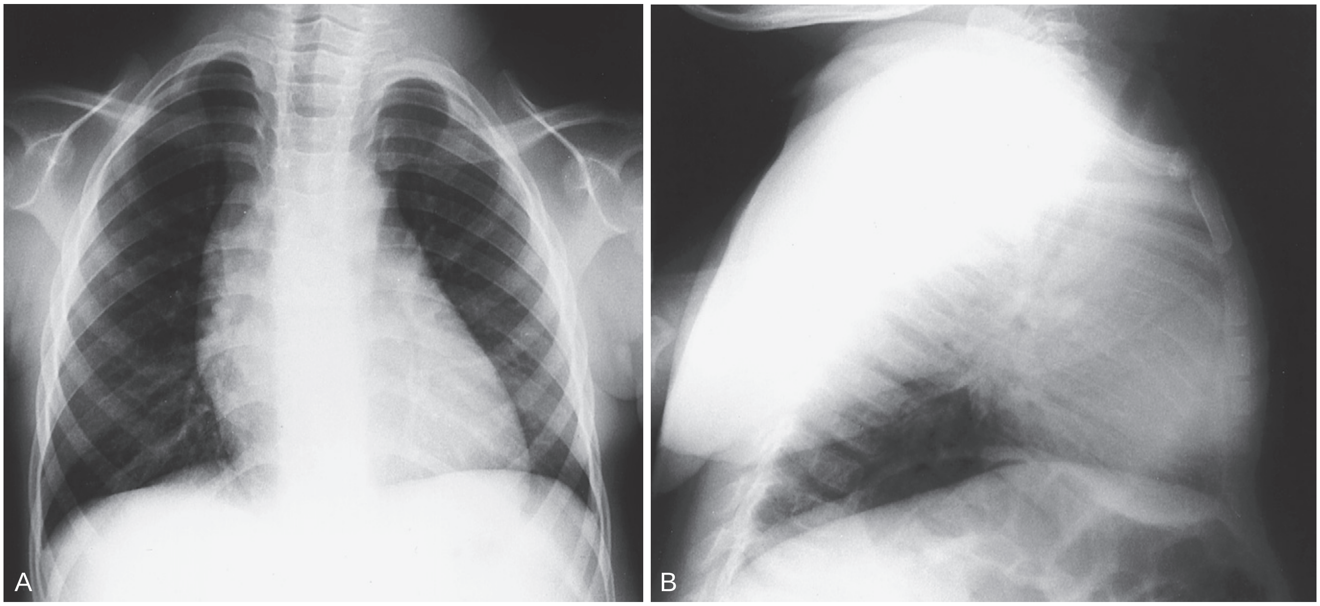

**FIGURE 64-4** A 5-year-old boy presented with a superoanterior mediastinal mass noted to be separate from the pericardial silhouette on an anteroposterior chest film (**A**). Lateral chest radiograph (**B**) reveals sternomanubrial prominence and a mass anterior to the trachea. This mass turned out to be a teratoma.

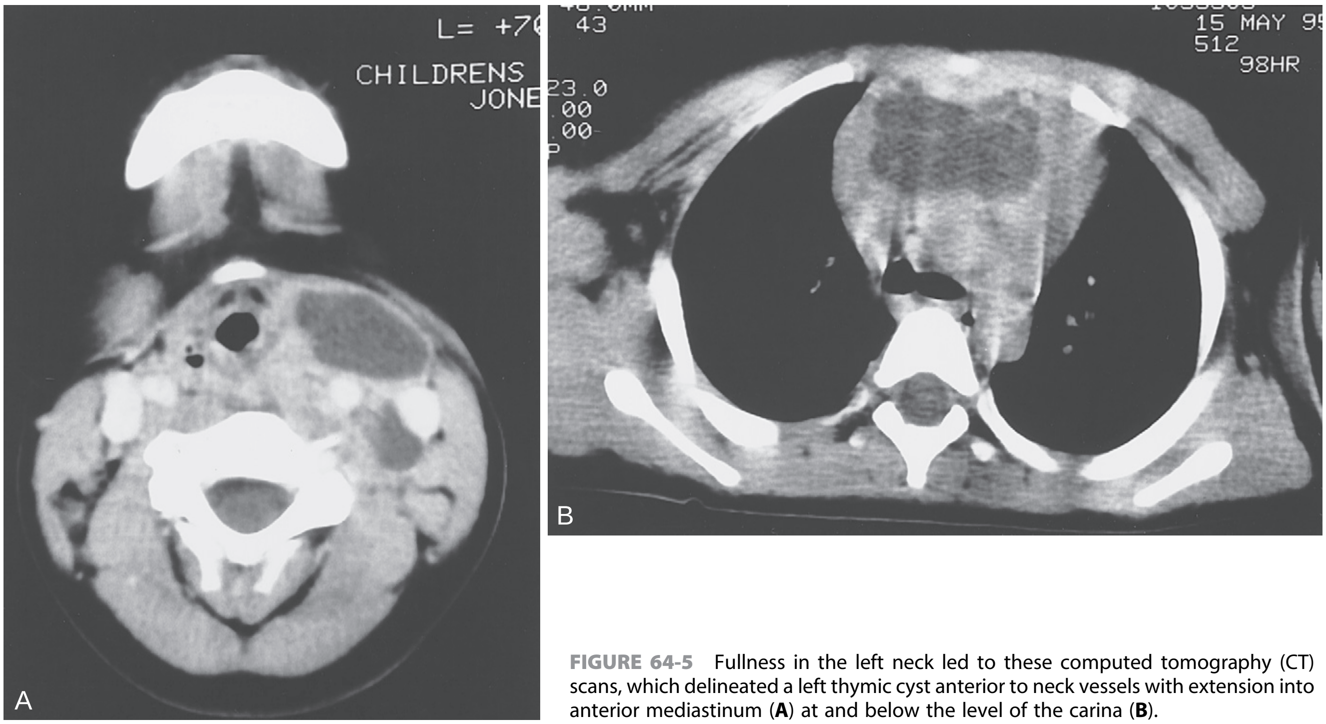

**FIGURE 64-5** Fullness in the left neck led to these computed tomography (CT) scans, which delineated a left thymic cyst anterior to neck vessels with extension into anterior mediastinum (**A**) at and below the level of the carina (**B**).

symptoms because of mass effects and can create a cosmetically unacceptable appearance. The cysts are lined with ciliated, respiratory epithelium; contain lymphocytes as well as normal thymic tissue; and often show inflammatory and granulomatous changes. Thymolipoma is a benign tumor, possibly hamartoma, of mixed fatty and thymic tissue. Resection results in diagnosis and cure.

Thymomas are rare in children, accounting for less than 1% of mediastinal tumors, with only 20 well-documented cases of malignant thymoma in children in the literature.[92–95] These tumors originate in the thymic epithelium and are usually aggressive.[96] Treatment is multimodal, but outcome is poor.

Although the thymus is located in the anterior and superior mediastinum, ectopic thymic tissue can be found in the

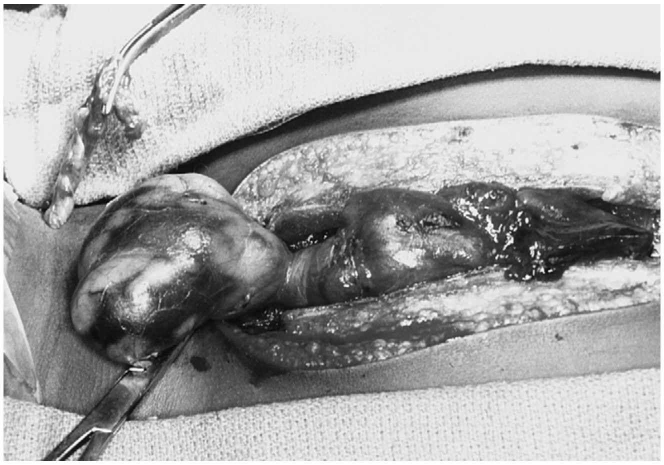

**FIGURE 64-6** Thymic cyst mobilized from the mediastinum through sternotomy before removal of the cervical extension in the same patient as in Figure 64-5.

neck and posterior mediastinum as well.[97–99] Benign thymic hyperplasia is a physiologic enlargement of the thymus gland no longer believed to cause respiratory embarrassment, although rapid enlargement has led some authors to recommend resection.[100,101] If necessary, a short course of prednisone shrinks the normal thymus gland and helps differentiate it from nonlymphoid mediastinal masses. MRI can also be helpful.[99,102] Mediastinal radiation is of historical interest, only because it had an unacceptably high association with thyroid carcinoma. Exploration is recommended only when malignancy cannot be ruled out, as in benign nodular thymic hyperplasia. Nodular thymic hyperplasia is usually asymptomatic and is usually recognized as a superior mediastinal mass on an incidental chest film. CT reveals a solid, asymmetric, nonenhancing mass within a thymic lobe. Peripheral blood and bone marrow studies are normal. Operation in these instances reveals a lymphoid mass within one lobe of the thymus with histologic compression of adjacent normal thymus. Analysis of lymphocytes in the mass reveals a normal ratio of T and B lymphocytes. Today, most thymic lesions can be resected using thoracoscopic techniques.

### TERATOMAS, DERMOID CYSTS, AND GERM CELL TUMORS

After lymphoma, teratomas are the most common tumors of the anterior mediastinum. They also have been reported in other subdivisions of the mediastinum.[103] These tumors are discussed in Chapter 37.

## Middle Mediastinum

In the classical anatomic description, the middle mediastinum is circumscribed by the pericardium.[82] As such, pericardial cysts may be the only true common middle mediastinal cysts. Pericardial cysts are benign, thin-walled, fluid-containing cysts lined with mesothelium. It is postulated that the pericardium forms from a series of disconnected lacunae in the mesenchyme that later coalesce to form the pericardial sac. Occasionally, one of these lacunae persists as a pericardial cyst. They are nearly always asymptomatic and are often discovered on routine chest films or at autopsy. The classical description is that of a cystic mass lying anteriorly in the chest at either cardiophrenic sulcus, although the right side is more common. Historically, thoracotomy was recommended to establish a definitive diagnosis. Currently, CT provides a sufficiently characteristic appearance to allow accurate diagnosis, thus allowing nonintervention unless the cyst is large. If the diagnosis is uncertain, these can be excised or unroofed thoracoscopically as well.

## Posterior Mediastinum

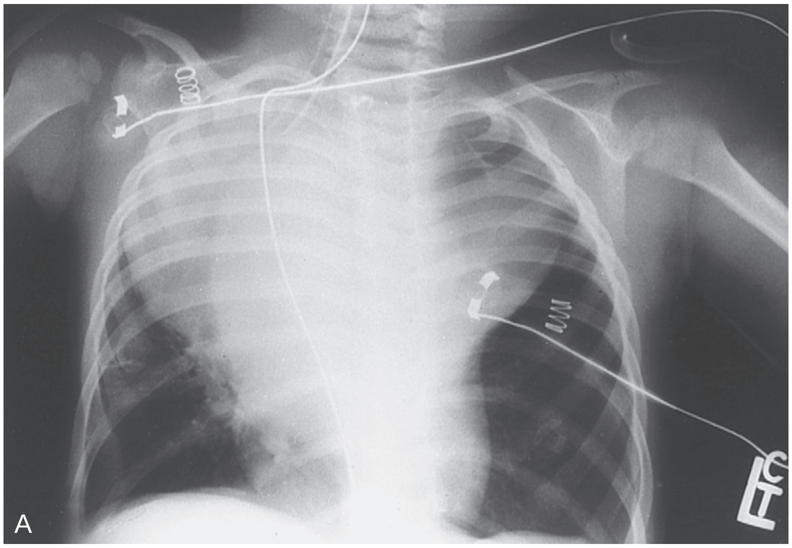
The posterior mediastinum lies behind a plane passing in front of the tracheal bifurcation and extending posteriorly to the paravertebral sulci.[82] The posterior mediastinum is the site of a heterogeneous group of cysts, neoplasms, and inflammatory processes in children. Most common of these lesions is the spectrum of benign to malignant neurogenic tumors of the sympathetic nervous system. In the young, the most common tumor is a malignant neuroblastoma, and in the older child, the most common tumors are benign ganglioneuromas; both of these lesions are discussed in Chapter 31.

### FOREGUT DUPLICATION CYSTS

Foregut duplication cysts are reasonably common in pediatric specialty centers. The nomenclature of these lesions varies considerably. They can be subdivided clinically and pathologically into (1) enteric duplications and cysts (lined by intestinal epithelium), (2) bronchogenic cysts (lined by respiratory epithelium), and (3) neurenteric cysts (associated with vertebral anomalies or having a connection with the nervous system). Enterogenous is a confusing historical term and in various reports has included each of the aforementioned categories. The generic term foregut duplication cyst is a more accurate embryologic description with subdivision into bronchogenic or enteric cysts determined by the histology of the mucosa lining the cyst wall.[104] In fact, all three endodermal derivatives may be found in the occasional foregut duplication, supporting a common embryologic derivation for foregut duplication cysts.

### BRONCHOGENIC CYSTS

Bronchogenic cysts (Fig. 64-7) develop from abnormal budding of the tracheal diverticulum or ventral portion of the foregut. These cysts can be found in a variety of locations from paraesophageal to paratracheal, perihilar, or intraparenchymal,[105] depending on the level at which the abnormal budding occurred in the development of the foregut or tracheobronchial tree. It has been reported that about two thirds of bronchogenic cysts are located within the lung parenchyma, with the remainder in the mediastinum, but this distribution varies between different reports. Rarely, they can be found in remote locations, such as the tongue, neck, back, and even below the diaphragm [78,106–109]



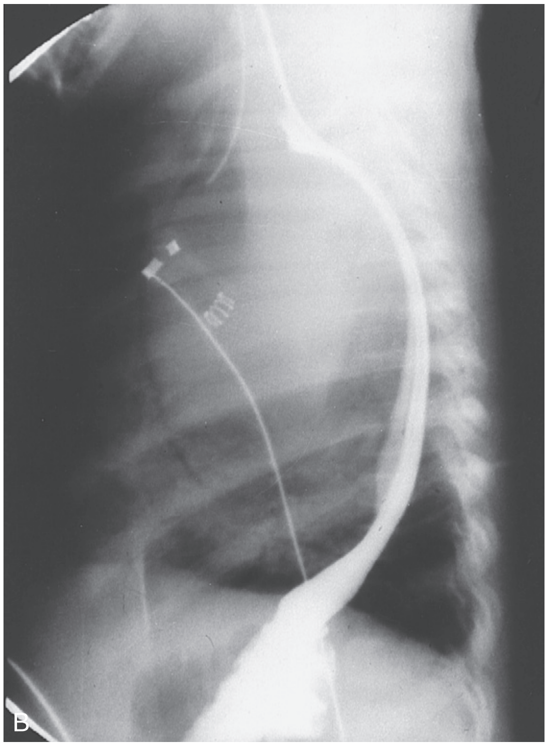


**FIGURE 64-7** **A,** Bronchogenic cyst. Central tracheobronchial compression with respiratory distress was demonstrated in this 15-month-old boy transferred to the intensive care unit in critical condition. He had been treated for a year for symptoms of asthma. **B,** Lateral view shows remarkable tracheal compression with tracheoesophageal separation confirmed by contrast agent in the esophagus.

Histologically, bronchogenic cysts are thin walled, lined with bronchial epithelium, and filled with mucus. They can be single or multiple and are white or pinkish. Cartilage has been reported in the wall of these cysts, and air-fluid levels may be present. The cysts have no predilection for the right or left side. Although they do not usually communicate with the tracheobronchial tree, they may do so from inception or the communication may be acquired from superinfection.

Diagnosis in older children often results from identification of an incidental mass on chest radiograph obtained for an unrelated reason. Infants usually present with respiratory symptoms, and the mass may be obscured on plain film by associated atelectasis and infection (Figs. 64-8 and 64-9).[110–112] In this case, the diagnosis can be delayed, but CT usually confirms the diagnosis. Bronchogenic cysts have also been recognized on antenatal ultrasonography[113] and on esophagogram for other indications. The differential diagnosis includes foreign body, lobar emphysema, pneumonia, bronchial stenosis, and pneumothorax.

Bronchogenic cysts should be excised to avoid the complications of infection, hemorrhage, or sudden death from rapid expansion under tension. A risk of malignant transformation does exist, as malignancy has been reported in two adult patients with bronchogenic cysts and adenocarcinoma has been reported arising from a bronchogenic cyst in an 8-year-old girl.[114] Excision should be accomplished without injury to the bronchial or esophageal wall. Small cysts in the pulmonary hilum may not be visualized until the mediastinal pleura is opened. Cyst resection is usually straightforward, but occasionally, limited parenchymal lung resection or lobectomy may be required. In the majority of patients, bronchogenic cysts are amenable to thoracoscopic resection.[115,116] An error in recognition may lead to unnecessary resection of emphysematous lung tissue rather than removal of a cyst producing bronchial obstruction. Complete excision is recommended; recurrence 25 years after incomplete resection has been reported.[117] Although there are reports of transbronchial drainage, we do not recommend that approach.[118]

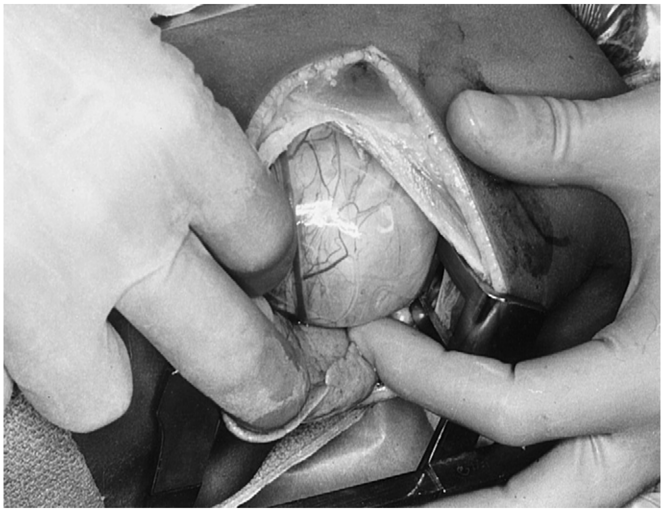

**FIGURE 64-8** Urgent thoracotomy in the same patient as in Figure 64-7 showed a large unilocular cyst. It was aspirated of infected mucus to relieve bradycardia and then removed from its attachment to the posterior trachea. The microscopic appearance is shown in Figure 64-9.

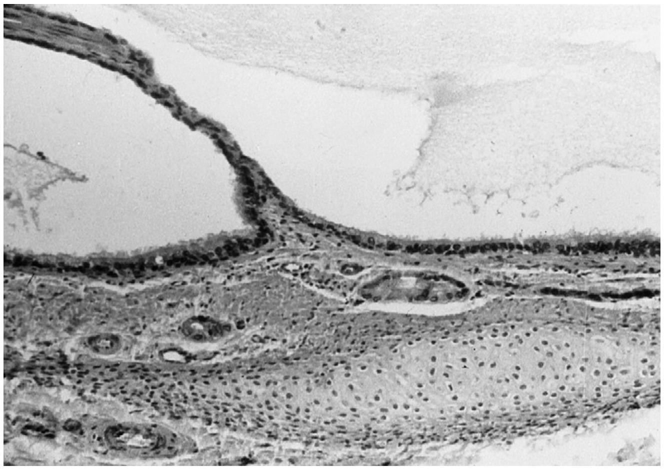

FIGURE 64-9 Microscopically, this bronchogenic cyst wall is lined by ciliated respiratory epithelium and contains bronchial cartilage, characteristic of bronchogenic cysts and evidence that they are central bronchial developmental anomalies (in contrast to cystic adenomatoid malformation, which is a peripheral parenchymal anomaly).

## ENTERIC DUPLICATION CYSTS

Enteric cysts arise from failure of coalescence of vacuoles early in development of the foregut. They are lined by esophageal or gastric epithelium surrounded by smooth muscle. They have been called variously enterogenic or enterogenous cysts, esophageal cysts, enteric cysts, and esophageal duplications. Gastric mucosa is often seen, and intramural adrenal cortical rests have been reported.[119] Enteric cysts may be located throughout the posterior mediastinum and in the neck. Although most commonly integral to the wall of the esophagus, they may communicate with the lumen of the esophagus or exist completely separate from the structure of origin. A number of large thoracoabdominal enteric cysts have been reported, either ending blindly in the abdomen or connecting with the lumen of the stomach, jejunum, ileum, or pancreatic duct.[78,120] Biliary reflux during bronchoscopy was reported in a case of an enteric duplication cyst that penetrated the diaphragm and connected the carina with the biliary tree.[111] There is a 12% incidence of associated malformations. Most of these are additional enteric duplications.[104,121] Two cases of prenatally diagnosed intrathoracic enteric duplication cyst associated with hydrops have been treated with placement of a thoracoamniotic shunt in utero.[122]

In most series, enteric cysts are asymptomatic at presentation. Chest radiograph and CT are the mainstays of diagnosis (Figs. 64-10 and 64-11). Although $^{99m}$Tc pertechnetate, abdominal ultrasonography, barium swallow, or MRI may occasionally be useful adjunctive procedures; the goal of preoperative studies is less an attempt to make a definitive diagnosis than to provide information to aid in operative planning. Treatment consists of complete surgical excision either by thoracotomy or thoracoscopy. If necessary, as in long tubular duplications, the mucosal lining of a foregut duplication

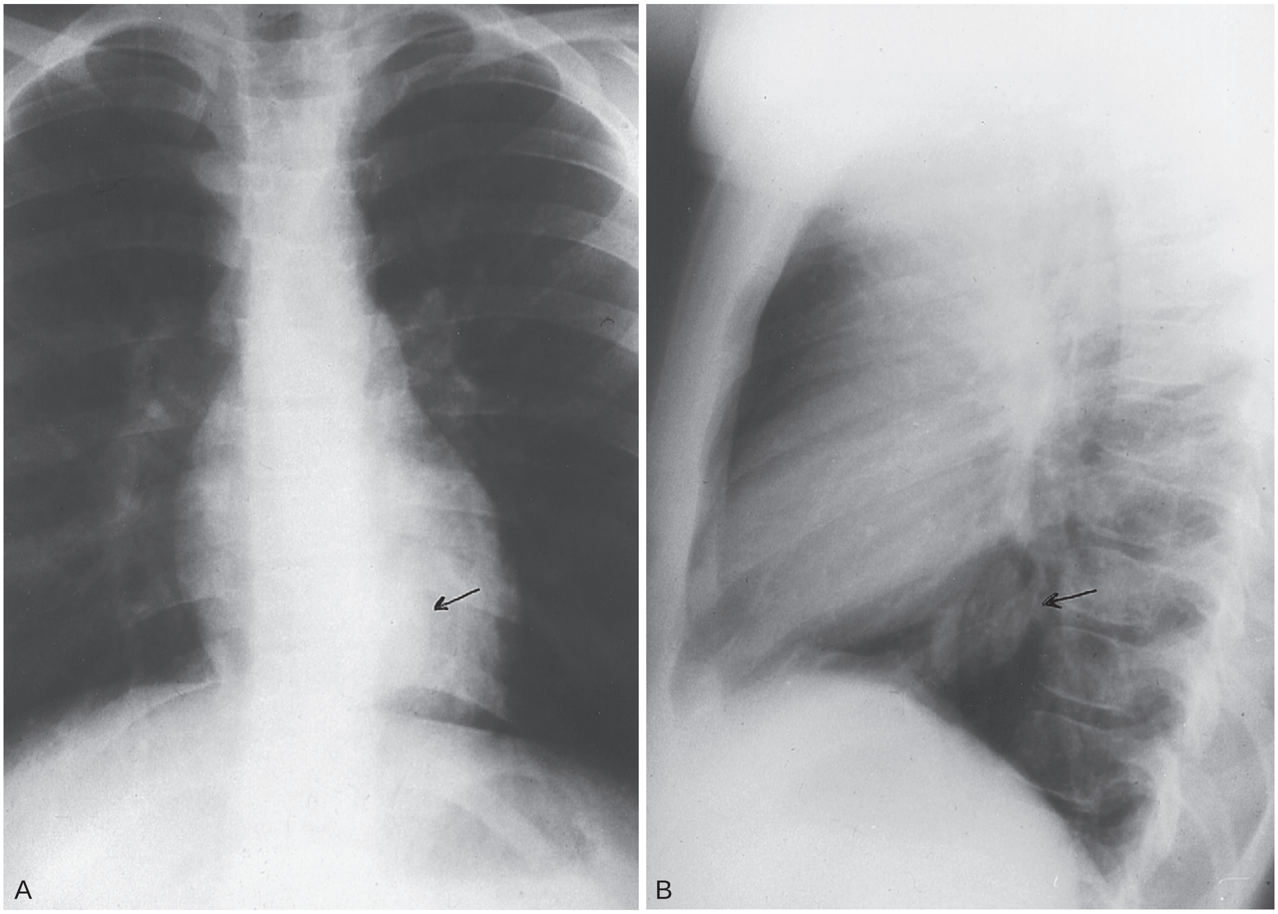

FIGURE 64-10 **A,** Incidental finding of an asymptomatic mediastinal mass behind the cardiac silhouette on anterior chest radiograph (*arrow*). **B,** On lateral film, the lesion was located just inferior and posterior to the base of the heart (*arrow*) and adjacent to the esophagus.

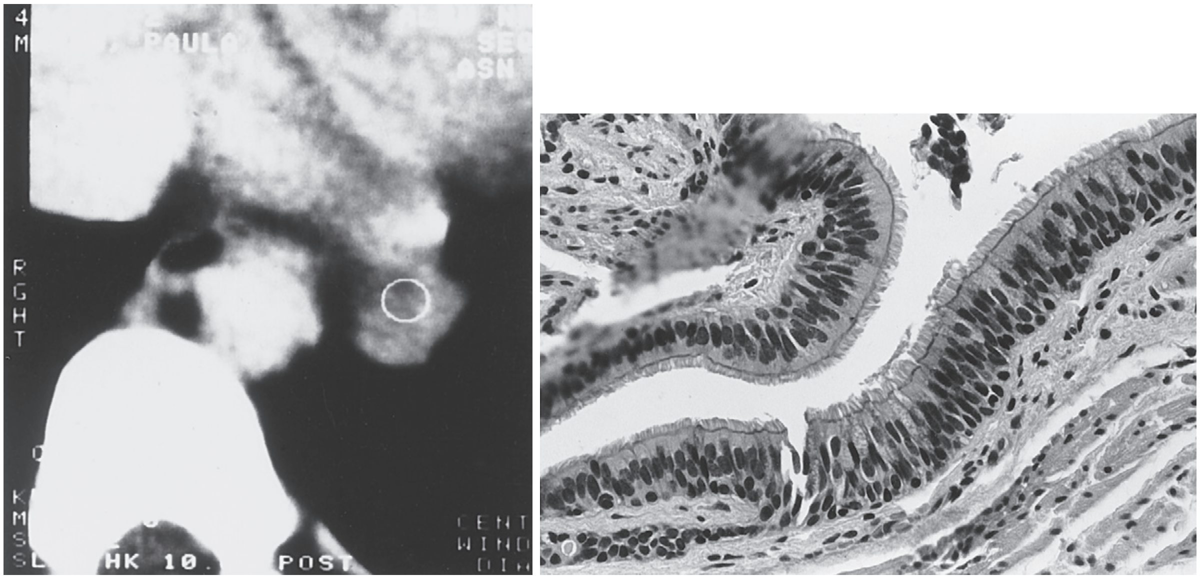

A B

**FIGURE 64-11** **A,** Computed tomography (CT) scan further delineates the lesion in the patient shown in Figure 64-10 (*ring marker*). CT is probably the most useful imaging approach for patients with mediastinal tumors. **B,** Operative findings revealed a single cyst with esophageal mucosal lining, and microscopic examination confirmed the presence of esophageal mucosa.

may be stripped, leaving the common muscular wall intact.[123] Marsupialization is no longer recommended. These are benign lesions, and esophageal integrity should be preserved.

## NEURENTERIC CYSTS

Neurenteric cysts are rare foregut duplications that also have connections to the spinal canal, sometimes with the dura. Although they most commonly present as intrathoracic masses, they may also present as an intraspinal mass. The coexistence of a cystic posterior mediastinal mass with adjacent hemivertebrae should raise suspicion of a neurenteric cyst as well as anterior myelomeningocele.[124] Neurenteric cysts are thought to form early in development when the notochord and foregut are in apposition, either by failure of complete separation or by herniation of foregut endoderm into the dorsal ectoderm.[125,126]

Histologically, neurenteric cysts have alimentary tract mucosa, well-developed muscle walls, and no serosa. Gastric mucosa may be present, so signs of inflammation and ulceration may occur.[125] Symptoms often include pain or neurologic findings (or both). MRI is indicated when a posterior mediastinal mass is associated with vertebral anomalies. Prompt excision is mandatory. Paraplegia and death owing to meningitis have been reported.[118] Although some authors report leaving the neural connections intact, most recommend total excision with simultaneous laminectomy if necessary.[124,127,128]

Other miscellaneous entities enter into the differential diagnosis of rare posterior mediastinal cystic masses. Anterior thoracic meningoceles are seen in older children and are thought to be progressive degenerative lesions associated with vertebral anomalies.[27] MRI should distinguish this lesion from a neurenteric cyst.

## MISCELLANEOUS MESENCHYMAL CYSTIC TUMORS

Mesenchymal tumors may occur throughout the mediastinum and may compromise the airway. They originate from connective tissue, lymphatic tissue, smooth and striated muscle, fat, and blood vessels. As a group, they constitute less than 5% of mediastinal masses in children.

Mesenchymal tumors derived from blood and lymph vessels are the most common varieties in children, especially lymphangiomas. In most patients, lymphangioma presents as a superior or posterior mediastinal extension of a cervical lesion; however, primary mediastinal lymphangiomas do occur.[129,130] Hemangiomas are even less common. The pathophysiology and management of both lesions are discussed in Chapter 125. The most common complication after surgical resection of mediastinal lymphangioma is lymphatic fluid leak. Treatment of this complication by aspiration, chest tube drainage, and fibrin glue application (if drainage alone fails) is usually effective. Lymphangiomas recur in at least 15% of cases after resection; so, long-term follow-up is important.

CHAPTER 65

# Lesions of the Larynx, Trachea, and Upper Airway

Dana Mara Thompson, J. Paul Willging, and Robin T. Cotton

Lesions of the upper airway, namely the larynx and trachea, can present with life-threatening airway obstruction. The etiology of obstructive airway disease is often multifactorial and includes anatomic, congenital, and inflammatory problems, many of which are managed by surgical intervention. A variation of clinical signs and symptoms are associated with airway obstruction. Signs of acute airway obstruction are stridor, respiratory distress, apnea, cyanosis, pallor, tachypnea, use of accessory muscles of respiration and retractions, and mental status changes. Chronic airway obstruction may present with similar signs and symptoms and may develop long-term complications of airway obstruction and hypoxia, such as failure to thrive, poor weight gain, pulmonary hypertension, and pectus excavatum. Regardless of whether the airway is acutely or chronically obstructed, stridor is the most useful noninvasive clinical examination finding for determining location of the obstruction in the airway. Stridor occurs as a result of turbulent air flow through a narrowed lumen and is present in virtually all children with airway obstruction, except those on the brink of complete asphyxia. The phase of respiration in which the stridor is heard will help the astute examiner to better determine the location of the lesion. Inspiratory stridor typically occurs in obstructive lesions above the glottis, such as laryngomalacia and vocal cord paralysis. Biphasic stridor is heard in a fixed obstruction below the glottis in the subglottis or trachea. Expiratory stridor usually represents an obstruction in the intrathoracic airway, such as tracheomalacia. Obstructive lesions of the airway may be mistakenly diagnosed as asthma on the basis of a respiratory "wheeze;" therefore a high index of suspicion and correlation with other clinical examination findings are essential so that a potentially critical or surgically correctable cause of airway obstruction is not overlooked.

Endoscopic evaluation of the airway has revolutionized the diagnosis and management of the obstructed airway. Endoscopic evaluations are divided into those done with the child awake and those done with the child under sedation or general anesthesia. Flexible fiberoptic nasopharyngoscopy and laryngoscopy is done with the child awake. This technique permits safe, rapid examination of the nose, hypopharynx, supraglottis, and glottis in virtually all children, despite age or lack of cooperation. The awake state allows for evaluation of the dynamics of supraglottic tone, vocal fold mobility, and the impact of fixed obstructing lesions of the larynx. Examination under the influence of sedation or general anesthesia can alter the findings; therefore a significant cause of airway obstruction, such as laryngomalacia or vocal cord paralysis, could be overlooked. Direct examination of the airway under general or sedated anesthesia remains the mainstay in diagnosis and confirmation of lesions that obstruct the airway, particularly those below the glottis that cannot be accurately evaluated by awake fiberoptic examination. Airway endoscopy confirms the presence of suspected laryngotracheal pathology, such as subglottic stenosis and tracheal stenosis.

The goal of any evaluation and management of airway obstruction caused by laryngeal or tracheal disease is to establish and maintain a safe and stable airway. The number of children that require surgical intervention for airway obstruction has increased. This is due in part to the development of long-term intubation and ventilation techniques in the 1960s, which allowed increased survival rates for critically ill premature newborns. As a result of prolonged intubation, these infants were able to survive, however, with an entirely new spectrum of long-term health problems, including those of the airway, particularly the larynx and trachea.

## Airway Pathophysiology and Diagnostic Considerations

The larynx is the entry point for air into the tracheobronchial tree and respiratory system. Without a functioning larynx, the remainder of the respiratory system is compromised. The phylogenetic purposes of the larynx are respiration and protection of the lower airway from aspiration. Voice is an evolutionary and secondary function of the larynx. The pediatric airway differs from the adult airway in structure and function. The infant larynx is approximately one third of its adult size, measuring approximately 7 mm in the sagittal dimension and 4 mm in the coronal plane. The vocal cords are 6 to 8 mm long. The subglottic space is approximately 4.5 mm across

and is the narrowest portion of the upper airway, bounded by the cricoid cartilage, the only complete ring of cartilage in the upper airway. Therefore only 1 mm of mucosal edema in this portion of the infant airway can obstruct the airway by 40%. As the airway space and dimensions grow with age, mucosal edema causes less compromise of the airway. The cartilaginous framework of the larynx and trachea is softer and more pliable in infancy. This can lead to a tendency to collapse under external compression or air pressure gradients, which may lead to airway obstruction as seen in laryngomalacia and tracheomalacia. As the infant grows and the cartilage matures, symptoms of these conditions often spontaneously improve and resolve without intervention. In the infant, the larynx sits high in the neck at the level of vertebrae C2 and C3, directly behind the nose, with approximation of the velum, tongue, and epiglottis, thereby functionally separating respiration from swallowing. Because neuromuscular function for airway protection is not fully developed at this stage, this intended anatomic relationship allows the infant to safely breathe and feed at the same time without aspirating. With this anatomic relationship, however, any obstruction of the nasal cavity can cause significant obstruction of the airway, which also causes feeding difficulty. In conjunction with neuromuscular maturation, the position of the larynx descends in the neck. By 2 years of age, the larynx descends to C4, thereby creating less of a separation between the functions of breathing and swallowing. By age 6 years, the larynx has descended to its adult location directly behind C6. Airway and swallowing symptoms tend to be exaggerated if neuromuscular function is compromised or has not matured in conjunction with descent of the larynx.

# Tracheotomy

Tracheotomy is a means of managing severe airway obstruction caused by nearly all the airway lesions discussed in this chapter. Because it is the sine qua non procedure to bypass an obstruction in the airway, indications, technique, and complications will be discussed prior to the review of specific obstructive laryngotracheal lesions. The three major indications for long-term tracheotomy in children are airway obstruction, ventilatory support, and pulmonary toilet. Most children with tracheotomy tubes in place for airway obstruction undergo the procedure as very young infants, either for acquired subglottic stenosis related to prolonged endotracheal intubation or for congenital lesions that compromise the airway. Because of its morbidity and the tremendous psychosocial and developmental implications of a child with a tracheotomy, all alternative interventions before proceeding to tracheotomy should be explored and exhausted.

## TRACHEOTOMY TECHNIQUE

The technique of pediatric tracheotomy preferred by the authors is as follows. The patient is taken to the operating room, and the airway is secured with an endotracheal tube. Because the typical landmarks for tracheotomy may be difficult to identify because of the small size of the larynx and cricoid, tracheotomy in the emergent setting is best done with a secured airway, either by intubation or rigid bronchoscopy. A vertical incision is made over the midline of the neck, its superior extent at the cricoid cartilage. Subcutaneous fat is removed with electrocautery, and the fascia is divided in layers in the midline. The strap muscles are separated at the raphe, and the thyroid isthmus is divided with the electrocautery. Vertical 4-0 nonabsorbable "stay sutures" are placed though the third and fourth tracheal cartilage rings on the right and left sides just off the midline and tied loosely. Gentle tension is applied to these sutures to elevate the tracheal rings, and then the airway is entered with a blade in the midline between the third and fourth rings. As seen in Figure 65-1, the stoma is created by placing 4-0 chromic gut sutures through the cut edge of the trachea and sewn to skin. Some authors note that this technique fashions a more "permanent" stoma and may result in a persistent tracheocutaneous fistula after decannulation. Because the major sources of mortality in pediatric tracheotomy are accidental decannulation or inability to replace an obstructed tube, the authors feel that the added margin of safety, particularly in the first few days, is justification for the approach outlined. In addition, pediatric tracheotomies are rarely short term, and even without the skin sutures, the tract tends to epithelialize over time.

The endotracheal tube (or bronchoscope) is withdrawn, an appropriate-sized tracheotomy tube is inserted, and ventilation is assured bilaterally. As seen in Figure 65-2, the previously placed stay sutures are labeled specifically for the right and left sides and then taped to the anterior chest wall to serve as emergency traction lines in the event of accidental

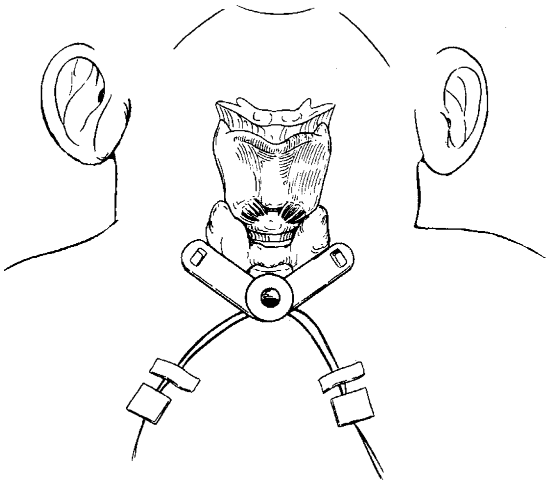

FIGURE 65-2 Labeling stay sutures.

decannulation. The tracheotomy tube is secured around the neck with cotton twill ties. A tracheotomy tube, particularly if it does not have an inner cannula, should never be directly sewn to the skin of a child. In the scenario of a life-threatening mucous plug obstructing the tube, particularly in the immediate postoperative period when the tract has not fully epithelialized, having a tube secured to the skin presents a significant challenge for removal and replacement with a patent clean tube. Postoperative deaths have occurred in this scenario. Ideally, the position of the tracheotomy tube is evaluated by passing a telescope through the glottis, along the tracheotomy tube. This allows the surgeon to ensure that the tip of the tube is proximal to the carina. This technique also allows the surgeon to evaluate the fit of the tube within the lumen of the trachea. This relationship is ideally co-linear and co-centric without any rubbing or encroachment on the anterior or posterior tracheal wall. If assessment by this method is not possible, a flexible bronchoscope can be passed through the tube to verify that the tip is proximal to the carina. The tracheotomy tube is changed, and the stay sutures are removed in 5 days once the tract has epithelialized. These patients should be managed in a monitored in-hospital setting, at least until the tract has epithelialized and a successful change of the tracheotomy tube has occurred.

## TRACHEOTOMY COMPLICATIONS

There are perioperative, postoperative, and long-term complications of tracheotomy, many of which can occur at any time a tracheotomy tube is in place. Perioperative complications following tracheotomy tube placement are rare. The most serious perioperative complications are pneumothorax and major vessel bleeding, particularly from an innominate artery that may be just below the sternum in an infant. A chest radiograph should do be done at the end of the procedure to ensure that there is no pneumothorax or pneumomediastinum. The most common immediate postoperative complications can be life threatening and include mucus plugging and accidental decannulation. The diameter size of tracheotomy tube cannulas for children are significantly smaller than for adults; therefore any occlusion of the tube by mucus could lead to complete airway obstruction, particularly in the child who is totally dependent on the tracheotomy to breathe. Likewise, the stoma into the airway for the tracheotomy tube is much smaller in the child. If the tube were to accidentally dislodge, the increased work of breathing causes further collapse, and a "sucking-in"–like closure at the stoma that makes it difficult to breathe through, and challenging to replace the tube. This effect is even more dramatic in the immediate postoperative time, when the stoma has not fully matured. Because these complications are life threatening, every precaution should be done to ensure that the tracheotomy tube is patent and carefully suctioned and, at the same time, secured around the neck to prevent accidental decannulation.

Any child with a tracheotomy tube for a prolonged time period is likely to develop a minor or major complication. As in the immediate postoperative period, mucous plugging and accidental decannulation are the most serious and life-threatening complications that can occur. Accidental decannulation remains a major concern throughout the time a child has a tracheotomy tube. It is particularly concerning as a young child develops the manual dexterity to remove his or her own tube. Accidental removal could prove to be a fatal event in the child with near-total obstruction of the airway above the tracheotomy tube. Although not universally adopted, many recommend a home apnea monitor or a pulse oximeter to assist caregivers in detecting such a situation. In many cases, the child will still be able to breathe comfortably through the stoma and care should be taken with replacing the tube rapidly, but safely. Hastily performed insertion of the tracheotomy tube may result in creation of a false tract leading to airway compromise where none existed.

Complications related to local infection of either the skin or soft tissue surrounding the stoma (cellulitis), the tracheal mucosa (tracheitis), or the tracheal cartilage (chondritis) are rare in the mature tracheotomy tract. By adapting the skin directly to the cut edge of the tracheal cartilage, epithelialization of the tract is accelerated and healing promoted. Nevertheless, some patients may develop local infections after the perioperative period. Typically, these individuals have some underlying predisposition to breakdown and bacterial invasion, such as drug-induced immunosuppression, primary immunodeficiency, or diabetes. Treatment is with local antimicrobial packing, frequent dressing and cannula changes, and systemic antibiotics. The choice of antibiotics is dictated by culture. Staphylococcal and pseudomonal infections are frequently seen in the intensive care unit setting. Aggressive infections can lead to chondritis, with breakdown of the wound, exposure of the great vessels, and extension of infection into the mediastinum.

Suprastomal granuloma formation is a nearly universal consequence of the presence of a chronic foreign body in the airway. Although some authors recommend routine removal of this tissue at regular intervals, this is not necessary in all patients. Overly aggressive removal of granulomas leads to more frequent recurrences, further arguing against routine excision.[1] Granulomas that completely obstruct the suprastomal airway require removal because of the potential for complete airway obstruction if the tube becomes blocked or displaced as well as to preserve phonation. Parents are usually the first to note symptoms or findings that may suggest suprastomal granuloma formation. Most common are progressive loss of voice and difficulty changing the tracheotomy tube. The most lethal of all late tracheotomy complications is that

of innominate artery erosion at the level where the artery crosses the anterior tracheal wall. This complication can occur as a result of increased pressure from the tip of the tracheotomy tube against the anterior tracheal wall, which leads to granulation tissue formation, weakening of the cartilage, and eventual erosion if not identified. Rigid and inappropriately curved tubes are notorious for causing this, thus emphasizing the importance of appropriate tracheotomy tube size selection. Often, a sentinel bleed of bright red blood will alert the clinician to impending arterial rupture. For this reason, even small amounts of suctioned blood should be evaluated fully by a surgeon.

In the same manner that the anterior wall of the trachea can be eroded by the continued pressure of a tracheal cannula, the posterior wall can break down as well. This is fairly uncommon as a late complication, although the presence of an indwelling nasogastric tube worsens the situation by trapping the posterior wall between two rigid foreign bodies. The diagnosis is suspected in patients with unexplained recurrent pneumonia or pneumomediastinitis. In a ventilated patient, eructation will occur with each inspiratory breath. This complication is traditionally managed by an open surgical procedure, with interposition of healthy muscle between the trachea and the esophagus.

With increased surgical experience, improved surgical techniques, identification, and management of comorbidities that affect outcomes, and improvement in postoperative care, the indications for airway expansion surgery have been extended to patients with laryngotracheal stenosis as the primary definitive operation, thus avoiding tracheotomy[2–7] for many of the airway lesions that may have traditionally required one for initial management.

# Lesions of the Larynx and Subglottis

## LARYNGOMALACIA

Laryngomalacia (LM) is the most common laryngeal anomaly and cause of stridor in infancy. The clinical presentation is that of inspiratory stridor that is worse with feeding, agitation, and supine position. The symptoms are usually present at birth or shortly thereafter. Symptoms peak at 4 to 8 months of age and usually resolve between 18 to 24 months of age.[8,9] Mild forms of the disease present with inspiratory stridor and usually no other constitutional symptoms. Those with moderate disease usually have feeding problems, because it can be difficult for infants to coordinate the suck/swallow/breath sequence in the setting of airway obstruction. Many of these infants who fall into this category have gastroesophageal reflux disease (GERD) and laryngopharyngeal reflux (LPR) and benefit from antireflux treatment and measures.[9–11] Why there is such a high incidence of GERD in this patient population is poorly understood. One theory is that increased intrathoracic airway pressure from the proximal airway obstruction promotes reflux. Another contributing factor could be immature reflexes that regulate esophageal motility causing poor esophageal clearance. GERD in this patient population, as in other infant populations with airway problems and apnea, may be related to frequent relaxation events of the lower esophageal sphincter.[12] Infants with severe laryngomalacia develop life-threatening complications of airway obstruction that can lead to pectus excavatum formation, failure to thrive, chronic hypoxia, pulmonary hypertension, and cor pulmonale. These patients require surgical intervention.[9,13–16] The diagnosis is suspected by auscultation of the stridor but must be confirmed by flexible laryngoscopy. This examination must be done with the infant awake, in order to demonstrate the cyclic collapse of the supraglottic tissues into the laryngeal inlet. The influence of general anesthesia can obscure these findings. Other typical findings are that of an omega-shaped epiglottis and forward prolapsing arytenoid cartilages obstructing airflow and a complete view of the vocal folds. This examination is also done to ensure that there is no other significant supraglottic pathology contributing to the stridor. The etiology of this condition remains elusive. Proposed theories include abnormal airway anatomy,[17,18] immature cartilage formation, delay in neuromuscular maturation, and abnormal integration of the peripheral and central neuromuscular reflexes responsible for laryngeal tone and function.[9]

Laryngomalacia is usually a self-limiting disease that rarely requires surgical intervention. Surgical intervention is recommended in those who develop life-threatening episodes of airway obstruction or complications of hypoxia as described previously. Tracheotomy was the treatment of choice for this condition until the mid-1980s when techniques of supraglottoplasty were introduced.[15,19,20] Tracheotomy bypasses the site of laryngeal obstruction until the condition resolves spontaneously, usually after 18 to 24 months. Tracheotomy can be avoided by performing a supraglottoplasty. As seen in Figure 65-3, this is accomplished by microsurgical removal of the redundant prolapsing tissue seen in the area of the arytenoid cartilages and release of the aryepiglottic folds tethering the position of the epiglottis.[15] Long-term results with this approach have generally been excellent, with reversal of symptoms in 80% to 100% of cases.[9,13,15,16,21–24] Outcomes, however, are dependent on the number of medical comorbidities present. Up to 45% of patients with severe laryngomalacia that require surgery have at least one major medical comorbidity (neurologic disease, cardiac disease, a syndrome, or anomaly) in addition to GERD/LPR that may affect outcomes of surgical intervention.[9,25,26] Most infants who have two medical comorbidities or less, including GERD/LPR, benefit from supraglottoplasty where symptom improvement rates range from 70% to 100%, and revision rates or complications are less than 8%.[9,25,26] Revision supraglottoplasty or tracheostomy will be required in 19% to 45% of infants and is directly influenced by the number and type of medical comorbidity.[9,23–26] Infants younger than 2 months of age who do not have significant comorbidities also have higher supraglottoplasty revision rates.[26] The authors' experience is that if two of these medical comorbidities are present, in addition to LPR, the infant is 5 times more likely to require revision supraglottoplasty, and if all three comorbidities are present, the infant is 10 times more likely to require a tracheostomy for management despite aggressive management of reflux disease.

Infants with laryngomalacia and syndromes associated with micrognathia, such as the CHARGE association (colobama, heart disease, atresia choanae, retarded growth or development or central nervous system anomalies, genital hypoplasia, ear anomalies and/or deafness) and the Pierre Robin sequence, will do worse because of the retrodisplacement of the tongue base collapsing on the epiglottis, in addition to supraarytenoid tissue redundancy and short aryepiglottic folds. Supraglottoplasty or epiglottic suspension procedures usually are unsuccessful.[27]

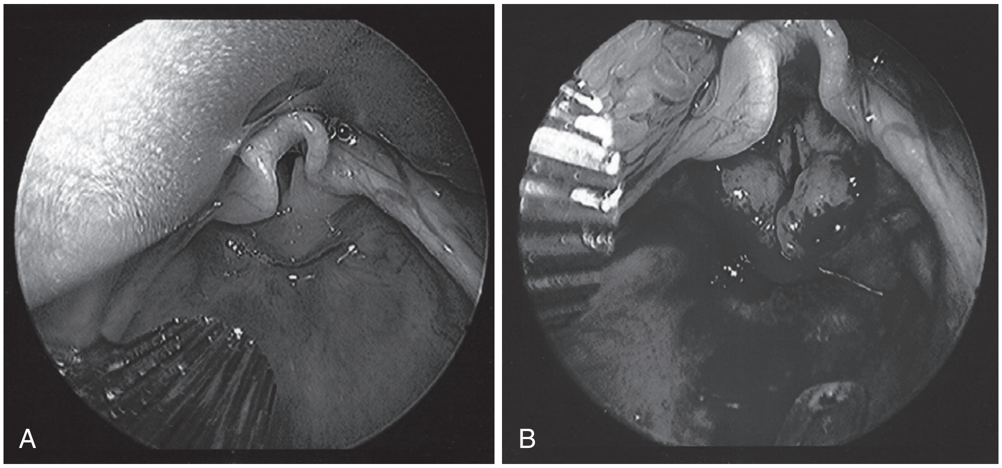

FIGURE 65-3 Laryngomalacia before (**A**) and after (**B**) supraglottoplasty.

Because of the severity of airway obstruction, this patient group is traditionally managed by tracheostomy placement until they grow out of the micrognathia or it is corrected by mandibular distraction, although subperiosteal release of the floor of the mouth muscles provides an attractive alternative.[28,29]

Supraglottic stenosis is the most severe complication of this operation and can occur after overzealous removal of tissue or failure to control for acid reflux disease, which may enter the airway and cause injury to tissues, leading to haphazard scarring.

## LARYNGEAL ATRESIA AND WEBS

Laryngeal webs are congenital (Fig. 65-4, *A*) or acquired (see Fig. 65-5). Congenital laryngeal webs and atresias are rare. The embryologic origin is failure of recanalization of the larynx during prenatal development. A child born with velocardiofacial syndrome or a 22q11.2 deletion that presents with respiratory distress and a weak cry will likely have a laryngeal web that will require surgical intervention.[30] An atresia or a web of sufficient size will present at birth as aphonia and rapid asphyxia if not immediately addressed. A thin web with a small residual airway may be ruptured by intubation. Often this is the only treatment needed; however, these infants should be followed closely so that appropriate intervention occurs if airway obstruction develops. Thick webs and atresias make emergent intubation by standard techniques difficult if not impossible. In this setting, survival of the infant may be dependent on securing the airway with a 2.5 rigid bronchoscope and, if that is not possible, obtaining a surgical airway. Surgical management of thick webs and atresias requires a tracheostomy tube until the larynx is larger and more amenable to surgical intervention.[31] Surgical correction usually requires a laryngofissure (vertical split of the thyroid cartilage on the anterior midline) with anterior airway division across the atretic region and placement of costal cartilage in the anterior cricoid and cervical trachea, similar to a laryngotracheal reconstruction for subglottic stenosis, which is discussed later in this chapter. Timing of reconstruction is dependent on many factors, including age of the child and surgeon experience.

Thin and moderate anterior webs are not usually diagnosed or suspected at birth and may or may not have airway

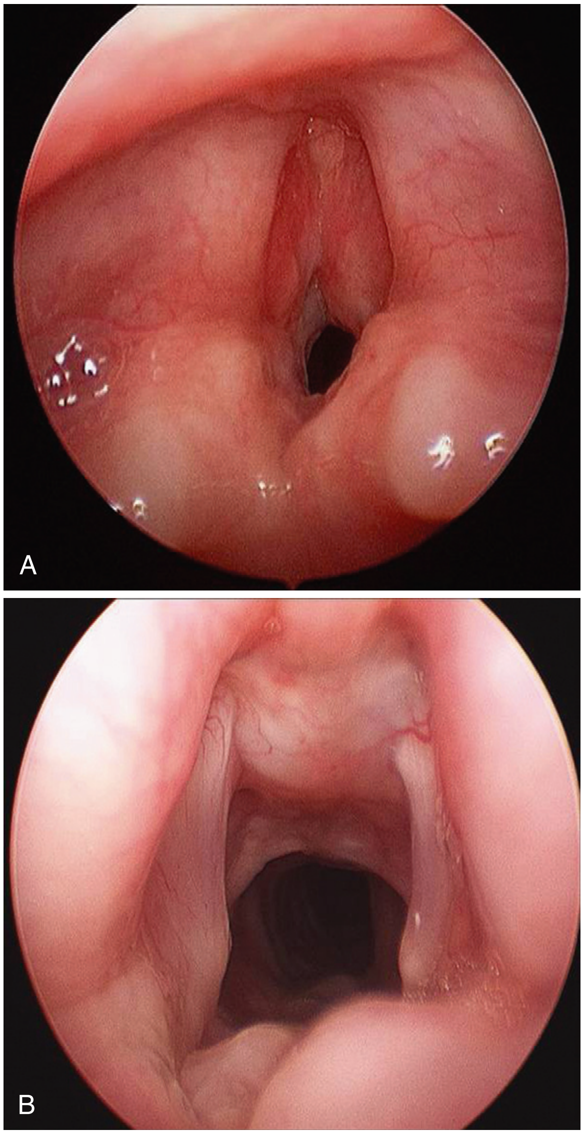

FIGURE 65-4 Congenital web in child with velocardiofacial syndrome. **A,** Before anterior graft reconstruction. **B,** After anterior graft laryngotracheal reconstruction with placement of the graft between the vocal cords. *(See Expert Consult site for color version.)*

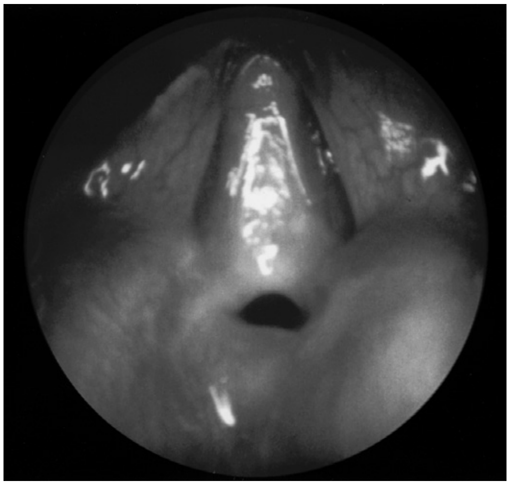

FIGURE 65-5 Acquired web.

obstructive symptoms. The most common presenting symptom is hoarseness. The primary goals of management are to provide a patent airway and to achieve a good voice quality. This is challenging, because vocal cords have a tendency for fibrosis and granulation tissue formation after surgical interventions. Traditionally, the treatment of choice for these thin and moderate laryngeal webs is laryngofissure and placement of a stent or keel, when the surgeon feels the child has grown appropriately. Select laryngeal webs can be managed with endoscopic lysis and off- label topical mitomycin-C application, even in infants under 1 year of age.[32] This technique may allow congential webs to be successfully managed at a younger age. However, long-term outcomes of this technique are not available, and it is unknown if infants treated by this method eventually need laryngotracheal reconstruction to maintain a patent airway. Moderate and severe webs that have a thick plate extending into the immediate anterior subglottis just below the vocal cords are difficult to successfully manage with endoscopic techniques or laryngofissure and keel placement. Because these webs often present with airway obstruction, aggressive intervention is required, such as tracheotomy or airway reconstruction, whereby the web is divided and a cartilage graft placed between the vocal cords (Fig. 65-4, *B*). Long-term results in the management of webs depend on the severity of the original lesion. Surgically treated thin webs often heal with minimal disruption of phonation, while thicker plates with associated subglottic stenosis have less satisfactory results, particularly those that require cartilage grafting.[33]

Acquired laryngeal webs are also uncommon (Fig. 65-5). Etiology is usually from direct laryngeal trauma, where the medial surfaces of both vocal cords are disrupted, and they heal together, forming a web. This is most commonly seen in the management and treatment of laryngeal papillomas, usually caused by overzealous removal of papilloma disease at the anterior glottic commissure, particularly in the setting of laryngopharyngeal reflux.[34]

## VOCAL CORD IMMOBILITY: VOCAL CORD PARALYSIS AND VOCAL CORD FIXATION

Vocal cord movement requires intact neurologic function of the vagus nerve and free rotation of the cricoarytenoid joint. The action of abduction of the vocal cords from the midline opens the glottic inlet for airflow into the tracheobronchial tree. Airflow is restricted if vocal cord abduction does not occur. Vocal cord immobility is caused by failure of the vocal cords to abduct. There are two primary etiologies of vocal cord immobility, vocal cord paralysis, and vocal cord fixation. Injury of the vagus nerve anywhere along its course from the skull base to the thoracic cavity or injury of the recurrent laryngeal nerve causes neurogenic vocal cord paralysis. Paralysis can be congenital or acquired. Acquired immobility is usually caused by a stretch injury, pressure encroachment, inflammatory insult, trauma, or sectioning of the nerve itself. In this setting, the cricoarytenoid joint is mobile, but the neuromuscular function is compromised. A traumatic or inflammatory process in the cricoarytenoid joint causes vocal cord fixation. In this setting, the function of the joint that is required for mobility is fixed, but the neuromuscular function is intact. Fixation and paralysis can coexist. Regardless of the etiology of immobility, failure of one or both of the vocal cords to abduct can lead to stridor and airway obstruction.

Unilateral vocal cord immobility rarely causes stridor or airway obstruction, except occasionally in very young infants, particularly in the setting of mucosal edema, where the cross-sectional diameter of the airway is already small. In the setting of bilateral vocal cord immobility, both cords lie in the midline, thereby limiting air flow through the glottis. This may present with severe life-threatening symptoms and airway obstruction, requiring an immediate artificial airway. Some infants and children have mild symptoms, occurring only during periods of upper respiratory tract infection, and may not require a tracheotomy. Most children with bilateral vocal cord immobility require tracheotomy early in the course of the disease, prior to definitive surgical therapy. Because it is bilateral immobility that most commonly leads to airway obstruction, the discussion of surgical treatment will be limited to management of bilateral immobility.

Management and treatment of airway symptoms of bilateral cord immobility is based on the etiology and site of involvement along the vagus nerve. In neonates and infants, bilateral vocal cord paralysis may have a central etiology, most commonly a Chiari malformation or hydrocephalus. Caudal displacement of the brainstem as seen in a Chiari malformation causes pressure on the brainstem at the site of origin of the vagal nuclei and nerves. Recognition and diagnosis of this is important to prevent other complications of a Chiari malformation. Vocal cord paralysis can be cured once the Chiari malformation is decompressed if done in a timely fashion. Hydrocephalus leads to increased compression of the fourth ventricle. This can also cause compression of the vagal nuclei and nerves. Decreasing the intracranial pressure by shunt placement is often curative[35,36] and should be the initial management prior to consideration of tracheotomy or airway surgery. Infants with a central etiology of bilateral vocal cord paralysis and who fail central decompressive procedures will require a tracheotomy for airway safety. These groups of patients often go on to develop other lower cranial nerve problems and aspiration that keep them tracheotomy tube dependent; they are generally not good candidates for other surgical procedures to achieve decannulation. If the vagal nerves are intact, and the etiology of bilateral vocal cord paralysis is a localized insult to the vagal nerves, such as a stretch injury from obstetrical trauma, infection, or extrinsic compression, an observational period is often warranted if there are no acute

symptoms of airway obstruction. The paralysis is frequently transient in these patients who are otherwise healthy. If the etiology of vocal cord paralysis is traumatic with direct nerve injury where function is not expected to return, a tracheotomy is required until another procedure can be done to expand the glottic opening. This situation may be seen in "fixed wire" neck trauma with nerve injury[37] or nerve injury as a complication of thyroid surgery.

Bilateral vocal fold immobility resulting from fixation occurs when the synovial joint surfaces of the cricoarytenoid joint become fixed, thereby not allowing vocal fold abduction or adduction. In this setting, the vagal nerve is usually fully functional and physically intact. The most common cause of fixation of the joint is some type of direct trauma to the joint area itself, such as intubation or neck trauma dislocating the cricoarytenoid joint. Once the joint is injured, an inflammatory process occurs, causing an arthritic-like process. Juvenile rheumatoid arthritis can also cause bilateral immobility.

Whether the cause of vocal fold immobility is paralysis or fixation, surgical approaches for treatment in children are similar. The fact that there is a wide variety of surgical approaches suggests that no one procedure is ideal. The goal is to open the posterior glottic airway enough to allow adequate airflow without exposing the patient to increased risk of complications from aspiration. The procedures described are often done after the airway has been secured and is stable with a tracheotomy tube. More recently, many of these surgical techniques have been used as the primary surgery, with the goal of avoiding a tracheotomy. The decision to do definitive primary surgery depends on the acuity of airway obstruction, age of the child, and ability to protect the airway against aspiration.

Repositioning or removal of structures and tissue in the posterior glottis, namely the arytenoid cartilage and mucosa, are well-described techniques of opening the airway in the setting of bilateral vocal cord immobility. These include arytenoid lateralization, arytenoidopexy, partial arytenoidectomy, and cordotomy.[38–41] These procedures can be done alone or in combination with the goal of decannulation. The surgical approach can be external through a laryngofissure or endoscopic using a carbon dioxide ($CO_2$) laser or a combination of both. Endoscopic $CO_2$ laser removal of the vocal process of the arytenoid and a portion of the posterior vocal cord has been successfully used in some series.[41,42] The management challenge of this technique is treatment of postoperative granulation tissue formation, which may lead to airway obstruction.[43] Recent meta-analysis and retrospective studies evaluating outcomes of surgically managed bilateral vocal cord paralysis in children suggest that laryngofissure with partial arytenoidectomy, combined with a vocal cord lateralization procedure, results in the highest decannulation rates when compared with $CO_2$ arytenoidectomy and cordotomy procedures or arytenoidopexy procedures alone.[44,45] These same studies conclude that open external procedures appear to be more effective as a first-line treatment in pediatric vocal cord paralysis, with arytenoidopexy with or without partial arytenoidectomy offering an attractive first-line surgical option. They also conclude that $CO_2$ laser procedures, although having limited success as a primary procedure, are effective for revision. Although these procedures have been effective in achieving decannulation and maintaining airway patency, long-term outcomes on aspiration and voice are unknown. Recent reports suggest that endoscopic placement of sutures to lateralize the vocal cords is an option to achieve a patent glottic airway.[46–48] Short-term results suggest the technique is more successful in adolescents and adults. The authors' experience with this technique in infants and children has resulted in variable outcomes. Long-term outcomes are unknown.

Posterior graft laryngotracheoplasty is another effective technique to open the posterior glottis.[49,50] Through a laryngofissure with extension into the first two rings of the trachea, the posterior cricoid lamina is incised and distracted, thereby separating the arytenoid cartilages. Inserting a costal cartilage graft into the distracted posterior cricoid lamina stabilizes the position of the arytenoid cartilages. Although published series of this procedure are small, the decannulation rate after posterior approaches is near 100%.[44] Endoscopic posterior cricoid split and rib graft insertion has been successfully accomplished in selected children with bilateral vocal cord paralysis, thereby avoiding the need for a tracheotomy or other endoscopic vocal cord ablation procedures that could compromise voice.[6,51]

## RECURRENT RESPIRATORY PAPILLOMATOSIS

Recurrent respiratory papillomatosis (RRP) is the expression of human papillomavirus (HPV) infection in the mucosa of the upper aerodigestive tract. Papillomas involving the larynx are the most common laryngeal tumor in children, and the larynx is the most common site of occurrence in the aerodigestive tract (Fig. 65-6). Adult laryngeal papilloma disease is usually solitary, whereas papillomas of childhood tend to occur in clusters and have an incredible propensity for recurrence. Clinical presentation of laryngeal papilloma is progressive airway obstruction, dysphonia, and possible progression to aphonia. RRP is most commonly associated with HPV-6 and HPV-11 subtypes. Subtypes 16 and 18 are rarely associated with RRP but, if present, have a higher risk of malignant transformation. These viral particles are present in adjacent and clinically normal sites of the respiratory tract but are expressed primarily in anatomic locations of juxtaposed epithelium, hence the high predilection for the vocal cords.[52] The other common location is at an area of mucosal injury, such as a tracheotomy site.[52] The vector of transmission is controversial. Pediatric RRP and vaginal condyloma acuminata are

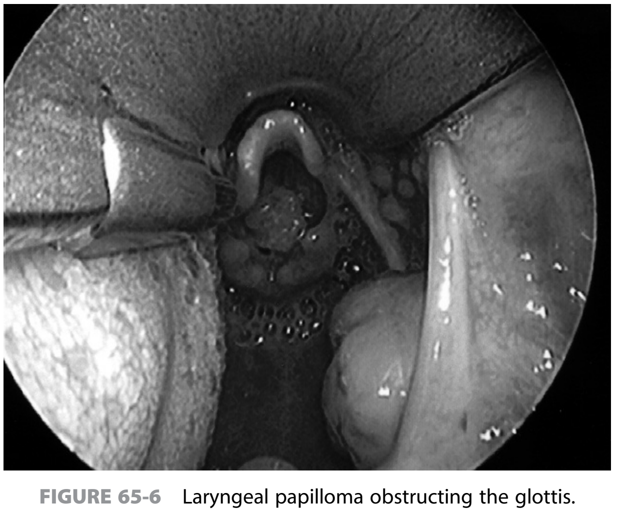

FIGURE 65-6 Laryngeal papilloma obstructing the glottis.

both caused by HPV subtypes 6 and 11, thus leading most researchers to believe that vertical transmission from mother to child is taking place in most cases. Although unusual, vertical transmission to children born by cesarean section of mothers with vaginal warts has also been documented.[53]

The natural course of RRP is extremely variable, with no obvious patient-related risk factors to aid in prognosis. The estimated mean number of procedures per child for their disease is 19.7, with an average of 4.4 procedures per year. Many cases have been seen to regress spontaneously in adolescence, but others go on to extensive disease involving the trachea and bronchial tree, with a high fatality rate from untreatable airway obstruction. Less commonly, the papilloma may undergo malignant degeneration to squamous cell carcinoma. For this reason, interval histologic examination of the obstructing tissue is important.

Pediatric RRP continues to be an extremely difficult management problem for otolaryngologists. The goal of surgical treatment is to maintain a patent airway while providing a usable voice and to prevent spread of disease into the distal airway.

Although the mainstay of surgical management has traditionally been the $CO_2$ laser, newer surgical techniques have demonstrated efficacy in the management of pediatric RRP patients, including powered instrumentation, the laryngeal shaver,[54] and the pulse-dye laser.[55,56] In comparison with the $CO_2$ laser, the pulse-dye laser is thought to not cause damage to the vocal fold epithelium; thus some propose that more aggressive surgical excision to the vocal structures is possible while minimizing compromise to voice.[55] Removal of papillomas using the microdebrider results in improved perceptual and objective voice outcomes in comparison with the $CO_2$ laser ablation.[57] Regardless of the surgical technique used, scarring, stenosis, and web formation in the larynx are all the results of overly aggressive or inexpertly performed endoscopic removal of the disease. Care must be taken to avoid injury to vital structures. The papillomas can be removed down to the level of the vocal ligaments, but the cords themselves should not be incised. When working in the anterior commissure, the far anterior glottis where the vocal cords meet, bilateral resection should not be done to avoid web formation. Even in experienced hands, the incidence of minor scarring in the anterior glottis may be as high as 25%.[58] Aggressive resection beyond that necessary to maintain a safe airway will not improve the long-term prognosis for remission, but may contribute to late morbidity.

The role of tracheotomy in the surgical management of laryngeal papillomatosis is controversial. Most surgeons try to avoid tracheotomy if at all possible. The mucosal injury at the tracheotomy site encourages growth of papillomas outside of the larynx, thereby increasing the probability of distal spread of the disease. The rate of tracheal spread in patients requiring tracheotomy has been reported as high as 50%.[59] It is possible, given the variable degree of aggressiveness of RRP, that patients who have distal spread of disease represent a subset of the patient population with a predetermined propensity to disseminate beyond the larynx who would require a tracheotomy regardless. Patients who develop life-threatening airway obstruction from aggressive disease within or beyond the larynx, which cannot be managed by endoscopic procedures, should have a tracheotomy placed until the disease can be controlled with further surgical intervention and adjunctive therapy. If a tracheotomy is placed, the clinician should make every attempt possible to decannulate as soon as possible, both to limit potential distal airway dissemination and to relieve the child of the burden of tracheotomy. The traditional adjuvant medical therapies used for pediatric RRP are interferon-alpha 2a, retinoic acid, and indol-3-carbinol/diindolylmethane (I3C/DIM). The most recently introduced adjunctive therapy is cidofovir. Cidofovir is an acyclic nucleoside phosphonate derivative with antiviral activity used for the treatment of cytomegalovirus retinitis in patients with acquired immunodeficiency syndrome. Off-label use of cidofovir injected directly into the region after removal of laryngeal papilloma has demonstrated efficacy in selected patients. In addition, promising research efforts are being done to develop vaccination therapy for pediatric RRP.

Gardasil (Merck) and Cervarx (Glaxo-Smith-Kline) are two vaccines shown to be effective against the human papilloma virus. Gardasil is a quadrivalent vaccine, protecting against HPV types 6, 11, 16, and 18, while Cervarx stimulates a response only to HPV types 16 and 18. These vaccines were developed with virus-like particles (VLP) that simulate the surface of the HPV. The vaccines are manufactured in the yeast *Saccharomyces cerevisiae*. Yeast-derived vaccines have a long safety record after administration in both adults and children.

Vaccination trials show excellent response rates to the recommended three-injection series, with 99.7% of those vaccinated developing an antibody response. Vaccination to the HPV provides protection to those not previously infected with the virus. The vaccination does not appear to have any effectiveness for treating established chronic HPV infections.[60] The vaccine is currently recommended for females 9 to 15 years of age. This is treating them before their first sexual encounter and during a time when their immune response is higher, compared with women aged 18 to 26. Older women were found to have lower immune response rates to the vaccine and have the added potential for previously contracting the HPV through sexual contact.[61] Older women may benefit from the vaccine if they have not been previously infected with the viral subtypes in the vaccine.

The quadrivalent vaccine, Gardasil, has the potential to significantly reduce the incidence of RRP in children. Encouraging primary care physicians to offer the vaccination to females prior to their becoming sexually active will be important. Encouraging families to vaccinate their young girls will also take significant time to explain the benefits. The question of whether males should be vaccinated has yet to be determined. It is reasonable to consider reducing the overall exposure of individuals to HPV by treating males as part of an overall societal strategy for reducing the impact of this disease on society.

## LARYNGOTRACHEAL STENOSIS AND SUBGLOTTIC STENOSIS

Laryngotracheal stenosis may be characterized by etiology and area involved. Areas of involvement include the supraglottis, glottis, subglottis, and upper trachea. A single area or multiple areas can be involved. Stenosis of the larynx is congenital (Fig. 65-7) or acquired (Fig. 65-8). Congenital stenoses are believed to be the result of failure or incomplete recanalization of the laryngeal lumen that occurs by the 10th week of gestation. Congenital subglottic stenosis is

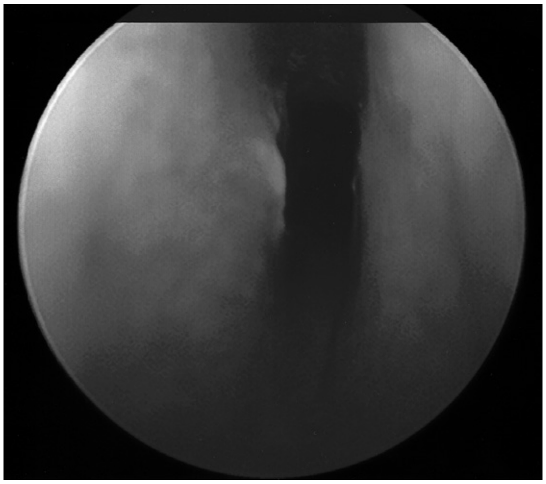

**FIGURE 65-7** Congenital subglottic stenosis with an elliptically shaped cricoid.

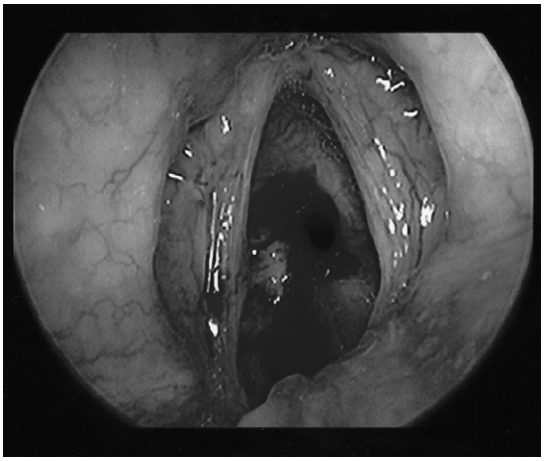

**FIGURE 65-8** Acquired subglottic stenosis.

histopathologically divided into a membranous stenosis and a cartilaginous stenosis (Table 65-1).

A congenital stenosis exists when the lumen of the cricoid region of the airway measures less than 4 mm in a full-term infant or 3 mm in a premature infant with no prior history of intubation. As seen in Figure 65-7, the typical appearance of a congenital cartilaginous stenosis is that of an elliptic-shaped cricoid cartilage. The definition of what may be a congenital or an acquired stenosis can be somewhat arbitrary, because children with congenital subglottic stenosis may develop secondary soft tissue stenosis and scarring from injury, thereby developing an acquired stenosis. This most commonly occurs from prolonged intubation; so, the true incidence of congenital subglottic stenosis is difficult to determine. Of the areas involved in stenosis, the subglottis is the most common. Most subglottic stenoses that require surgical management are acquired. An example of acquired stenosis is seen in Figure 65-8. The principles of surgical management discussed are applicable to both congenital and acquired disease.

Subglottic stenosis (SGS) essentially did not exist until after 1965 with the introduction of prolonged endotracheal intubation and ventilation of neonates.[62] As very-low-birthweight infant survival increased, so did the number of patients with secondary laryngotracheal stenosis, with the incidence of SGS in surviving neonates as high as 97%.[63] Fortunately, advances in the technique of endotracheal intubation and tube stabilization, along with the implementation of softer materials for endotracheal tubes, have decreased the incidence of laryngotracheal stenosis in surviving neonates to 0.9% to 8.3%.[64] With the proliferation of lifesaving advancements in medicine and surgery, we are seeing children survive disease processes who would have not survived 20 years ago. These children also develop other chronic diseases as a result of treatment, with subglottic stenosis being one of them. The numbers of toddlers, children, and adolescents who are now developing stenosis of the larynx has increased, but the exact percentages are unknown. The nature of the stenosis can be soft or firm, or commonly a combination of both. Causes of soft tissue stenosis are submucosal mucous gland hyperplasia, ductal cysts, fibrous and granulation tissue, and laryngopharyngeal reflux of gastric acid causing mucosal edema. Firm stenoses are usually associated with an abnormally shaped or thickened cricoid cartilage, or mature scar tissue. The Myer-Cotton grading system is the most widely used for documentation of the degree of obstruction (Fig. 65-9). Endotracheal tube sizing has become the most widely used means of grading and assessing the degree of stenosis.[65]

**TABLE 65-1**
**Classification of Congenital Subglottic Stenosis**

| *Cartilaginous Stenosis* | *Soft Tissue Stenosis* |
|---|---|
| Cricoid cartilage deformity | Granulation tissue |
| Normal shape | Submucosal fibrosis |
| Small for infant's size | Submucosal gland hyperplasia |
| Abnormal shape | |
| Large anterior lamina | |
| Large posterior lamina | |
| Generalized thickening | |

Successful laryngotracheal reconstructive surgery requires a carefully formulated plan. This plan includes identification and management of significant medical comorbidities that have the potential to contribute to poor outcomes. The plan also requires accurate identification of the type of stenosis in all areas of the larynx and upper trachea involved, because the stenosis can be multilevel and require more than one type of intervention. The treatment plan is tailored to the specific patient, his medical comorbidities, and the anatomic problem. This treatment plan is best developed by a multidisciplinary team approach, including the pediatric otolaryngologist, pediatric surgeon, pulmonologist, gastroenterologist, anesthesiologist, intensivist, and appropriate allied health personnel.

Any laryngeal stenosis can be effectively managed by placement of a tracheotomy. Long-term morbidity and mortality associated with tracheotomy tube placement has encouraged advancements in laryngotracheal reconstructive procedures (LTR) to either avoid tracheotomy tube placement or to achieve decannulation.

Associated medical comorbidities, particularly cardiopulmonary disease, must be addressed, stabilized, and managed prior to considering surgical intervention. Children who require significant ventilatory support or medical support are not good candidates for laryngotracheal reconstruction. Evaluation of swallowing function is essential to help determine airway protection ability and aspiration risk so that preoperative and perioperative accommodations can be made to minimize the complications of aspiration. Patients with significant aspiration are usually not good candidates for LTR.

The influence of gastroesophageal reflux on laryngotracheal stenosis cannot be overemphasized. GERD is an etiologic factor in acquired subglottic stenosis. Clinical and animal studies demonstrate that the presence of acid in the region of the larynx negatively affects healing.[66–72] Perioperative and postoperative aggressive medical and sometimes even surgical[70] antireflux therapy is recommended in the setting of LTR surgery. Prospective and retrospective studies evaluating long-term outcomes of reflux control in LTR surgery are not available.

Surgical management of laryngotracheal stenosis is individualized to the patient, and no single operative approach will work for all patients. Each patient presents with multiple variables that must be considered and include the location and extent of the stenotic area, medical comorbidities, airway protection and swallowing function, age, and weight. Surgical options include endoscopic techniques, expansion surgery, and resection surgery. Methods used are dependent on the degree and location of the stenosis. In general, grade I stenoses are usually managed by endoscopic techniques. Grade II stenoses may be approached with either endoscopic or open techniques, depending on location and extent of the lesion. Grade III and IV lesions almost always require open surgical reconstruction.

## Endoscopic Airway Surgery for Laryngotracheal Stenosis

Grade I and II stenoses can be approached with endoscopic techniques. Over the past 5 years, with advances in endoscopic techniques and the introduction of improved instrumentation, endoscopic techniques are also being applied to selected grade III stenoses. The $CO_2$ and potassium-titanyl-phospate (KTP) lasers, because of their precise tissue characteristics, have been the most widely used modalities. The laser is useful for treating early intubation injury with granulation tissue accumulation, subglottic cysts, thin circumferential webs, and crescent-shaped bands. Predisposing factors to failure of endoscopic laser treatment of SGS are previous failed endoscopic procedures, significant loss of the cartilaginous framework, thick, circumferential cicatricial scarring greater than 1 cm in length, and posterior commissure involvement. A complication of laser treatment of SGS is exposure of perichondrium or cartilage causing perichondritis and chondritis, which may lead to further scar formation.

Airway dilation techniques have been applied for the management of airway stenosis since the advent of bronchoesophagology. The traditional methods involved bougienage techniques, including cattail dilators and endotracheal tubes. Although these techniques are effective and still used by many surgeons, the sheering forces generated across the area of stenosis may lead to scarring and require ongoing serial dilations[73] or more aggressive open airway surgical management. The introduction of balloon dilation of the airway has shown promising outcomes. As seen in Figure 65-10, airway specific balloon catheters are designed to exert a radial pressure at the site of stenosis; the diameter is selected based on the anticipated normal age-related size of the airway. Unlike traditional dilation techniques, the radial pressure applied to the stenosis has shown less scarring and better long-term results, often obviating the need for tracheotomy or open airway reconstruction.[74,75] Balloon dilation is also effective for emergent stabilization of a patient's airway until a definitive open procedure can be performed. As seen in Figure 65-10, balloon dilation is also used as an adjunct to recurrent airway stenosis after successful open airway reconstruction.[76]

Another adjunctive tool used in the management of laryngotracheal stenosis is the microdebrider. In contrast to the blades used for the management of laryngeal papilloma, a number of more aggressive cutting blades have been designed for management of laryngeal and tracheal stenosis and granulation tissue. The theoretical advantage of the blade compared with a laser is less thermal damage with potentially less scar formation.[77,78]

Moderate and severe cases of laryngotracheal stenosis, in particular those involving the posterior glottic and posterior subglottic areas, can be successfully managed endoscopically

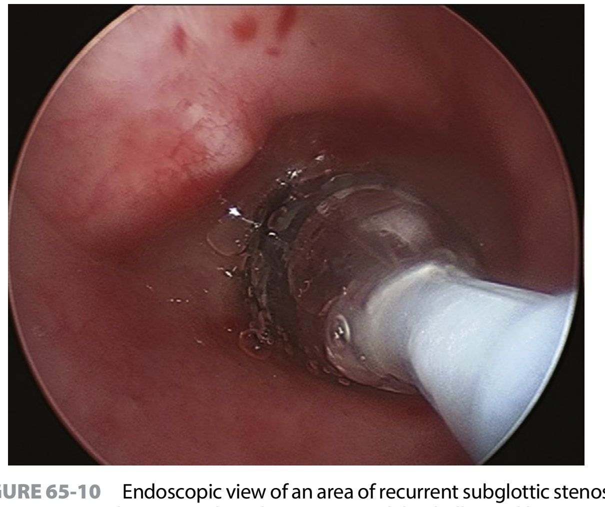

**FIGURE 65-10** Endoscopic view of an area of recurrent subglottic stenosis following open laryngotracheoplasty managed by balloon dilation. *(See Expert Consult site for color version.)*

by performing $CO_2$ laser–assisted endoscopic cricoid split and placement of a posterior costal cartilage graft between the distracted cricoid plate as previously described for the management of bilateral vocal cord paralysis.[6,51] This evolutionary technique is becoming a viable alternative to open airway surgery or tracheotomy as more surgeons gain experience and endoscopic instrumentation continues to evolve.

Achieving optimal results for endoscopic procedures often involves the use of adjunctive therapies to minimize scarring and stenosis. Mitomycin C is a potent antibiotic derived from the *Streptomyces caespitosus* bacteria shown to modify wound healing at the molecular level and minimize postsurgical scar formation. Off-label topical application of mitomycin C is a well-described adjunct that has been shown to minimize recurrent tracheal granulation tissue formation and cicatrix formation after manipulation. The mechanism of the drug's anticellular action has not been definitively characterized. It is known, however, that mitomycin C is a prodrug that is activated into toxic forms that produce oxygen free radicals, creates single-strand DNA breaks, and cross links DNA.[79] Another adjuvant is the intralesional injection of steroid preparations into the stenotic area to minimize inflammation, granulation, and scarring.

### Open Airway Surgery for Laryngotracheal Stenosis

Open surgical reconstruction is recommended when the endoscopic methods to establish a patent airway are inappropriate or have failed. Anterior cricoid split is considered one of the expansion surgical techniques. It is used predominantly in a neonate with anterior subglottic narrowing who fails multiple attempts at extubation despite adequate pulmonary reserve. In this setting, the narrowing at the level of the cricoid cartilage is corrected by dividing the cricoid ring in the midline. This decompresses the mucosal edema and expands the cricoid lumen when an endotracheal tube is placed through the area. The endotracheal tube is left in place for 5 to 10 days. Dexamethasone sodium phosphate is initiated 24 hours before extubation and continued for 5 days after extubation. This technique leads to successful extubation in 66% to 78% of patients.[80] As seen in Table 65-2, before considering using this technique in a neonate, several clinical criteria must be met to increase the probability of successful extubation following anterior cricoid split.

In the authors' hands, this technique has nearly been replaced by anterior cricoid split with the placement of a small auricular cartilage or thyroid alae graft, followed by endotracheal intubation for 3 to 7 days. Outcomes comparing decannulation rates of cricoid split versus cricoid split with placement of the cartilage graft have not been formally reviewed.

**TABLE 65-2**

| Criteria for Performing an Anterior Cricoid Split |
|---|
| Extubation failure on at least two occasions secondary to subglottic laryngeal pathology |
| Weight greater than 1500 g |
| No ventilator support for at least 10 days before repair |
| Supplemental $O_2$ requirement less than 30% |
| No congestive heart failure for 1 month before repair |
| No acute respiratory tract infection |
| No antihypertensive medication for 10 days before repair |

Multiple open procedures have been described and are used to expand the stenosed airway. These procedures and their applications have evolved over the past 30 years. Fearon and Cotton[80a] introduced laryngotracheal reconstruction (LTR) with cartilage interpositional grafting in 1972 with placement of a cartilage graft between a split anterior cricoid and upper trachea. This method has become one of the most common techniques of expanding stenotic airway segments. Anterior grafting alone is typically used in grade II and grade III stenoses that do not involve the posterior glottis or posterior subglottis. With involvement of the posterior glottis or subglottis, the posterior cricoid plate lamina is split with or without the placement of an interpositional graft, depending on the degree of the stenosis. The grafts may be placed anteriorly, posteriorly, or in both locations depending on the degree of stenosis. This problem is more commonly seen in grade III and grade IV stenosis. Partial cricotracheal resection (CTR) has evolved into another option for surgical management of selected grade III and IV stenosis.[81–86] In this operation, the stenotic region of the anterior cricoid plate and any involved tracheal stenotic segment is resected, and the trachea is mobilized to allow an end-to-end anastomosis. As seen in Figures 65-11 and 65-12, the posterior trachea and trachealis muscle is anastomosed with the posterior cricoid plate and its mucosa. The anterior wall of the trachea is then mobilized superiorly, and secured to the thyroid cartilage.[81–83,86]

The traditional approach to LTR surgery involves several stages of reconstruction[87–90] where the expansion operation is done, and a stent (Silastic sheeting or Teflon) is placed to

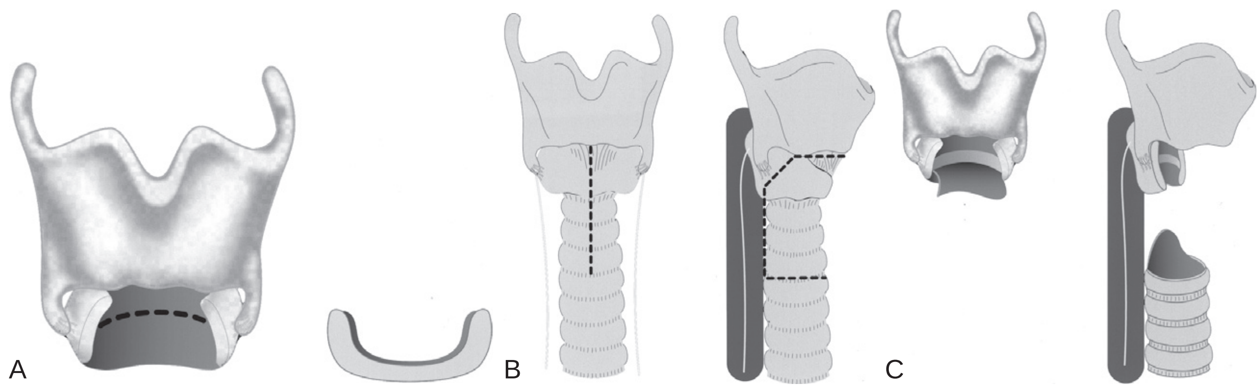

**FIGURE 65-11** Cricotracheal resection. **A,** Resection of the anterior cricoid with a mucosal incision in the posterior cricoid. **B,** View of resection of a scarred airway with preservation of the recurrent laryngeal nerves. **C,** Resection complete with a cuff of posterior tracheal mucosa.

stabilize the reconstruction. The stent is left in place above a tracheotomy stoma (suprastomal stent) for 4 to 6 weeks. After removal of the stent, and once the surgical site has healed with a patent subglottis, the tracheotomy tube is downsized until the child tolerates and is able to breathe around a plugged tracheotomy tube. Once this is accomplished, the tracheotomy tube is removed. This process of reconstruction and decannulation can take weeks to several months. The morbidity and potential mortality of a tracheotomy tube is well recognized in children. With staged reconstruction and stent placement, the child is left with little or no airway above the tracheotomy tube, which is life-threatening if the tube accidentally falls out or becomes occluded. Long-term stenting has additional morbidities of granulation tissue formation, infection, dislodgment of the stent, dysphagia, and aspiration. To address these risks and circumvent some of these problems, single-stage LTR (SSLTR) evolved. In the authors' hands, staged procedures are still done in children with compromised pulmonary reserve or complex multilevel stenosis that require prolonged stenting.

Single-stage LTR (SSLTR) involves surgical correction of the stenotic airway with a short period of endotracheal intubation, thus avoiding the need for prolonged laryngotracheal stenting and tracheotomy tube dependency. The airway must have adequate cartilaginous support to consider SSLTR as a surgical option. SSLTR requires a comprehensive understanding of the principles of airway reconstruction and extensive experience on the part of the surgeon, anesthesiologist, intensivist, and nursing staff. Postoperative care of these patients can be complicated.[2,91,92] The experience at our institution of 200 SSLTR cases showed that 29% of patients were reintubated, and 15% required postoperative tracheostomy. The overall decannulation rate was 96%. We also found that the use of anterior and posterior costal cartilage grafting, age less than 4 years, sedation for more than 48 hours, a leak pressure around the endotracheal tube of greater than 20 cm $H_2O$, and moderate/severe tracheomalacia significantly increased the rate of reintubation. The duration of stenting did not affect outcomes. Children with anterior and posterior grafts and those with moderate or severe tracheomalacia were more likely to need a postoperative tracheostomy. SSLTR can be effectively used in the treatment of pediatric laryngotracheal stenosis. However, diligent preoperative assessment of the patient's airway and comorbidities, surgical skill and experience, and meticulous postoperative care are important to the success of this operation. The ultimate goal of laryngotracheal reconstruction is tracheotomy decannulation or prevention. The rate of decannulation varies with the severity of stenosis and the method of reconstruction. Surgical management of pediatric subglottic stenosis is challenging. Multiple operations may be required to achieve eventual extubation or decannulation. There is no specific model to predict the outcome of pediatric airway reconstruction surgery. A review of the experience at our institution shows that decannulation rates for double-stage laryngotracheal reconstruction for Myer-Cotton grades II, III, and IV are 95%, 74%, and 86%, respectively. Decannulation rates for SSLTR for Myer-Cotton grades II, III, and IV are 100%, 86%, and 100%, respectively. Our experience is that children with Myer-Cotton grade III or IV disease represent a significant challenge, and refinements of techniques are needed to address this subset of children.

Surgical management of grade IV stenosis represents the most difficult group to obtain good results. We have found that refinements in surgical technique and application of cricotracheal resection (CTR) as the primary operation for grade IV stenosis has improved the decannulation rates from 67% in the 1980s to 86% in the 1990s.[93] Our experience also shows that patients who undergo CTR have higher decannulation

rates than patients who have laryngotracheal reconstruction (LTR) with anterior and posterior costal cartilage grafting (92% vs. 81%). CTR patients are less likely to need additional open procedures to achieve decannulation (18% vs. 46%).[93] Patients with grade IV stenosis and other areas of the larynx and trachea involved often require extended CTR with the application of cartilage grafting and arytenoid procedures. Extended CTR procedures are those beyond isolated resections and anastomosis. Interposition grafts can be incorporated into the closure of a CTR. Arytenoidectomy, vocal cord lateralization, and epiglottic repositioning procedures are common extended CTR procedures.

## HEMANGIOMA

Subglottic and tracheal hemangiomas are benign congenital vascular tumors that are derived from mesodermal rests. The lesions are relatively uncommon, accounting for 1.5% of all congenital laryngeal anomalies, with a 2:1 female predominance.[8] Patients are usually asymptomatic at birth but present with stridor or "croup" within the first few months of life; 85% present in the first 6 months,[94] and 50% have cutaneous hemangiomas present at the time of diagnosis.[95] Infants with a subglottic hemangioma and cutaneous facial hemangiomas in a "beard" distribution should be evaluated for PHACES syndrome, which is the acronym for posterior fossa malformations (P), segmental facial hemangiomas (H), arterial anomalies (A), cardiac defects (C), eye abnormalities (E), and sternal defects (S). An infant who presents with stridor and a cutaneous hemangioma warrants an airway evaluation to detect the presence of a hemangioma. Asymmetric subglottic narrowing is the classic finding on soft tissue neck radiographs. Endoscopic diagnosis is usually made without biopsy because of the lesion's typical appearance of a compressible, asymmetric, submucosal mass with bluish or reddish discoloration most often found in the posterolateral subglottis (Fig. 65-13,*A*). Because the lesion may be the "tip of the iceberg" and extend into the thoracic cavity, select cases should have imaging either by magnetic resonance imaging (MRI) or computed tomography (CT) angiogram before treatment is initiated.

Subglottic and tracheal hemangiomas will have a rapid growth phase that slows by 12 months, followed by slow resolution over the subsequent months to years. Most will show complete resolution by 5 years. However, subglottic hemangiomas are associated with 30% to 70% mortality when left untreated. Therapeutic and surgical management of this problem is directed at maintaining the airway, while minimizing potential long-term sequelae of the treatment itself. Historical methods of management include external beam radiation, radium and gold implants, and sclerosing agents, and they are no longer used because of the associated morbidity. Current management options include tracheotomy, laser partial excision, systemic or intralesional steroids, open surgical resection, systemic interferon alpha-2A, and systemic propranolol. Bypassing the obstructing lesion with a tracheotomy and waiting for the expected involution will provide for the optimal anatomic result and is considered by many to be the standard of care by which all other treatment options need to be measured. However, as previously discussed in this chapter, there are risks associated with a tracheotomy as well

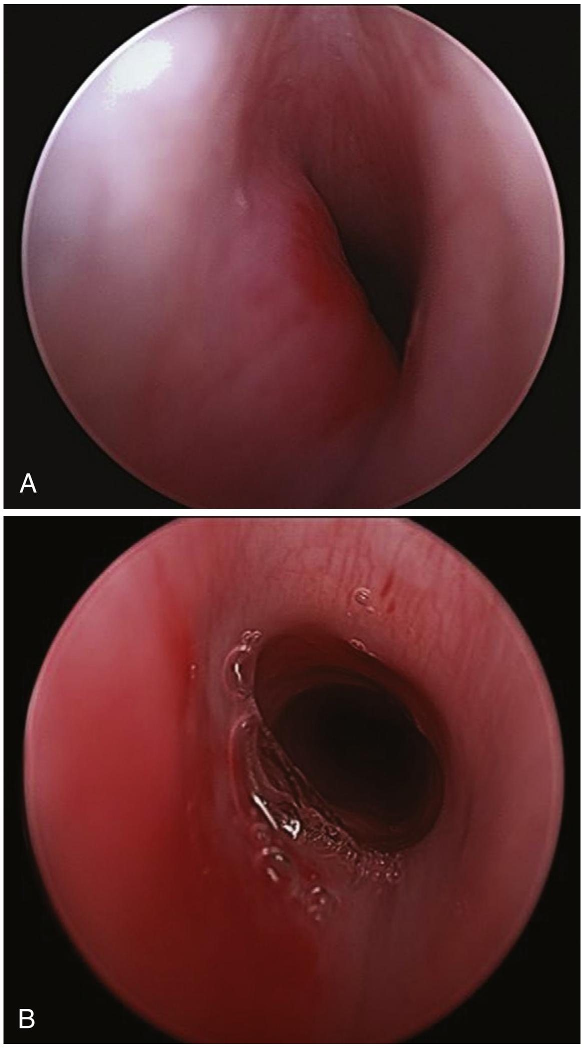

**FIGURE 65-13** Subglottic hemangioma in a 4-month-old infant. **A,** Before propranolol therapy. **B,** Two months after propranolol therapy. *(See Expert Consult site for color version.)*

as the delay in speech and language that is routinely encountered when children require a tracheotomy at a young age. Additionally, scarring in the subglottis often occurs as a result of the involution process that may require an endoscopic or open surgical reconstruction to manage the resultant subglottic stenosis to achieve decannulation.

Systemic corticosteroids for treatment of subglottic hemangiomas were introduced in 1969 by Cohen[96] and are used both as primary and adjuvant therapy. Steroids decrease the size of the hemangioma and accelerate involution by an unknown mechanism. Steroids are thought to decrease hemangioma size by blocking estradiol-induced growth[97] or by directly increasing capillary sensitivity to vasoconstrictors. Systemic steroids are shown to reduce the size of the hemangioma, but only approximately 25% of cases resolve completely with this treatment alone.[98] Risks of long-term steroid use include growth retardation, cushingoid face, and increased susceptibility to infection, including life-threatening *Pneumocystis carinii* pneumonia.[99] Using an alternate-day dosing regimen in the smallest possible doses may reduce these effects. Successful avoidance of tracheotomy can be achieved by endoscopic intralesional injection of corticosteroids into the hemangioma, with or without

short-term intubation.[100] This approach, however, often requires 30 to 50 days of total intubation time while the patient is undergoing serial injections, thereby increasing intubation-related morbidity and cost.[101]

Endoscopic surgical management with the $CO_2$ laser was first reported in 1980 by Healy and colleagues.[102] Isolated unilateral subglottic hemangiomas are usually the best type and location for $CO_2$ laser treatment. In carefully selected patients, partial resection of the hemangioma with $CO_2$ laser, with or without systemic corticosteroids, is successful.[103] The authors' experience is that systemic steroids are usually a necessary adjunct. Other reports show that the KTP laser is a good tool for management of subglottic hemangiomas, with a low incidence of complications.[104,105] The KTP laser is preferentially absorbed by hemoglobin, making this laser system well suited for the treatment of vascular tumors such as a hemangioma. Long-term outcomes of this technique are not available.

Interferon alpha-2A has been used in children with obstructing hemangioma who were unresponsive to laser and/or corticosteroid therapy, achieving a 50% or greater regression of the lesion in 73%.[106] Interferon alpha-2A requires prolonged therapy, because it does not promote involution but inhibits proliferation by blocking various steps in angiogenesis. The side-effect profile of neuromuscular impairment, spastic diplegia, neutropenia, skin slough, fever, and liver enzyme elevation,[106] limits its use to therapy of last resort and will likely relegate it to a historical treatment option in the near future.

To avoid the complications of the previously mentioned management strategies, open excision of subglottic hemangiomas was revisited in the late 1990s to the mid-2000s to provide a more definitive treatment. Several studies show that this strategy is effective for selected patients and should be considered in corticoresistant or corticodependent, circular or bilateral hemangiomas,[3] large life-threatening hemangiomas[4,5] and is even an alternative to tracheotomy placement.[101,107,108] The surgical technique is similar to SSLTR. The airway is opened at the level of the cricoid cartilage, followed by a submucosal dissection with or without microscopic dissection to excise the hemangioma. An anterior cartilage graft is usually placed, and the patient is intubated for 5 to 7 days.[107,109] Similar to airway reconstruction surgery for subglottic stenosis, appropriate institutional resources and a team is required for successful outcomes.

Propranolol, a nonselective beta blocker was serendipitously discovered as a treatment option by noting rapid regression of hemangiomas in infants treated with propranolol for cardiopulmonary conditions. Since this landmark report of Léauté-Labrèze and colleagues in 2008,[110] it has become the emerging treatment option for hemangiomas. Beta-2 receptors for propranolol are expressed in hemangioma endothelial cells. The mechanism of action of propranolol in the treatment of hemangiomas remains unclear, but it is hypothesized to work through antiangiogenesis, with decreased production of vascular endothelial growth factor and fibroblast growth factor-β (VEGF and FGF-β, respectively) or by inducing cellular apoptosis.[110] Since that initial report, others have reported successful management of subglottic hemangiomas,[111–118] including those that extend into the mediastinum,[114] at a dose of 2 mg/kg/day, with near immediate response (Fig. 65-13, *B*). The duration of treatment required is not known, but published reports suggest a mean duration of 6 months; however, the treatment course may need to extend through the expected rapid growth phase until the early involution phase.[115,119] Up to 47% of patients may be partial responders,[119] whereby adjunctive therapies, including steroids, endoscopic laser excision, or open surgery may be required.[119,120] Propranolol is an attractive therapeutic alternative, because it may avoid the risk of surgery and can avoid the common adverse effects of prolonged high-dose steroid use, but it is not without its own potential risks, which include bradycardia, hypotension, hypoglycemia, as well as potential exacerbation of reactive airways disease.[119] Routine monitoring of blood pressure and glucose is required. Further clinical experience with this treatment modality is required to determine if it may render surgical treatment of subglottic hemangiomas obsolete.

## LARYNGEAL AND LARYNGOTRACHEOESOPHAGEAL CLEFTS

Congential laryngeal and laryngotracheoesophageal clefts are rare conditions that can be characterized by a posterior midline deficiency in the separation of the larynx and trachea from the hypopharynx and esophagus (Fig. 65-14). The incidence is less than 0.1%, and the majority of cases are sporadic. There is a strong association with other anomalies (56%), most commonly esophageal atresia and tracheoesophageal fistula (EATEF) in 20% to 27%.[121] Six percent of children with EATEF have a coexisting laryngeal cleft. In these patients, the laryngeal cleft goes undetected in three quarters until persistent aspiration, despite successful EATEF repair, prompts further investigation.[121] Laryngeal or laryngotracheoesophageal clefting is commonly associated with a syndrome, most commonly G syndrome, VACTERL association (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia, and limb defects), and Pallister-Hall syndrome.[122]

The degree of clefting may be relatively minor, involving only a failure of interarytenoid muscle development, or can extend to the carina and even into the mainstem bronchi. Multiple classification systems have been used to describe laryngeal clefts, differentiating them by the length of the cleft. The most commonly accepted classification system is the

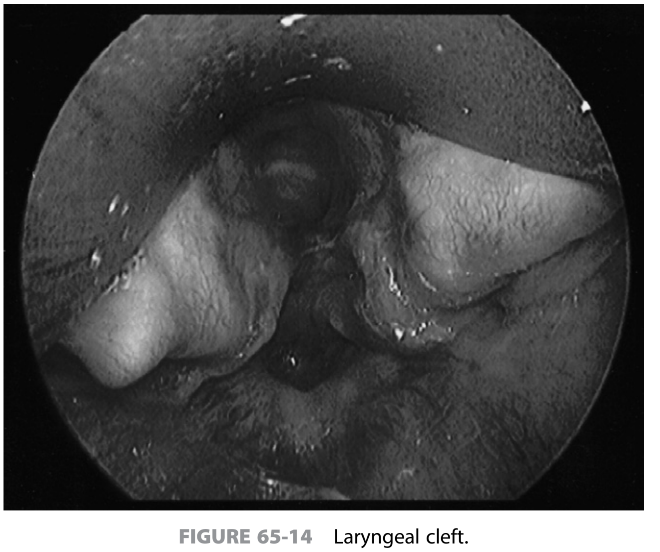

**FIGURE 65-14** Laryngeal cleft.

Benjamin-Inglis classification,[123] describing a type I cleft as interarytenoid to or below the level of the vocal process, type II as having partial extension through the posterior cricoid plate, type III as extending completely through the cricoid plate, and type IV as extending through the larynx and into the cervical or intrathoracic trachea and esophagus. The range of symptoms will vary depending on the length of the cleft. Patients with any degree of clefting may present with stridor, cyanosis associated with feeding, aspiration, and recurrent pulmonary infections. Type IV clefts, if not addressed immediately, are incompatible with life. Although radiographic contrast studies may suggest aspiration, the best single study for identifying a laryngeal cleft is careful endoscopic examination. The arytenoids need to be parted to obtain adequate visualization, because the larynx may be obscured by redundant esophageal mucosa prolapsing into the glottic and subglottic lumen. Most type I clefts do not require surgical intervention, unless significant swallowing or respiratory symptoms are present.[124,125] Most of these can be managed conservatively with aggressive medical management of gastroesophageal and laryngopharyngeal reflux and swallowing therapy.[121,125] When surgical intervention is required for these small clefts, endoscopic repair is successful in over 80%, with open repair reserved for endoscopic failures.[121,126,127]

In contrast to the type I clefts, surgical repair is required in nearly all type II to IV clefts. An anterior approach through a laryngofissure is historically the most commonly approach used. The advantage of this approach is excellent exposure of the entire defect without risk to the laryngeal innervation. Complete laryngotracheoesophageal clefts (type IV) that extend to the carina may require a posterolateral approach to allow for a two-layer closure and may require extracorporeal circulation. Some surgeons choose to place a tracheotomy if not present prior to surgical repair. Single-stage repair using endotracheal intubation as a short-term stent without tracheotomy is the preferred technique by the authors.

As more surgeons gain experience with endoscopic airway surgery, endoscopic techniques are being applied to repair type II and type III clefts.[125,127–129] Through an operating laryngoscope, the edges of the cleft are demucosalized with either sharp dissection or a $CO_2$ laser and a one-layer or two-layer closure is completed with absorbable suture. There is general agreement that a successful endoscopic repair is preferable to a successful open repair, primarily because the former preserves the anterior commissure and thus results in better voice outcomes. Robotic surgical applications may even further the endoscopic surgical options, but more experience is needed to determine if robotic techniques prove to be better than standard techniques.[128]

# Tracheal Lesions

## TRACHEOMALACIA

Tracheomalacia is a condition where the tracheal wall cartilage is soft and pliable. The cardinal symptom of tracheomalacia is stridor with increased respiratory effort that leads to dynamic collapse of the airway. Tracheomalacia is usually congenital, and the congenital forms are either primary tracheomalacia or secondary. The etiology of primary tracheomalacia is unknown. It is a common cause of stridor in infancy. It is differentiated from laryngomalacia in that the phase of stridor is in expiration; however, laryngomalacia and tracheomalacia can coexist, and the child may have both inspiratory and expiratory stridor. Most infants with primary or isolated tracheomalacia outgrow the condition by 18 months of age. Secondary tracheomalacia occurs as a result of another coexisting condition.

The most common congenital condition that causes secondary tracheomalacia is extrinsic compression from a vascular anomaly, such as a vascular ring or innominate artery (Fig. 65-15, *A*). Severe airway symptoms resulting from such vascular anomalies include acute life-threatening events (ALTEs), infant apnea, recurrent pneumonia, stridor with severe airway obstruction leading to hypoxia, respiratory distress, and pectus excavatum. These life-threatening indications warrant surgical intervention. Surgically addressing the compressing innominate artery by aortopexy, innominate artery suspension or innominate artery repositioning, or correcting the causative vascular ring will often improve, if not reverse, the airway symptoms. (see Fig. 65-15)

Because of the embryologic development of the esophagus and tracheobronchial tree, there is a high probability that a child with EATEF will have some degree of tracheomalacia. In these patients, the tracheomalacia is most often found at the level of the fistula site. After repair of the TEF, a resultant

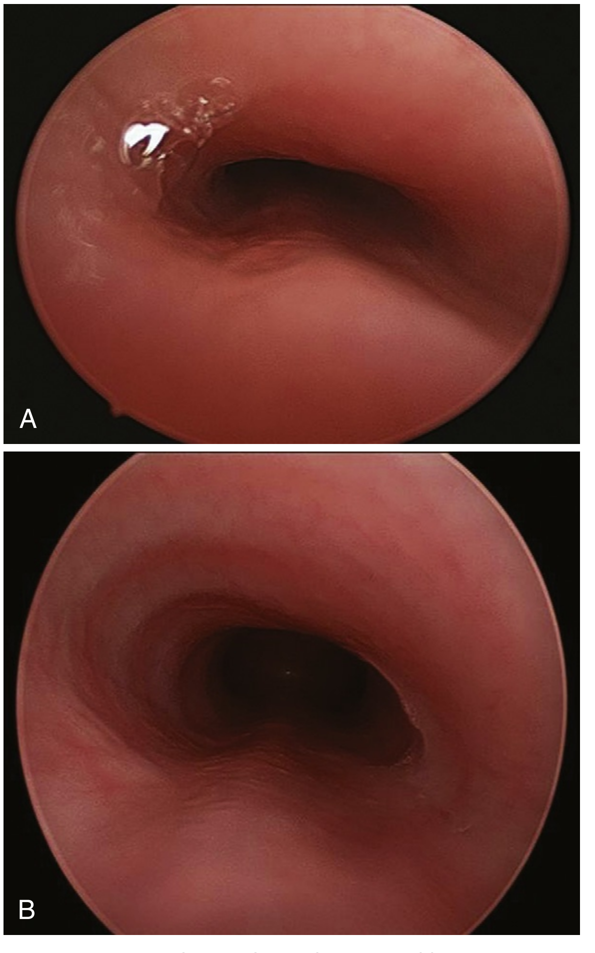

**FIGURE 65-15** Secondary tracheomalacia caused by innominate artery compression. **A,** Before aortopexy. **B,** After aortopexy. *(See Expert Consult site for color version.)*

tracheal pouch is often present. Some of these pouches will require intervention as discussed in the following section.

Acquired tracheomalacia may also develop in infants who require long-term ventilatory support with high-pressure endotracheal tubes or cuffed tracheotomy tubes. There is no good treatment for severe or life-threatening diffuse tracheomalacia other than bypassing and stenting the area with a tracheotomy tube and waiting for the child to grow. Methods of endotracheal stenting with angioplasty and Palmaz stents have been attempted in life-threatening cases with some success; however, stenting is associated with significant morbidity and mortality.[130]

## TRACHEAL POUCH

An acquired tracheal pouch is typically a sequela of TEF repair. Shallow, wide-mouthed pouches in the region of the carina are common, usually asymptomatic, and do not require surgical repair. In contrast, pouches that occur more proximally are more likely to be large, symptomatic, and require surgical intervention to alleviate associated respiratory symptoms or the risk of inadvertent intubation of the pouch with endotracheal or tracheotomy tubes, with a resultant inability to ventilate. The repair is generally based on division of the shared diverticular and tracheal wall. Various techniques for repair have been described, including endoscopic and open transcervical or transthoracic approaches. Johnson and colleagues[131] describe an endoscopic approach to divide the pouch using a Clickline biopsy forceps (Karl Stortz Endoscopy, El Segundo, Calif.), which is a True-Cut laparoscopic instrument with incorporated suction and cautery as a minimally invasive option for symptomatic tracheal pouches resulting from TEF repair.

## CONGENITAL TRACHEAL STENOSIS

Congential tracheal stenosis is a rare, potentially life-threatening anomaly that usually involves complete cartilaginous tracheal rings, and has proven to be difficult to treat. In 1964, Cantrell and Guild[132] classified congential tracheal stenosis into three categories: long-segment stenosis with generalized hypoplasia (22%), funnel-like stenosis (37%), and segmental stenosis (41%). Associated anomalies in children with congenital tracheal stenosis are common, with 24% having coexistent vascular anomalies, most commonly a pulmonary artery sling.[133]

Congenital tracheal stenosis usually presents with a history of biphasic stridor and possibly acute respiratory distress. Severe cases in neonates may require extracorporeal membrane oxygenation until a definitive surgical procedure can be executed.[134] A definitive diagnosis is best obtained with endoscopy (Fig. 65-16); however, meticulous endoscopic technique is required in the very young, because any airway edema or trauma caused by instrumentation may lead to an obstructive airway emergency that cannot be managed by intubation and ventilation, which would require emergent extracorporeal membrane oxygenation or cardiopulmonary bypass. Recent advances in three-dimensional magnetic resonance and computed tomography[135] imaging provide an alternative for diagnosis and follow-up. Additionally, magnetic resonance imaging or contrast-enhanced computed tomography, coupled to echocardiography, is frequently needed to identify associated cardiovascular abnormalities.

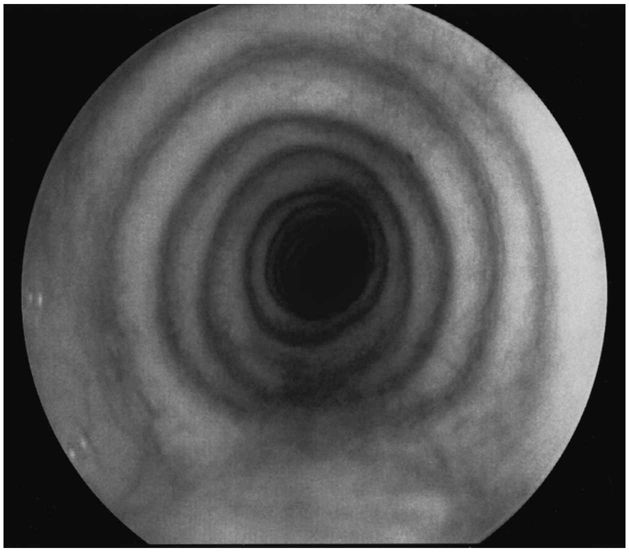

**FIGURE 65-16** Complete tracheal rings.

The management of congenital tracheal stenosis has evolved over the past 15 years with decreasing mortality rates. Segmental resection with primary anastomosis has been shown to be an excellent treatment option for stenosis, involving up to 50% of the trachea. However, there are a number of procedures used for long-segment stenosis, because historically none have been universally successful. In fact, Benjamin and colleagues, in 1981, recommended a nonsurgical approach because the 57% survival in this group of patients was higher than in their operated group.[136] Findings from the authors' institutions reiterate that nonoperative management of complete tracheal rings may be appropriate in selected patients.[137] We estimate that up to 10% of patients with complete tracheal rings will not require tracheoplasty. Selected patients must be asymptomatic or have minimal symptoms and demonstrate tracheal growth over serial examinations. However, the rate of growth remains to be determined. Surgery for long-segment tracheal stenosis has evolved over the past 25 years. Anterior tracheoplasty using pericardium was first described by Idriss and colleagues in 1984.[138] Since then, reported results of this technique reveal survival rates of 47% to 76% in the larger series.[139] Costal cartilage grafting for augmentation has had similar results[140] in a smaller number of patients. Other augmentation materials that have been tried include esophageal wall, rib, dura, and periosteum.

Slide tracheoplasty, as described by Tsang and colleagues[141] and modified by Rutter and colleagues,[142] involves a transverse division of the trachea in the middle of the stenosis and longitudinal incisions of the anterior portion on one end and the posterior portion on the other, sliding the two ends over each other, thus halving the length and doubling the diameter. In its original description, slide tracheoplasty was used for funnel-shaped stenosis. At the authors' institutions, this technique has evolved and has now become the preferred surgical approach for tracheal stenosis, regardless of the length of narrowing; furthermore, it is routinely applied successfully for the management of long-segment tracheal stenosis with less variable outcomes compared with previous techniques (Fig. 65-17).[142,143] Slide tracheoplasty using cardiopulmonary bypass support is a versatile and effective treatment for tracheal

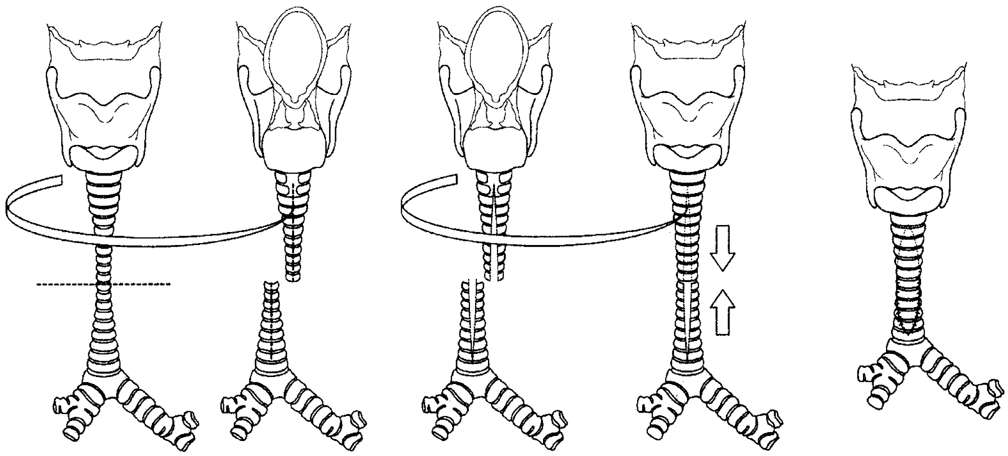

FIGURE 65-17 Slide tracheoplasty: transverse section of the trachea, with the proximal segment of the rings split posteriorly and the distal segment split anteriorly. Sliding of the two portions together doubles the circumference and halves the length.

stenosis in children even when combined with concurrent repair of congenital cardiac anomalies.[144] Slide tracheoplasty has also been described as a salvage procedure for failed patch tracheoplasty.[145] Another alternative is the use of tracheal homograft reconstruction in cases of severe long-segment and recurrent stenosis. An 83% survival rate is reported with this technique.[146,147] Long-term outcomes of homograft transplantation are currently not available. Use of this option is limited by the availability of cadaveric tracheal homografts and the potential for host rejection.

## Tracheobronchial Vascular Compression

Vascular compression of the tracheobronchial tree has been the subject of much discussion since 1945, when Gross described the first successful operation for a double aortic arch.[148] In 1963, Fearon and Shortreed[149] reviewed 104 cases and coined the term “reflex apnea” to describe the episodic apnea associated with airway vascular compression. In 1969, Mustard and colleagues[150] reviewed 285 cases and reported successful medical management in 86.3% of cases.

Indications for surgical management include reflex apnea and recurrent bronchopulmonary infections. In 1971, MacDonald and Fearon[151] divided the criteria for surgical intervention into absolute and relative criteria and added failure of medical management, greater than 50% compression of tracheal lumen, and associated airway and lung abnormalities to the existing criteria. In 1975, Moes and colleagues,[152] compared 60 children who were operated on for innominate artery compression of the trachea with 30 children who did not undergo surgery, noting that the appropriateness of surgical intervention was based not on the severity of compression seen at endoscopy or radiographically but on the severity of symptoms. In 1981, Strife and colleagues[153] concluded that the word “anomalous” should be omitted from innominate artery tracheal compression syndrome, because the origin of the innominate artery partially or totally to the left of the trachea was a normal finding in children as seen on aortogram in 96% of patients.

Vascular compression of the tracheobronchial tree has an overall incidence of 3%. The most common symptomatic true vascular ring is the double aortic arch, which occurs if the fourth aortic arches and the dorsal aortic root persist on both sides. In 1 in 2500 persons, the left arch has an atretic segment, but the right arch persists. A right-sided arch with a descending right aorta does not cause airway compromise. However, if there is an associated left ductus or an aberrant left subclavian artery, a loose vascular ring is formed that generally results in less airway compromise than a true double aortic arch. The pulmonary artery sling is the most symptomatic of the noncircumferential vascular anomalies and occurs when the left sixth arch resorbs and the left pulmonary artery arises as a large collateral artery from the right pulmonary artery, and passes between the esophagus and trachea to perfuse the left lung. This anomaly commonly results in significant compromise of the right mainstem bronchus and airway symptoms. In addition, 30% of patients with pulmonary artery slings have associated complete tracheal rings.[154] The aberrant right subclavian artery is the most common mediastinal vascular anomaly. However, because of its retroesophageal course, affected individuals may present with dysphagia but rarely with symptomatic airway compromise. Innominate artery compression of the trachea is not associated with a true vascular anomaly. The innominate artery normally passes from its origin on the aortic arch left of midline across the anterior trachea to the right side. It has been hypothesized that in patients who are symptomatic, the innominate artery is more taut than normal, and the tracheal cartilages are unusually compliant and more easily compressed, or that dilation of other structures, such as the heart, esophagus, or thymus, cause mediastinal crowding.

Respiratory compromise from tracheobronchial vascular compression is potentially life threatening but can present with subtle symptoms. A high index of suspicion is required to make the diagnosis. Patients with significant vascular compression usually present early with stridor, chronic cough, recurrent bronchitis and pneumonia, difficulty feeding and failure to thrive, and occasionally reflex apnea. Reflex apnea has been described as a reflexive respiratory arrest of variable duration that is secondary to stimulation of vagal afferent nerve fibers during swallowing and other forms of transient intrathoracic pressure changes.

Chest radiographs may provide some evidence of tracheal compression, and a barium esophagram can show relatively

characteristic filling defects that correspond to the various types of vascular compression. However, once vascular compression is suspected, the diagnostic modality of choice is magnetic resonance imaging, which will clearly demonstrate the mediastinal vascular anatomy as well as the size of the lower airway. Spiral computed tomography with intravenous contrast may be a useful adjunct or replacement to magnetic resonance.[155,156] Although today the diagnosis of vascular compression is usually known prior to undergoing endoscopy, bronchoscopy also reveals characteristic findings of compression, depending on the type of vascular ring or sling. Bronchoscopy provides an immediate visual assessment of the surgical results on relieving the compression and the degree of residual tracheomalacia present.

Nonsurgical management may be effective for the majority of innominate artery compression and loose vascular rings and slings that are mildly symptomatic. In contrast, moderately to severely symptomatic patients usually require surgical repair. Absolute indications for surgical treatment include reflex apnea, failure of medical management of severe respiratory distress after 48 hours, and prolonged intubation. Relative criteria include repeated episodes of lower respiratory tract infection, exercise intolerance, significant dysphagia with failure to thrive, or coexisting subglottic stenosis, asthma, cystic fibrosis, or symptomatic tracheomalacia after EATEF repair.

Innominate artery compression is relieved by aortopexy or reimplantation, with success rates of 93% to 100% and no reports of operative mortality or long-term morbidity.[157] Occasionally, aortopexy sutures can loosen, and the procedure needs to be revised.

Results of surgical treatment of vascular rings are also encouraging, with 70% to 92% obtaining complete resolution of symptoms.[158] Double aortic arch requires surgical division of the smaller of the two arches. The ductus arteriosus or aberrant subclavian artery is divided in the case of right aortic arch with left ductus arteriosus or aberrant left subclavian artery. In cases of severe tracheobronchial compression, residual tracheomalacia may persist for a variable period of time, and occasionally a tracheotomy is required to stent the malacic segment.

The pulmonary artery sling is corrected by dividing the aberrant left pulmonary artery at its origin and reimplanting it anterior to the trachea. There is a significantly increased morbidity and mortality rate in these cases, usually because of the associated complete tracheal rings.

CHAPTER 66

# Infections and Diseases of the Lungs, Pleura, and Mediastinum

Pramod S. Puligandla and Jean-Martin Laberge

## Lung Infections

Childhood pneumonia continues to be a significant global health problem affecting 150 million children around the world on an annual basis.[1] It is therefore not difficult to appreciate the burden pneumonia places on the health care system both from a medical and economic perspective. This chapter reviews the clinical presentation, diagnosis, etiologies, and management of pediatric pneumonia, with a special emphasis on the pediatric cancer patient and children infected with human immunodeficiency virus (HIV). We also focus on the management of complications that result from pneumonia, as well as additional specific disorders affecting the lungs, thorax, and mediastinum, including cystic fibrosis, pulmonary hemorrhage, spontaneous pneumothorax, chylothorax, and mediastinitis.

### EPIDEMIOLOGY

Acute respiratory infections represent a significant health burden for children across the globe. Indeed, these infections are the leading cause of hospitalization and outpatient visits in developed and developing countries alike.[2] The incidence of pneumonia varies between 0.03 episodes/child/year in developed countries to almost 10 times that rate in developing countries.[3–5] Pneumonia accounts for approximately 2 million deaths per year in children less than 5 years of age.[6,7] The vast majority of these deaths occur in developing countries, with greater than 50% located in sub-Saharan Africa,[8] where the rate of pneumonia parallels the rate of HIV infection.[1,9]

From an etiologic standpoint, studies have identified both *Streptococcus pneumoniae* and viral agents as the most common causes of respiratory infections.[3,10] In terms of age, respiratory syncytial virus (RSV) prevails in young children (<2 years), with a larger proportion of community-acquired pneumonia being attributable to *Streptococcus pneumoniae* in children older than 2 years of age.[3, 10,11] It is important to note that no causative agent may be identified in up to 25% of community-acquired pneumonia.[8]

### COMMUNITY-ACQUIRED BACTERIAL PNEUMONIA

#### *Streptococcus pneumoniae*

*Streptococcus pneumoniae,* or pneumococcus, is a major cause of morbidity and mortality around the world. It is the most common pathogen in infants and children and is responsible for approximately 500,000 cases of pneumonia per year in the United States.[12] Worldwide, up to 1 million deaths per year occur as a result of pneumococcus infection, with the majority of these deaths occurring in developing countries.[13–15]

Pneumococcus is a gram-positive coccus that is a part of the normal respiratory flora in children and adults. Colonization rates, particularly of the nasopharyngeal mucosa, appear to decrease with age, and are an important factor in the development of infection.[12] The symptoms of infection include fever, productive cough, tachypnea, dyspnea, malaise, and occasional emesis. On physical examination, patients have hypoxia and decreased breath sounds with crackles over the affected area. Radiographically, pneumococcal infections can be lobar, multi-lobar, or sometimes segmental (Fig. 66-1), and up to 40% of these patients will also have pleural fluid. Treatment is most often performed on an outpatient basis. However, antibiotic resistance is quite prevalent with this species, and this has led to changes in empiric therapy that may not be quite as effective.[16–19] For patients infected with a strain demonstrating low to intermediate resistance, penicillin and other β-lactam antibiotics are still effective.[20] Third-generation cephalosporins may be used in cases of high resistance or if there is no clinical improvement with conventional therapy.[8]

The use of heptavalent conjugate vaccines since 2000 has dramatically affected the impact of invasive pneumococcal disease by those strains contained within the vaccine.[21–23] It has also led to a reduction in the overall incidence of pneumococcal pneumonia[24] as well as the admission rates for

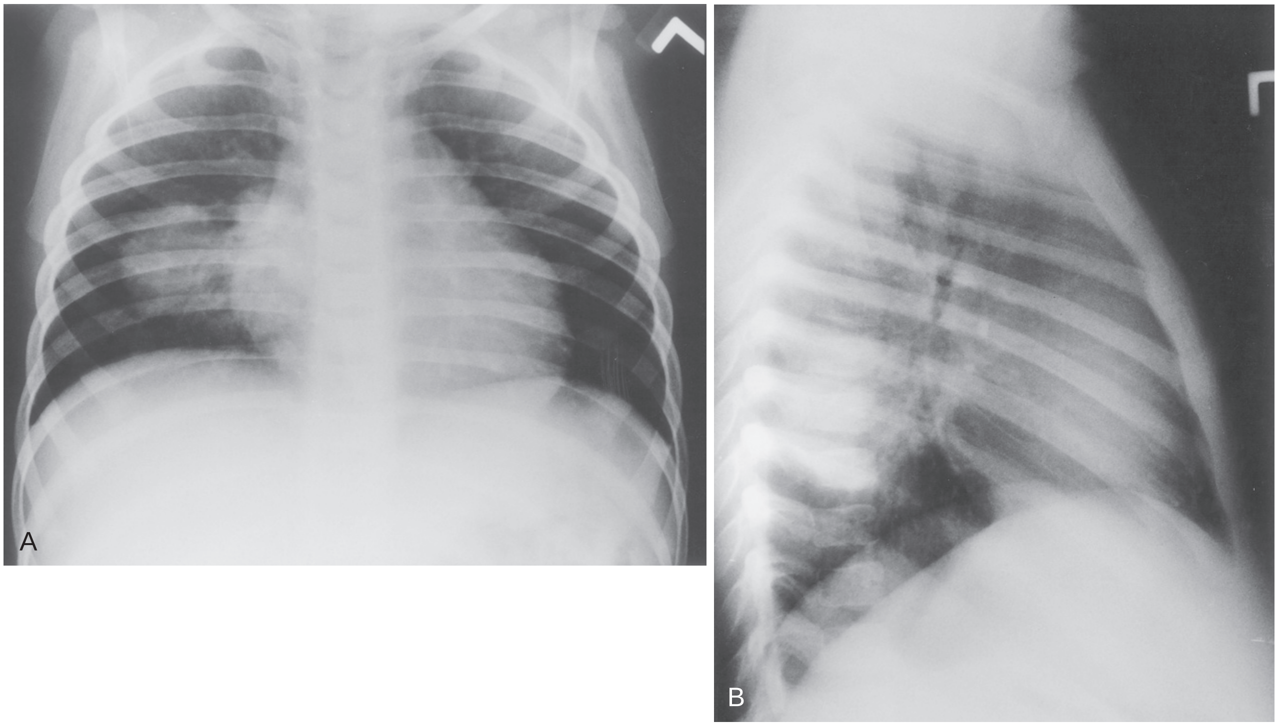

FIGURE 66-1 Chest radiograph of a 1.5-year-old boy with fever and dyspnea shows a typical round pneumonia of the superior segment of the lower lobe; an air bronchogram can be seen within the opacity. **A,** Anteroposterior view. **B,** Lateral view.

children less than 2 years of age.[25] However, invasive disease caused by nonvaccine serotypes has also increased, and these strains are now responsible for the majority of cases. To address this issue, a new 13-valent pneumococcal vaccine has been recently introduced that contains protection against an additional 6 serotypes that are currently responsible for 63% of invasive pneumococcal cases.[23]

### *Haemophilus influenzae*

More than 95% of invasive cases of *Haemophilus* are caused by the type B strain. Infections with *Haemophilus* usually occur in the winter and spring. The clinical presentation includes fever, tachypnea, elevated white cell count, and the presence of unilateral consolidation with pleural effusion on chest radiographs. Although extrapulmonary manifestations, such as meningitis and epiglottitis, may be more typical with this organism, *Haemophilus* can still cause pneumonia in infants and preschool-age children.[26] Treatment is based upon the susceptibility of these bacteria to β-lactam antibiotics because resistance has been reported to occur in more than 30% of isolates.[27] Third-generation cephalosporins can be used for those strains producing β-lactamase. The overall incidence of significant infections caused by this species has been dramatically reduced with the introduction of the *Haemophilus* vaccine. Global initiatives are currently underway to expand vaccine availability in developing countries where the burden and impact of *Haemophilus* infection is still unknown.[26]

### *Staphylococcus aureus*

These ubiquitous gram-positive cocci are commonly found on the skin and nasal mucosa, with 20% to 30% of the population being normal carriers of this bacterium. *Staphylococcus aureus* produces toxins and enzymes that form the basis of the lesions produced by this pathogen—a pyogenic exudate or an abscess. Staphylococcal infections are usually progressive, occurring in infancy and early childhood. Although community-acquired pneumonias with *Staphylococcus aureus* were generally thought to be uncommon, recent reports suggest an increasing incidence.[28] Patients generally present with fever and rapidly develop respiratory symptoms that may have been predated by flulike symptoms. Clinical and radiologic deterioration quickly ensues if left untreated. Radiographically, primary pneumonias display unilateral lobar consolidation. Secondary infection/pneumonia usually involves a prolonged febrile illness and is often accompanied by positive blood cultures. These infections commonly present as diffuse bilateral infiltrates on chest radiographs.

Staphylococcal pneumonias may be associated with pleural effusions, empyema, lung abscesses, or pneumatoceles. The latter lesions require follow-up until complete resolution (see later). More important, necrotizing pneumonia can occur when community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) strains produce Panton-Valentine-leukocidin (PVL).[29] PVL-producing MRSA strains are highly virulent, leading to rapidly progressive cardiorespiratory compromise and a mortality of greater than 50%.[28,30] Treatment involves the use of appropriate antistaphylococcal antibiotics, but widespread resistance to penicillin and methicillin is problematic. If resistance or penicillin allergy exists, other agents, including vancomycin, macrolides, and clindamycin may be used. The latter may be a useful toxin-neutralizing agent in cases of PVL.[30] The duration of treatment is usually 3 to 4 weeks with fevers persisting for up to 2 weeks after the institution of therapy.

### *Mycoplasma* and *Chlamydia*

*Mycoplasma pneumoniae* and *Chlamydia pneumoniae* are unique pathogens that can cause respiratory infections in children of all ages, including preschool-age children.[31,32] These organisms represent clinically significant causes of atypical pneumonia and have similar sero-epidemiologic profiles. Infection is spread by person-to-person contact and usually involves a 1- to 2-week incubation period. The presentation of atypical pneumonias is very similar to that of viral respiratory infections. There is a gradual onset of symptoms, including sore throat, hoarseness, and rhinitis, with or without fever. These upper respiratory tract symptoms progress to the lower respiratory tract over several days and include cough, pleuritic chest pain, rales, and rhonchi. Although *Mycoplasma* can produce chills, headache, skin rashes, and myalgias, chlamydial pneumonia is generally indistinguishable from other causes. Interestingly, *Chlamydia* may be responsible for acute chest syndrome in up to 20% of children with sickle cell disease.[31] Classically, these infections display interstitial infiltrates with a unilateral subsegmental distribution, but *Mycoplasma* can also lead to lobar consolidation and effusion. The diagnosis is usually made on clinical grounds based upon the history and physical examination. Other adjunctive tests, including polymerase chain reaction (PCR), culture, and serology, can also be used to confirm the diagnosis.[33,34] Macrolides (erythromycin, clarithromycin) are the mainstay of therapy for these infections.[35]

### *Mycobacterium tuberculosis*

Childhood tuberculosis (TB) is a global health problem. Although the vast majority of cases occur in developing countries, especially sub-Saharan Africa, increasing rates have also been reported in developed countries.[8] TB causes significant morbidity and mortality in children, and their infection serves as a future reservoir of disease.[36] The development of latent infection or progressive disease after exposure is dependent on many factors, including age, immune status, inoculation size, and host factors (i.e., nutritional status, previous vaccination).[37] Children are much more likely to progress to active disease than adults, with the risk being highest in those less than 2 years of age. Pulmonary TB, the most common site of infection, often becomes symptomatic 4 to 12 months after exposure and is more common in infants and adolescents than in children between 5 and 10 years of age for unknown reasons.[38] However, only 5% to 10% of children with latent infection will progress to active disease after the age of 3 years.[36] Indeed, the aggressive treatment of infection during the early stages of disease can have a major impact on morbidity and disseminated infection in the future. In North America, surgical complications of tuberculosis have been dramatically reduced secondary to effective medical therapy and intensive follow-up. Recent reports on the epidemiology of tuberculosis in developed nations have common themes: (1) immigrants and their children have the highest incidence of tuberculosis, (2) more serious disease occurs in young children, and (3) skin testing and screening play an important role in identifying children with tuberculosis.[36] Antibiotic resistance continues to be a significant problem and arises almost exclusively from the inadequate treatment of adults with high bacterial loads. Nonetheless, children often suffer the consequences of contracting drug-resistant species.[39]

Childhood TB differs from the adult form because primary pulmonary tuberculosis is a disease of the lymphatic system, the "primary complex."[36] Primary TB results in secondary damage to the lungs through obstruction or damage to the large airways, leading to atelectasis, chronic infection, and bronchiectasis. Most primary infections heal without residual lesions in the lung other than the Ghon complex (calcium deposit in a mediastinal or hilar lymph node). The healing of the primary lesion is believed to be associated with a positive host–organism balance, which has been attributed to either a strong natural host resistance or to a small initial inoculating dose. If defense mechanisms are unable to control the primary infection, tuberculous pneumonia progresses with caseation, often accompanied by pleural effusion. The clinical manifestations include fever, cough, and occasionally hemoptysis. Suspicion of TB should be raised in any child with chronic cough, history of contact with an adult with tuberculosis, failure to thrive, or the inability to recover from infection despite adequate treatment.[40]

The diagnosis of TB is difficult due to the slow growth of organisms in culture. *Mycobacterium tuberculosis* may be obtained from sputum, bronchial washings, gastric aspirates, or other infected material.[41,42] In areas where TB is not endemic, a combination of known contact with a TB-exposed individual, positive tuberculin skin test, and radiographic findings often will suffice.[42] In endemic areas, this may be more difficult. Another novel diagnostic test is the blood interferon-γ–release assay.[36,43]

In children, a positive tuberculin skin test, defined as either greater than 15 mm in those without risk factors or greater than 5 to 10 mm in those with risk factors, indicates disease requiring antituberculous therapy. However, the skin test may be negative in immunosuppressed children, in those who are severely malnourished or in those with disseminated tuberculosis, as they are often anergic.[44] Antituberculous therapy may be indicated when the disease is suspected in such patients, because cultures may take several weeks to become positive. Antituberculosis therapy requires a multidrug regimen, and there is some evidence that drug levels may be affected by diet.[45] Furthermore, standard medications, such as rifampin, isoniazid, ethionamide, ethambutol, and pyrazinamide, can cause hepatotoxicity.

The main treatment for tuberculosis remains medical therapy, because these medications are often highly effective. However, surgery may be required for pulmonary tuberculosis in which significant damage to a localized area of the lung has occurred and in those for whom medical therapy is ineffective. In these cases, surgery aids to reduce the bacterial load. This is an important consideration for patients with multidrug-resistant TB.[46] The operation should be conservative, usually consisting of a wedge resection, segmental resection, or lobectomy. The indications for surgical intervention in childhood tuberculosis include (1) the need to confirm a diagnosis, (2) major airway obstruction by extraluminal lymph nodes, (3) chronic airway compromise or stenosis, (4) tuberculosis-induced bronchiectasis, (5) airway obstruction by intraluminal material, (6) hemoptysis, and (7) chronic cavitary lesions. Furthermore, pleural disease, in particular empyema, may be effectively treated by tube thoracostomy, thoracoscopy and debridement, video-assisted thoracic surgery (VATS), or thoracotomy.[46]

### Atypical Mycobacteria

Atypical mycobacterial species were first identified in the 1950s.[47] The incidence of infection with these organisms was relatively stable until the 1980s, when an increase in incidence concurred with the HIV epidemic.[48] Many more organisms are being identified because of more sophisticated culture techniques, as well as the increased number of immunocompromised patients.[49] The most common presentation of atypical mycobacterial infections is cervical lymphadenitis. The incidence of pulmonary infections with atypical mycobacteria in immunocompetent patients is low. However, it is frequently observed in patients with cystic fibrosis and in patients infected with HIV[50] (see next section). The most common subtypes responsible for pulmonary infection include the *Mycobacterium avium* complex. Other important species include *Mycobacterium kansasii, abscessus, xenopi,* and *malmoense*. The portal of entry is the oropharynx. Clinically, immunocompetent patients may have minimal symptoms or present with fatigue and chronic cough with wheezing. The diagnosis may be suspected on chest radiographs and high-resolution computed tomography. Although nodular interstitial lung disease may occur, pulmonary parenchymal involvement is usually rare. Rather, enlarged lymph nodes may compress bronchi leading to atelectatic changes and segmental collapse.[50] Chronic bronchial obstruction may also lead to bronchiectasis.[51] The laboratory diagnosis of atypical mycobacteria can be made with sputum samples using PCR techniques.[52,53] The relapse of infection after treatment used to be a common occurrence in the premacrolide era, because anti-tubercular medications are less potent against atypical mycobacteria than tuberculosis. Thus many patients required surgical excision of affected regions of the lung. However, with the development of macrolides (erythromycin, clarithromycin), azalides (azithromycin), and newer nonmacrolide antibiotics (ciprofloxacin), surgery is rarely indicated for pulmonary disease.[54] In contrast, atypical mycobacterial cervical lymphadenitis is best treated by surgical excision of the affected lymph nodes, with antibiotic treatment reserved for patients with unresectable lesions or disseminated disease.

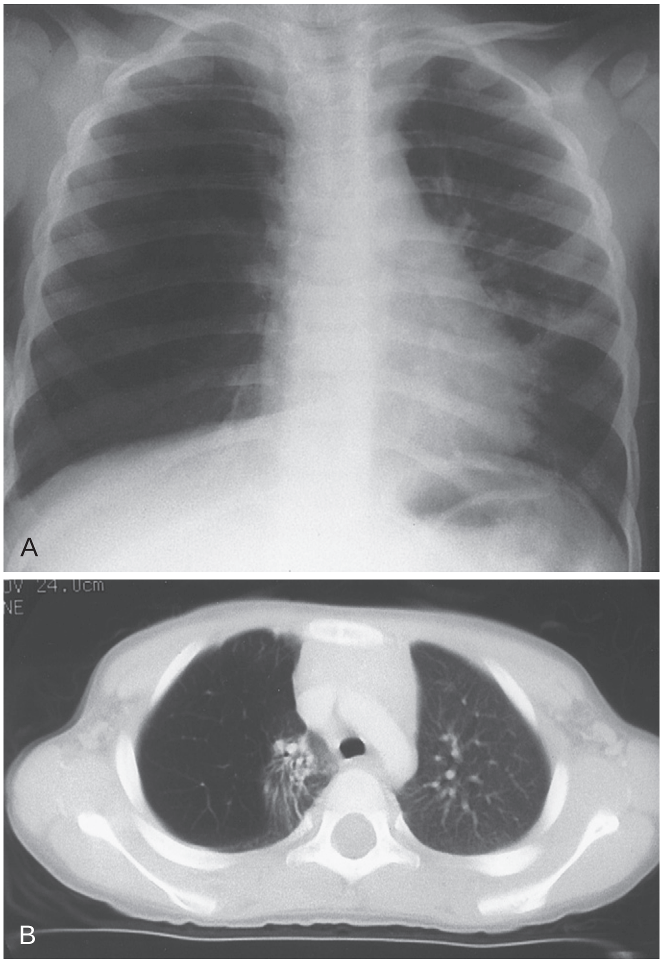

**FIGURE 66-2** **A,** Chest radiograph in a 3-year-old child with acquired lobar emphysema who developed pneumonia with respiratory syncytial virus. **B,** Computed tomographic scan of chest reveals collapsed upper lobe and emphysematous middle lobe.

## VIRAL INFECTIONS

### Bronchiolitis

Bronchiolitis is a major cause of respiratory infection in young children, and is responsible for 2% to 3% of all hospital admissions in children less than 1 year of age.[55] Pathogens that have been implicated include respiratory syncytial virus (RSV), parainfluenza, influenza, and adenoviruses. Peak times for infection occur during early winter through spring, with the mode of transmission being direct contact. Initially starting as an upper respiratory infection with rhinorrhea, cough, and low-grade fever, lower respiratory symptoms may subsequently progress rapidly over the ensuing 24 to 48 hours. At this time, patients may present with tachypnea, retractions, and wheezing. High fever is not uncommon, while young infants may also present with apnea. Radiographically, patients exhibit hyperinflation, interstitial pneumonitis, and occasionally pleural thickening. Acquired lobar emphysema also occasionally develops (Fig. 66-2). Rarely, lung resection may be indicated, but in most patients the hyperinflation resolves with time.

Several patient populations are at increased risk for RSV. These include premature infants, patients less than 6 weeks of age, and children with chronic lung or congenital heart disease.[56] Northern Aboriginal populations also have some of the highest rates of infection in the world,[57] whereas Hispanics are the group most affected in the United States.[58] Overall, the mortality from RSV has been estimated to be 2.9 per 100,000.[59] A presumptive diagnosis of bronchiolitis can often be made on the clinical presentation and is supported by radiographic impressions. Confirmation of infections requires a nasopharyngeal aspirate using a rapid immunosorbent assay.[55] The treatment for bronchiolitis is generally supportive with supplemental oxygen, maintenance of hydration, and close monitoring. In severe infection, particularly in at-risk populations, mechanical ventilation may be required. Interruption of transmission is paramount to prevent epidemics on the hospital wards; thus strict hand washing and the segregation of affected patients is also very important. Bronchodilators and inhaled steroid medications have a limited role in the overall treatment plan but have been

demonstrated to improve clinical scores.[60,61] Vaccinations against RSV should be provided to high-risk children.[62] Although most infections are self-limited, there is increasing evidence to support a link between previous RSV infections and the development of childhood asthma.[63]

### Human Metapneumovirus

Initially identified in 2001, human metapneumovirus (hMPV) has been demonstrated in most parts of the world.[64] Most children appear to be affected by 5 to 10 years of age.[65] Clinically, infection with this pathogen is indistinguishable from infection with RSV, although it tends to affect older infants.[66] However, coinfection with hMPV and RSV has been shown to cause a more severe bronchiolitis.[67] Recently, a reverse transcription PCR technique has become the method of choice for the diagnosis of hMPV infections.[68] Treatment is generally supportive. The effectiveness of antiviral medications against hMPV requires more investigation.[69] Monoclonal antibody vaccines are currently under development.

## PARASITIC INFECTIONS

### *Echinococcus*

*Echinococcus* (hydatid disease) is a parasitic tapeworm infection of sheep and dogs that is transmissible to humans. Infections are common in Egypt, the Middle East, and Australia. Once rare, hydatid disease in North America has increased because of immigration.[70] Cysts occur in the liver, spleen, and lungs. Most patients who present with pulmonary disease are children. These cysts should be removed, because 30% of these lesions may eventually rupture,[71] producing pleural effusions, bronchial seeding, and occasionally acute anaphylaxis.[70] Some children with hydatid lung disease are asymptomatic, while others experience a nonproductive cough. Chest radiographs typically demonstrate a single large pulmonary nodule or a large cyst(s) with an air-fluid level (Fig. 66-3). Computed tomography (CT) and magnetic resonance imaging (MRI) can also be used to provide more detail or to identify occasional lesions that are not apparent with conventional radiography despite the presence of symptoms.[72] Medical therapy with mebendazole has been recommended for patients with small cysts or asymptomatic disease.[8] Patients with secondarily infected or symptomatic/enlarging cysts will usually require pulmonary resection.[71,73,74] There is some evidence that primary surgical resection of large or complicated hydatid cysts without prior medical therapy may decrease postoperative complications and shorten hospital stay.[75] For the surgical management of hydatid cysts, gentle manipulation of lung tissue, careful control of cyst contents to avoid spillage, and a parenchyma-sparing approach is recommended. Thoracoscopic resection has also been described.[76] Percutaneous drainage of these cysts with injection of antiscolicidal agents has been described but with only partial success.[77]

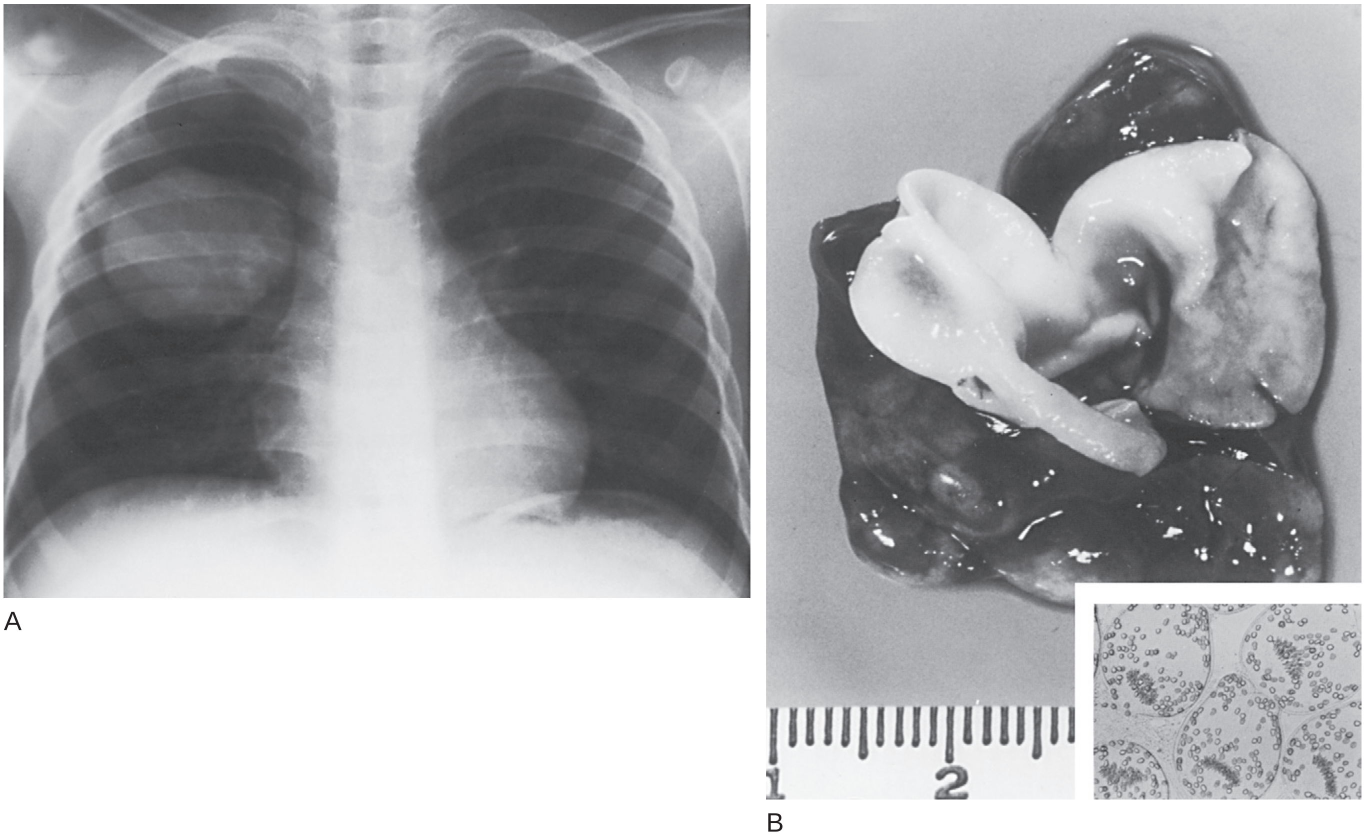

**FIGURE 66-3** Echinococcal cyst in a 4-year old Native American boy whose family lived in a sheep-herding area and owned several dogs. A large, homogeneous, spherical mass is visible in the right lung in (**A**) posteroanterior radiograph. At wedge resection (**B**), the opened cyst contained proglottids with scolices and hooklets. The boy recovered without complications. (*Inset*, 400×)

## THE IMMUNOCOMPROMISED PATIENT

### Pediatric Cancer Patient

Overall, cure rates for all types of childhood cancers have approached 80%.[78] This significant improvement has been the result of improved chemotherapy regimens, improved agents, and increased intensity of therapy. A persistent obstacle for these patients, however, is the threat of infectious complications. Indeed, the single most important factor contributing to the risk of infection is the degree of neutropenia. Neutrophil counts below $0.5 \times 10^9$/L place patients at a significantly increased risk of bacterial infection.[79] If the duration of neutropenia is prolonged, the incidence of fungal infections is also increased.[80]

The lung is the most common site of opportunistic infection in the immunocompromised cancer patient.[81] The incidence of pneumonia in this population ranges from 0.5% to 10%.[82] The mechanism of infection is either from the aspiration of pathogens from the upper airway into the tracheobronchial tree or by hematogenous spread. The immune system can be affected in many different ways depending upon the type, duration, or intensity of chemotherapy. Indeed, combination chemotherapy can impair multiple, different facets of the immune response as a result of the different mechanisms of action of these medications. Furthermore, many cancer patients have intrinsic immune defects related to their underlying malignancy, which further increases their risk of infection.[83]

***Bacterial Infections*** Bacterial infections represent the most common cause of pulmonary infection early in the course of chemotherapy. Several factors, including bacteremia, aspiration, ciliary dysfunction, decreased pulmonary toilet, impaired mucosal barriers, indwelling catheters, and endotracheal intubation may predispose pediatric cancer patients to pulmonary infections.[83,84] Deficiencies in immunoglobulins as a result of immunosuppression also place these patients at risk of infection by encapsulated bacteria, such as *Streptococcus pneumoniae* and *Haemophilus,* because of improper opsonization.[83] *Legionella* infections are also more prevalent in those patients with T-cell defects such as lymphoma. The risk of infection in stem cell transplantation patients has been reported to be 15%, with one quarter of these infections occurring within the first 30 days after transplantation.[85]

Overall, gram-negative bacilli are the most common pathogens responsible for pulmonary infection in pediatric cancer patients.[85] The most common gram-negative species include *Pseudomonas*, *Klebsiella,* and *Enterobacter*. Patients with gram-negative infections present with early pulmonary infiltrates, which can be sufficiently treated with β-lactams, cephalosporins, and/or aminoglycosides. *Pseudomonas* infections generally require double antibiotic coverage. Infiltrates persisting longer than 7 days of treatment are usually caused by these same species that possess intrinsic antibiotic resistance, therefore necessitating a change to the treatment protocol. Gram-positive infections usually involve *Staphylococcus aureus*, *Streptococcus pneumoniae,* and group A *Streptococcal* spp. for which β-lactams, cephalosporins, and vancomycin are usually sufficient for treatment. Furthermore, empiric gram-negative antibiotic coverage for neutropenic patients has led to a rise in *Staphylococcus aureus* and *Streptococcus viridans* infections.[85] *Listeria* usually produces late and refractory infiltrates. Nocardial pulmonary infections are uncommon but very severe, leading to pulmonary necrosis and a predisposition for central nervous system spread.[83] Sulfonamides are the treatment of choice for this organism.

***Fungal Infections*** Fungal infections represent a common cause of morbidity and mortality in highly immunocompromised patients. The incidence is highest in those receiving chemotherapy for malignancy, those with chronic granulomatous disease, and those with hematopoietic stem cell transplants, and this appears to be increasing with advances in the care of these patients as well as improved diagnostic methods.[86,87] Two important fungal infections observed in pediatric cancer patients are *Aspergillus fumigatus* and *Candida* spp.

The lung is the most common site for an invasive infection with *Aspergillus fumigatus,*[85] and the most frequent portal of entry for this fungus is the upper airway. Its incidence has been estimated to be 5% in two pediatric series, but this may be an underestimate because of poor diagnostic yield.[88,89] However, case-mortality has been estimated to be between 50% to 60%, especially in hematopoietic stem cell transplantation patients.[90] Hospital epidemics have occurred secondary to the inhalation of shed spores from contaminated air-conditioning units and from nearby building construction or renovation sites.[91] However, the incidence of such infections can be reduced with the use of laminar flow and high-efficiency filters.[92]

*Aspergillus fumigatus* infections can be rapidly invasive. Necrosis and hemorrhage result from the invasion and thrombosis of pulmonary arteries and veins. This, in turn, leads to the development of cavitary lesions. Plain chest radiographs are not as sensitive for *Aspergillus* as CT scans because these infections may present with diffuse infiltrates, nodular disease, or cavitation (Fig. 66-4).[93] Voriconazole is considered

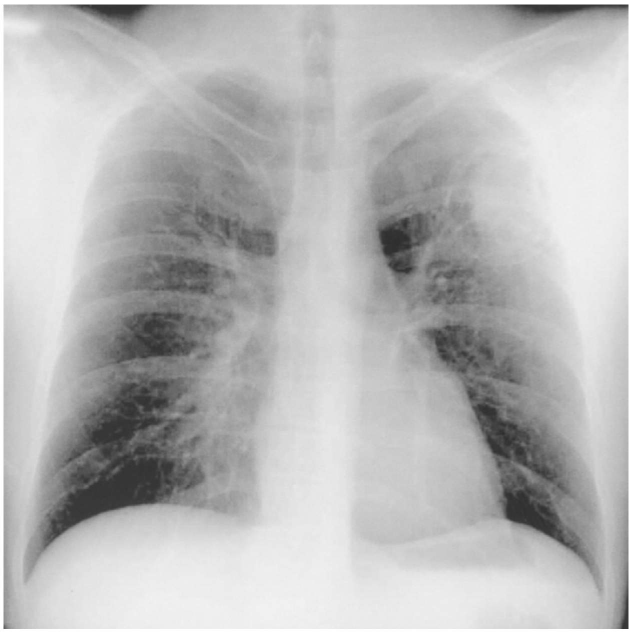

FIGURE 66-4 Left upper lobe aspergilloma with diffuse bilateral lung infiltrates in a 17-year-old patient with acute lymphoblastic leukemia undergoing intensive chemotherapy.

a first-line agent, and its effectiveness may be gauged by the recovery of white blood cells and granulocytes. Second-line agents include caspofungin and liposomal amphotericin B.[87] Surgical resection of disease may be required if no clinical improvement is observed.[94,95] In hematopoietic stem cell transplantation patients, the incidence of *Aspergillus* infection can be as high as 18.6%.[86] The diagnosis of aspergillosis may be difficult. Bronchoalveolar lavage (BAL) samples are positive in less than one third of patients.[96] Although polymerase chain reaction of these BAL samples may improve the yield, the gold standard for diagnosis is the identification of hyphae by histopathology or cytopathology. This may be possible with open or thoracoscopic lung biopsy, percutaneous needle biopsies, or transbronchial sampling.[83]

*Candida* spp. are the most common fungal organisms responsible for infection in immunocompromised patients,[97] with *Candida albicans* being the most common species causing invasive disease. Recent estimates place the rate of invasive infection at 47/100,000 admissions in the United States.[98] Risk factors for the development of candidemia include the presence of an indwelling central venous catheter, immunosuppression, parenteral nutrition, prolonged intensive care unit stay, and neutropenia.[93] Although the lung is not usually involved with *Candida*, it is the most common site of invasive infections.[87] Spread to the lung may occur hematogenously or from the aspiration of contaminated oropharyngeal secretions. Plain chest radiographs are usually nonspecific. Bronchoalveolar lavage can be useful in confirming the diagnosis but often a lung biopsy is required. First-line agents against *Candida albicans* include liposomal amphotericin B, fluconazole, and caspofungin.[87] However, certain strains of *Candida* have specific, intrinsic resistance to either the azoles and/or amphotericin (*Candida krusei* and *glabrata*). Caspofungin and other echinocandins, which affect fungal wall synthesis, are effective in cases of resistance or non–*Candida albicans* infection, previous azole use, if standard therapies are ineffective, or if the side effects of standard medications are limiting treatment.[87,93] However, it is clear that if left untreated, the prognosis of patients with candidal lung infections is uniformly poor.

***Viral Infections*** The susceptibility to viral infection depends on the extent to which host defense mechanisms have been affected. Indeed, pediatric cancer patients can be immunosuppressed because of their underlying disease process or the therapy they are receiving, and are thus generally unable to mount cellular and humoral responses against viral infection.[99] Difficulties in making a prompt diagnosis, especially with atypical clinical presentations, lead to delays in the initiation of appropriate management. Currently, reverse transcription PCR techniques allow for the rapid identification of offending viruses that are present in tissue, blood, sputum, stool, urine, nasopharyngeal aspirates, and cerebral spinal fluid. Immunocompromised children also shed virus for longer periods of time and may be the source of nosocomial infection, even if they no longer have symptoms.[100]

CMV infection is usually the result of the reactivation of a latent infection and occurs predominantly in patients receiving stem cell transplants.[101] The risk of CMV infection appears to be increased in patients who have concurrent graft-versus-host disease, receive frequent transfusions, or receive methotrexate or antithymocyte medications.[102] It presents with fever, headache, malaise, and myalgias that may precede the pneumonitis by 1 to 2 weeks. Radiographs are often nonspecific, demonstrating diffuse, nodular, or atelectatic changes within the lung. CMV can often be detected in the urine of patients with endogenous activation. Treatment includes the use of ganciclovir and immunoglobulins.[103]

Varicella pneumonia is rare in immunocompetent patients and may be difficult to diagnose because of the presence of few skin lesions and the predominant complaints of abdominal or back pain. Thirty percent of patients who have visceral involvement may develop pneumonia.[81] This can increase to 80% if they are receiving concurrent chemotherapy. Radiographically, these patients will present with diffuse bilateral fluffy infiltrates. If patients have been exposed to varicella, chemotherapy should be stopped for the period of incubation (up to 21 days). Passive immunization with varicella zoster immune globulin should be administered at this time. The treatment of active infection includes intravenous acyclovir.[100] Although herpesvirus infections are rare in the absence of concomitant gingivostomatitis, any signs of infection also require the prompt institution of acyclovir therapy. RSV infection can be very problematic in bone marrow transplantation patients because of their decreased T-cell–mediated immunity. Children with neutrophil counts less than $0.1 \times 10^9$/L or age less than 2 years are at increased risk of infection, with mortality rates up to 8.6%.[104] In general, supportive treatment is all that is offered, but severe infections may require ribavirin given by aerosolization in intubated patients or as an intravenous infusion for those who are not.[100] Preventive immunization with palivizumab has not been fully investigated in pediatric cancer patients, but new, more potent agents, such as motavizumab, may be considered as options for this population of patients.[105] Human metapneumovirus has also been shown, within 40 days post-transplant, to affect a small but significant number of patients receiving stem cell transplantation.[106]

***Pneumocystis jirovecii*** This unusual organism has properties of protozoa (susceptible to trimethoprim) as well as fungi (based on RNA studies) and is seen almost exclusively in patients who are immunocompromised. Infection with *Pneumocystis jirovecii* (previously known as *Pneumocystis carinii*) is usually the result of the reactivation of latent disease, but routine prophylaxis has dramatically reduced its incidence.[83] However, the risk of infection is dependent upon the level of immunosuppression. Indeed, bone marrow/stem cell transplantation patients, and patients receiving steroids are at particular risk. Unlike HIV-infected patients, the other main population susceptible to *Pneumocystis* infection, the cancer and hematopoietic transplantation patient is more likely to present with acute respiratory disease within the first several days of infection.[107] Furthermore, CD4 counts cannot be used as a marker for the institution of prophylactic therapy in cancer patients. Thus clinical parameters, dose and duration of corticosteroid, time from transplantation, and the use of other immunosuppressives will determine the use of prophylactic therapy. Patients usually complain of a fever, dry cough, and dyspnea. Progressive disease may present with hypoxia and respiratory distress. Radiographically, fulminant disease presents with bilateral hilar infiltrates that extend to the periphery of the lung (Fig. 66-5). The diagnosis is confirmed by histology and cytology that identifies trophozoite

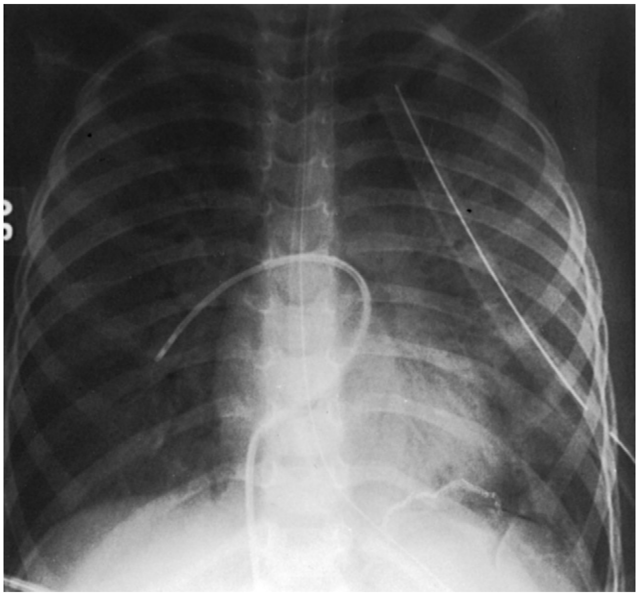

FIGURE 66-5 *Pneumocystis jirovecii (carinii)* pneumonia in a 5-year-old girl receiving chemotherapy for acute lymphocytic leukemia. Diffuse interstitial infiltrates are seen in both lungs. Biopsy of the lingula (note staples) demonstrated *P. jirovecii (carinii)*. A Swan-Ganz catheter is positioned in the right inferior pulmonary artery. Although her leukemia was in remission, the child died of respiratory failure from the pulmonary disease. (Currently with antibiotic prophylaxis, early institution of empiric therapy and diagnostic confirmation by bronchoalveolar lavage, such an outcome would be unusual).

cysts recovered by bronchoalveolar lavage. Trimethoprim/sulfamethoxazole (TMP/SMX) is the mainstay of treatment and prophylaxis.[107] Corticosteroids and supplemental oxygen are also useful for patients with severe infections. If no response occurs within 72 hours, a lung biopsy is indicated to confirm the diagnosis and to rule out concomitant infection with other pathogens. Mortality approaches 100% for untreated patients. If myelosuppression or rash develops secondary to TMP/SMX administration, pentamidine may also be used, but it has its own significant side effect profile, including nephrotoxicity and pancreatic insufficiency.[107]

## PEDIATRIC HIV PATIENT

Acute pneumonia is the most common severe infection in HIV-infected children in the United States. In developing countries, particularly in sub-Saharan Africa, respiratory infections are one of the most common causes of illness, hospitalization, and mortality in HIV-infected children.[108] The introduction of highly active antiretroviral therapy (HAART) in 1997 has dramatically improved the survival of HIV-infected adult patients in developed nations through the reconstitution of the immune system.[109] Indeed, HAART has dramatically reduced the incidence of opportunistic infections in HIV-infected children by more than 80%,[110] and its institution in infants has led to dramatic reductions in mortality.[111]

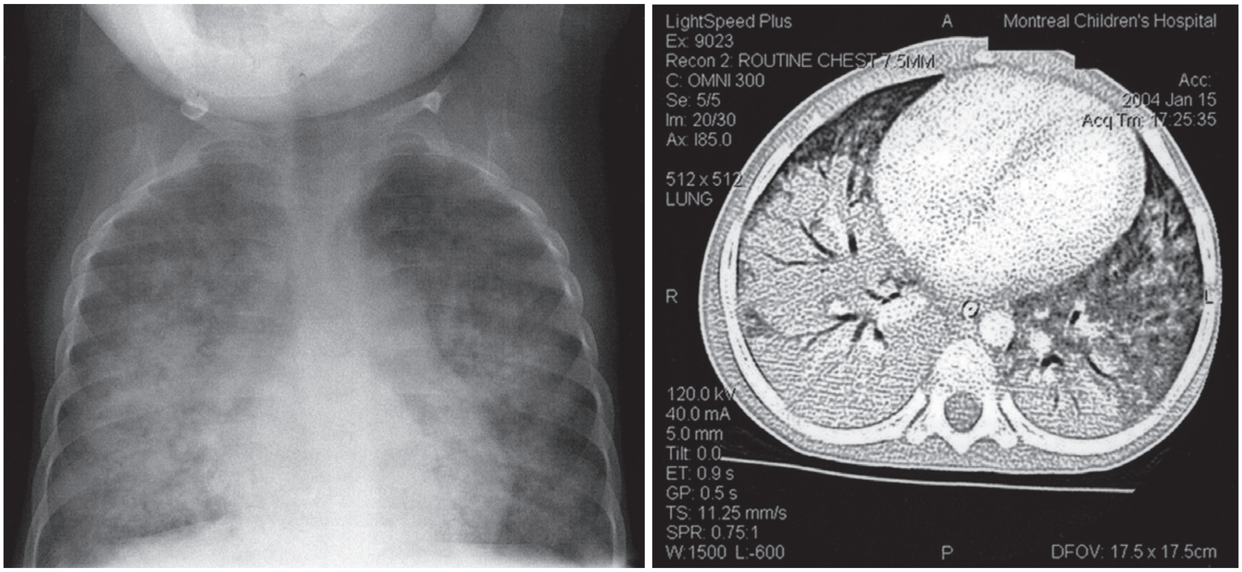
The most common organisms responsible for bacterial pneumonia in HIV-infected patients are *Streptococcus pneumoniae* (7.4%), *Staphylococcus aureus* (2.4%), *Haemophilus influenzae* type B (1.8%), *Escherichia coli* (0.8%), and *Salmonella* spp. (0.7%).[13,112] Antibiotic resistance is also more common in HIV-infected children, especially methicillin-resistant *Staphylococcus aureus* and extended-spectrum β-lactamase–producing enterobacteriaciae.[113] The clinical features of respiratory infections in children with HIV are similar to those with normal immune systems. However, patients with decreasing CD4 counts, severe immunosuppression, and previous acquired immune deficiency syndrome (AIDS)–defining respiratory infections are more likely to develop acute pneumonia.[114] Furthermore, these patients may be predisposed to recurrent infection and its sequelae, including bronchiectasis, abnormal lung parenchymal architecture, and bullous lung disease.[115] The diagnosis of pneumonia in HIV-infected children is based on clinical and radiographic findings. However, it is very important that opportunistic and mycobacterial infections be excluded in this population of patients. Furthermore, the differential diagnosis of pulmonary infiltrates for these patients also includes noninfectious causes such as lymphoid interstitial pneumonia and non-Hodgkin lymphoma. A lung biopsy may be required to confirm a diagnosis in these patients. The prevention of infection plays a key role in the management of these patients and includes the routine immunization against *Streptococcus pneumoniae* and *Haemophilus influenzae* type B, as well as prophylactic TMP/SMX for *Pneumocystis jirovecii* if required. Treatment should be initiated against the specific pathogen as soon as possible, but empirical therapy (cefotaxime or ceftriaxone) may be instituted while waiting for culture results.

### *Pneumocystis jirovecii*

*Pneumocystis jirovecii* infection is the most common organism identified in HIV-infected children admitted to hospital for severe pneumonia. It is most common in infants and is associated with a mortality rate of 50%.[109] The incidence of *Pneumocystis jirovecii* pneumonia, however, has decreased with the introduction of TMP/SMX prophylaxis and HAART.[116] Although there is currently insufficient data for children, recent adult series have demonstrated minimal recurrence of pneumocystis pneumonia with the discontinuation of prophylaxis in patients experiencing a good response to HAART therapy.[117] Currently, *Pneumocystis jirovecii* prophylaxis is still recommended for (1) HIV-exposed infants, starting at 4 to 6 weeks of age until infection is disproven; (2) for all HIV-infected infants younger than 1 year of age, regardless of CD4+ count; and (3) all HIV-infected children if their CD4+ counts are below age-specific thresholds.[118] The clinical presentation of *Pneumocystis* pneumonia, imaging, diagnostic maneuvers, and treatment were discussed in the previous section.[109]

### Lymphoid Interstitial Pneumonitis

Lymphocytic or lymphoid interstitial pneumonitis (LIP) is a chronic lymphocytic infiltrative process seen in children with HIV who are greater than 2 years of age and represents another AIDS-defining illness. Epstein-Barr virus has been implicated in its pathogenesis. LIP has been estimated to occur in 20% to 30% of vertically transmitted cases of HIV in the United States and Europe.[119] Patients often present with an insidious onset of respiratory symptoms that may be confused with tuberculosis. Other clinical findings include fever, digital clubbing, asymptomatic parotid swelling, symmetric lymphadenopathy, and hepatomegaly. The clinical course is benign but may predispose patients to bacterial and viral pneumonias, bronchiectasis, and bullous lung disease.[115,120] Plain radiographs can



A B

**FIGURE 66-6** **A,** Three-year-old child recently immigrated from Africa presented with a history of weakness and coughing, having been treated for pulmonary tuberculosis 2 years previously. Respiratory distress worsened, and intubation was required. **A,** Plain radiograph demonstrates a lung infiltrate with an alveolar pattern. **B,** Diffuse consolidation with air bronchogram, especially in the right lower lobe, can be appreciated on computed tomography. Human immunodeficiency (HIV) was suspected and later confirmed. Bronchoscopy and bronchoalveolar lavage were not diagnostic. Lung biopsy revealed lymphoid interstitial pneumonitis. He was treated with steroids and triple antiretroviral therapy and rapidly recovered.

demonstrate persistent reticulonodular infiltrates and hilar adenopathy that can be better appreciated by CT scan (Fig. 66-6). Lung biopsy is usually necessary to confirm the diagnosis and demonstrates significantly altered pulmonary architecture with an infiltration of CD8+ cells.[121] Systemic steroid administration over 4 to 6 weeks usually leads to resolution of the infiltrates. HAART has been shown to improve the clinical course of LIP and may reduce the prevalence of chronic lung disease associated with it.[116]

### *Mycobacterium tuberculosis*

The increase in the incidence of tuberculosis (TB) in children in developed countries has paralleled the increase of the disease in HIV-infected adults, the primary source of transmission to children.[38] The clinical features of TB in HIV-infected children are similar to immunocompetent patients but with a predilection for rapid progression, extrapulmonary and/or disseminated disease resulting from the impairment of cell-mediated immunity.[38,122] Radiographs often demonstrate lobar or diffuse infiltrates and atelectasis from bronchi compressed by hilar adenopathy. If a child is found to have TB, HIV testing should be undertaken. The diagnosis of TB is based upon the clinical, epidemiologic, and radiographic data available. The early morning gastric aspirate of retained overnight secretions is the best noninvasive culture technique for tuberculosis and may provide a better yield than more invasive procedures such as bronchoalveolar lavage and bronchoscopy.[123] However, induced sputum, using nebulized hypertonic saline[124] (using proper infection control procedures) and the string method,[125] are viable alternatives. Although the tuberculin skin test is a poor indicator of tuberculosis infection in young children with HIV, and is unable to differentiate between latent and active disease,[38] it is still considered a valuable diagnostic aid in HIV-infected children.[44] Whole blood interferon-γ assays have recently helped differentiate tuberculosis from atypical mycobacterial infections.[43] Prevention is the key, and a clear determination of the TB status of all adults in the household is essential. Currently, vaccination of HIV-infected children with bacillus Calmette-Guérin is not recommended because of the risk of disseminated disease.[126,127] For patients with significant exposure, regardless of skin test result, isoniazid is indicated. If a repeat tuberculin skin test in 3 months is negative, the medication can be stopped. Treatment of active infections includes a multiagent regime, but care must be taken to watch for interactions between antiretroviral and antituberculous medications.[38] HAART should be instituted once antituberculous treatment has been established (usually 2 to 8 weeks). However, for those patients with mild infection and minimal immunosuppression, HAART therapy may be deferred for up to 6 months while TB is being treated.

### Atypical Mycobacterial Infections

Several species of atypical mycobacteria are clinically significant in patients with HIV. These include the *Mycobacterium avium* complex, *Mycobacterium intracellulare*, *Mycobacterium lepraemurium,* and *Mycobacterium scrofulaceum*. These bacteria represent a major source of morbidity for HIV-infected children and usually cause systemic infection later in the course of AIDS. Previously, HIV patients infected with atypical mycobacteria had a 9- to 11-month life expectancy,[128] but with the advent of more effective treatments for HIV (i.e., HAART), and atypical mycobacteria, the disease is less common and the prognosis better. Indeed, the incidence of atypical mycobacterial infections in children was reduced from 1.2 to 0.3 cases per 100 patient years in a study evaluating opportunistic infection rates in children in the pre-HAART and post-HAART era.[129]

The clinical presentation of these patients usually involves failure to thrive, abdominal pain, and fatigue, but can also involve respiratory symptoms. Patients may have leukopenia,

thrombocytopenia, and an increased serum lactate dehydrogenase. The diagnosis is made through blood culture or biopsy of a normally sterile site, including bone marrow and lymph nodes. These microbiologic investigations will also eliminate the possibility of TB infection. In addition, a skin test or whole blood interferon-γ assay may be helpful initially to distinguish atypical mycobacterial infections from that of TB.[43] Prevention of infection is accomplished through protection of the immune system with effective antiretroviral therapy. Treatment of active infections can be accomplished with clarithromycin, azithromycin, rifabutin, rifampin, ethambutol, ciprofloxacin, or amikacin. It is important to remember that the rifamycins (i.e., rifampin and rifabutin) inhibit the metabolism of many antiretroviral medications.

### Viral Infections

CMV infection can present as chronic interstitial pneumonitis and is usually accompanied by retinitis, hepatitis, or colitis. It often occurs in severely immunosuppressed patients. Respiratory symptoms include nonproductive cough, dyspnea, and hypoxemia. Pneumonitis may be associated with concurrent *Pneumocystis jirovecii* infection. Radiographic findings include diffuse interstitial infiltrates. The diagnosis of CMV is made through PCR of the blood, identifying viral inclusions in bronchoalveolar lavage or biopsy specimens, or viral culture. However, the differentiation between active infection and asymptomatic viral shedding in HIV-infected patients is difficult and may complicate management regimes.[109] The preferred treatment is gangiclovir, particularly if gastrointestinal or retinal involvement is also identified.

### Fungal Infections

Systemic fungal infections are infrequent in HIV, because more commonly, fungal infections involve the skin or mucosa. Pulmonary mycoses are occasionally identified in children with HIV resulting from impaired T-cell immunity. Histoplasmosis is uncommonly reported in this group of patients. A primary pulmonary focus may progress rapidly to disseminated disease and become fatal if left untreated. Severe disease presents with fever, hepatosplenomegaly, pancytopenia, reticulonodular lobar infiltrates, and the occasional progression to septic shock. The diagnosis is based upon cultures of bronchoalveolar lavage samples or lung biopsy. Treatment involves the use of intravenous liposomal amphotericin B with or without itraconazole. Children with primary pulmonary disease should receive itraconazole for prophylaxis in the hope of preventing disseminated disease.

*Cryptococcus neoformans* and *Coccidioidomycosis* spp. infections are usually associated with disseminated infection, and 50% of these patients have concurrent pulmonary infection. Disseminated cryptococcal infections present with fever, headache, meningitis, pulmonary infiltrates, and confusion. The diagnosis is made through sputum, blood, or cerebrospinal fluid cultures and the direct examination of cerebrospinal fluid with India ink or latex agglutination. Treatment includes amphotericin B and fluconazole for several weeks followed by lifelong fluconazole prophylaxis. *Coccidioidomycosis* usually presents as disseminated disease affecting the lungs, brain, and skin. Fever, weight loss, cough, and an altered level of consciousness are often present. The diagnosis is made from sputum, bronchoalveolar lavage, or lung biopsy specimens. Acute infections are managed with amphotericin B, but recurrence is common, thus mandating secondary prophylactic therapy with fluconazole. *Aspergillosis* is another uncommon infection that usually presents with pulmonary disease and sinusitis. These patients experience fever, cough, dyspnea, and pleuritic chest pain. Sputum analysis, bronchoalveolar lavage, and, occasionally, lung biopsy are required to confirm the diagnosis. Voriconazole is the treatment of choice, although the echinocandins (i.e., caspofungin) have also been shown to be effective.

The immunocompromised pediatric patient is under the constant threat of infection. These patients require constant surveillance and aggressive management strategies. For patients with pulmonary infiltrates, broad-spectrum antibiotics should be started promptly, and depending on the presentation of the patient, an emergent bronchoalveolar lavage may be required to rule out *Pneumocystis jirovecii*. For persistent lung infiltrates, lung biopsy should be strongly considered. Indeed, the results of lung biopsy for patients with persistent lung infiltrates have been shown to impact on the management of these patients up to 90% of the time.[130]

## CYSTIC FIBROSIS

Cystic fibrosis (CF) is the most common autosomal recessive disease affecting whites and occurs in approximately 1 in 3,400 live births.[131] The prognosis for this disease has improved considerably over the last 30 years but has plateaued since the mid-1990s. The current life expectancy for patients with CF is more than 30 years of age. CF is characterized by thick, inspissated mucus, chronic infection, and neutrophil-dominated inflammation of the airways.[132] The cystic fibrosis transmembrane conductance regulator (CFTR) is a cyclic adenosine monophosphate–dependent chloride channel located on chromosome 7q21-31.[133] CFTR mutations lead to abnormal ion transport (increased sodium transport and failure to secrete chloride) and altered airway-surface liquid, resulting in viscous mucus and reduced mucociliary clearance, respectively. Bacterial penetration and proliferation within the thick and adherent secretions subsequently allows persistent infection and inflammation of the airways.[132] Furthermore, chronic inflammation, stasis of mucus, and airway obstruction ultimately lead to the pulmonary sequelae observed with long-standing cystic fibrosis.

The clinical signs and symptoms of CF can vary widely. Patients may be relatively asymptomatic, present with chronic illness, and fail to thrive, or complain of acute, recurrent exacerbations of pulmonary disease. However, the usual presentation is with the progression of a nonproductive cough to a loose productive cough with copious, purulent secretions. Classical physical findings include a barrel chest, rales, rhonchi, and digital clubbing with occasional cyanosis. Although initial pulmonary function tests demonstrate obstructive patterns, disease progression leads to the development of restrictive lung disease. The gold standard for the diagnosis of CF is the sweat test (elevated chloride $> 60$ mEq/L) or the identification of mutations in CFTR, the most common being $\Delta$F508. However, a negative result may not be as meaningful because of the limited number of commercially available analyses. However, DNA restriction fragment length polymorphism analysis from fetal DNA obtained by amniocentesis can help predict CF status in the fetus if the mutation within the family is known.

In the first decade of life, the most common organism isolated from cystic fibrosis patients is *Staphylococcus aureus* (40%), followed by *Haemophilus influenzae* (15%).[134] *Pseudomonas* is usually the first pathogen isolated in children less than 1 year of age, and greater than 80% are infected with this organism by 18 years of age.[135] Clinically, *Pseudomonas* is the most important pathogen in CF because it is able to form biofilms that enable bacteria to avoid normal clearance mechanisms and the penetration of antibiotics. *Pseudomonas* has also been associated with increased airway inflammation, a more rapid decline in lung function, and increased mortality.[136] *Burkholderia cepacia* is an organism with intrinsic antibiotic resistance. Patients infected with this organism present with high fevers, rapid pulmonary deterioration, and sometimes death. Viral infections may pose a special problem, particularly in young children, where they may predispose to secondary infection, the need for mechanical ventilation, and oxygen dependence. RSV prophylaxis has been recommended for these infants.[137]

The cornerstone of medical therapy for pulmonary disease in CF patients is the aggressive use of intravenous, oral, and nebulized antibiotics. Indeed, the increased life span of CF patients can be attributed directly to the development of effective antipseudomonal medications. Maintenance therapy is designed to prolong the period between pulmonary exacerbations with *Pseudomonas*. Nebulized tobramycin has been shown to be effective in eradicating *Pseudomonas* in early infection, as well as decreasing bacterial load, improving lung function, and decreasing hospital admissions.[138] Azithromycin has also been effective as an immunomodulator to reduce airway inflammation, thereby improving lung function in those with *Pseudomonas*. The clearance of abnormal secretions is of paramount importance and includes regular chest physiotherapy and postural drainage.[139] Mucolytic agents, such as dornase alpha, can help mobilize thick inspissated secretions in CF patients.[140] Attempts to reduce the inflammatory response with antiinflammatory medications, such as ibuprofen, may help to slow the progression of lung disease.[141] However, similar effects have not been demonstrated with inhaled corticosteroids.[142]

Adequate nutritional support and the early treatment of pancreatic insufficiency is another critical area for the medical therapy of patients with CF. Significant malnutrition may already be evident at the time of diagnosis in neonates and young children, even if they are asymptomatic. The imbalance between the increased energy needs of infants for growth and their impaired ability to achieve adequate nutritional intake can predispose to pulmonary complications. Recommendations are in place to help guide clinicians with regard to nutritional requirements and surveillance for children with cystic fibrosis.[143,144]

Pediatric surgeons may be involved in the care of these patients in several ways as they get older. Implantable intravenous access devices are useful for patients who frequently require antibiotics for pulmonary exacerbations. Nutritional management may require the use of a gastrostomy.[145] Pulmonary complications of CF, such as bronchiectasis, massive hemoptysis, and pneumothorax are discussed later, while gastrointestinal and hepatic complications are discussed in other chapters.

Lung disease is the main cause of premature death in cystic fibrosis, and lung transplantation remains the ultimate resort for patients with end-stage pulmonary disease. However, with the improved medical care of these patients, the need for lung transplantation has been delayed. Bilateral, sequential lung transplantation is the preferred approach for children with CF. Current data report overall survival rates of 77% to 89% and 55% to 80% at 1 and 5 years, respectively, and are much better than the survival rates of nontransplanted patients on the waiting list.[146] Furthermore, a comparison of children with and without cystic fibrosis who underwent lung transplantation had similar overall rates of survival at 1, 3, and 5 years.[147]

## BRONCHIECTASIS

First described by Laënnec in 1819,[148] bronchiectasis is the irreversible dilatation of the airways secondary to the inflammatory destruction of bronchial and peribronchial tissue. Currently, it has become an uncommon disease in developed countries and predominantly limited to the pediatric population.[149] However, the incidence of and morbidity secondary to bronchiectasis is still a problem in developing countries and certain indigenous populations in developed nations, such as the aboriginal peoples of Alaska and Australia.[150,151]

### Pathogenesis and Etiology

The pathogenesis of bronchiectasis follows three progressive stages. Initially, there is destruction of the ciliary epithelium, which is replaced with cuboidal squamous epithelium. In the early stages of disease (cylindrical bronchiectasis), there is localized damage to the elastic tissue of the airway in addition to edema and inflammation. Later in the disease (saccular bronchiectasis), the damage involves the muscle layers and cartilage of the airways, with anastomoses forming between pulmonary and bronchial arteries in the areas of saccular dilation. There is also evidence to support a host-mediated component to local tissue damage.

Numerous different hypotheses regarding the development of bronchiectasis have been proposed. It is clear that infection is the most common cause of bronchiectasis (Fig. 66-7). Bronchiectasis may not result from the index infection but is usually the result of concomitant or subsequent infection with many agents, such as TB and histoplasmosis, viruses, certain fungi, and occasionally *Mycoplasma*.[152] Cystic fibrosis is the most common genetic cause of bronchiectasis; here it occurs secondary to infection and bronchial obstruction with inspissated mucus. Other causes include the congenital absence of supportive airway cartilage (Williams-Campbell syndrome), tracheomegaly, Marfan syndrome, alpha-1 antitrypsin deficiency, foreign body aspiration, ciliary abnormalities (Kartagener syndrome), immunodeficiencies (IgA), asthma, and right middle lobe syndrome.[148,153] The distribution of bronchiectasis may give insight into the underlying cause. Patients with tuberculosis generally have unilateral involvement, while patients with CF and viral-induced disease have involvement of the upper lobes and lower lobes, respectively.

### Clinical Manifestations and Investigation

Most patients present during the preschool years with cough, profuse sputum, wheezing, and chest pain. Up to 50% may have digital clubbing, which is reversible. Bronchiectasis, demonstrated by bronchial dilation, bronchial thickening,

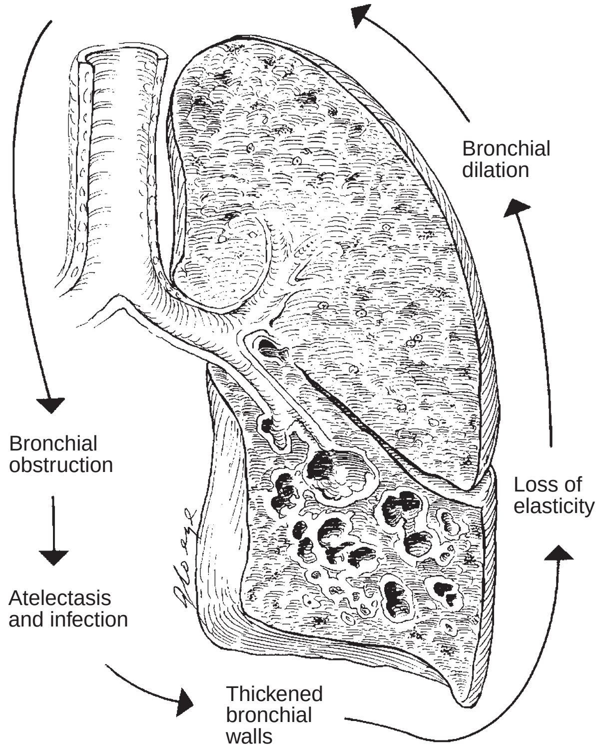


FIGURE 66-7 Diagrammatic representation of factors influencing the pathogenesis of bronchiectasis.

or a signet ring sign, may be apparent on chest radiographs. High-resolution computed tomography of the chest has replaced bronchography to document the pattern and severity of disease.[154,155] Findings include cylindrical or saccular dilatation of bronchi, pooling of secretions, and bronchial thickening (Fig. 66-8). Increased awareness and the wide availability of CT have also resulted in the earlier identification of bronchiectasis, and have brought into question the irreversibility of the process. Indeed, acute suppurative infections of the lung may cause *reversible* dilatation of the bronchi that may be confused with bronchiectasis.[156] A new classification system has been developed to describe the different stages of disease, including prebronchiectasis (reversible), high-resolution CT bronchiectasis (may reverse or progress), and established bronchiectasis (irreversible).[157]

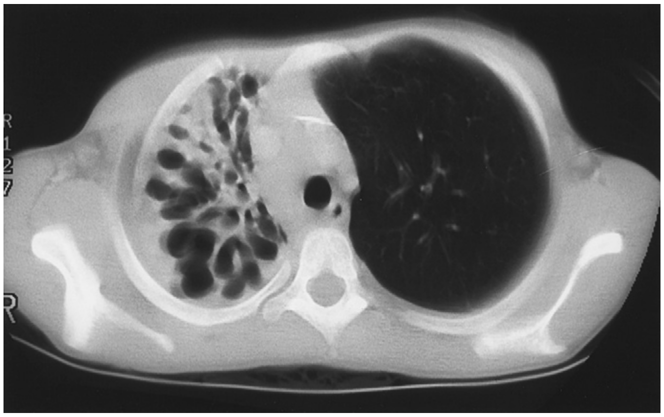

FIGURE 66-8 Computed tomographic scan of the chest of a 10-year-old girl with cystic fibrosis. Preoperative ventilation-perfusion scanning revealed no function of this bronchiectatic lobe. The patient underwent an upper lobectomy.

## Therapy

The treatment of bronchiectasis focuses on identifying and treating the underlying causes. Regular microbiologic surveillance, prolonged antibiotic therapy, and adequate nutritional support, with pancreatic enzyme replacement for patients with cystic fibrosis, are needed to prevent failure to thrive from recurrent infections and pulmonary exacerbations. Vaccination against *Streptococcus pneumonia* and *Haemophilus influenzae*,[158,159] postural drainage techniques with chest physiotherapy,[160] and mucolytics[161,162] are part of the armamentarium against disease progression. Bronchoscopy has also been used to temporarily help alleviate bronchial obstruction resulting from foreign bodies and inspissated secretions, or to aid in the preoperative or diagnostic evaluation of chronic lung infection.

Although the frequency of surgical therapy for bronchiectasis has declined over the last several years, there are still those patients who do not respond to medical therapy and would benefit from surgical resection. The main indications for surgery include (1) localized disease with severe and debilitating symptoms, such as profuse sputum, fetid breath, and severe cough, that significantly impacts quality of life; (2) life-threatening hemorrhage from localized disease; (3) resectable disease in the context of failure to thrive; and (4) resectable disease in an area of recurrent lower respiratory tract infections. Lesser indications for surgery include bilateral or nonlocalized disease or patients with only mild-to-moderate symptoms.[163]

The outcome of pediatric patients undergoing surgical resection has generally resulted in the cessation or improvement of clinical symptoms in the majority of patients. Indeed, several studies have demonstrated that 70% of patients are asymptomatic or improved after surgical resection for localized disease.[164–169] The morbidity in these series ranged from 10% to 24%. However, many patients present with more diffuse disease. Schneiter[163] and Otgun[170] both demonstrated the safety and improvement in symptoms with more extensive pulmonary resections for bronchiectasis. Most recently, Rothenberg described thoracoscopic resection for patients with severe, localized bronchiectasis.[171] In this series, nineteen patients, ranging from 14 months to 15 years of age, underwent successful thoracoscopic lung resection. The average length of stay was 3.6 days, and only 2 patients incurred complications (air leak and hydropneumothorax) that extended the length of stay. The main advantages of this approach, despite the technical challenges, were the avoidance of thoracotomy, and thus a faster progression to mobilization, reduced postoperative pain and the resumption of chest physiotherapy for a population with existing pulmonary morbidity. The common themes for the successful operative management of bronchiectasis are careful patient selection, preoperative evaluation and surgical technique, as well as an attempt to completely resect all diseased lung tissue.

## PULMONARY HEMORRHAGE AND HEMOPTYSIS

The etiologies of pulmonary hemorrhage and hemoptysis are wide ranging and may be classified according to the age of the patient or on the basis of underlying lung disease. In neonates, prematurity, pulmonary edema, respiratory distress syndrome, intracerebral bleeding, coagulopathy, and metabolic disorders can lead to pulmonary hemorrhage. For patients with chronic lung disease, bronchiectasis secondary to cystic fibrosis is the most common cause in the pediatric population. However, cavitary lung lesions, TB, neoplasms, retained foreign bodies, and frequent airway manipulation can lead to symptomatic hemorrhage. In otherwise normal patients, massive hemoptysis may be secondary to hemangiomas, congenital arteriovenous malformations, intralobar pulmonary sequestration, bronchopulmonary foregut malformations, unilateral pulmonary artery agenesis (resulting from the development of collaterals), and Ehlers-Danlos syndrome.

Hemoptysis in children can be classified as mild ($<$100 mL/day) or massive, if the amount is greater than 250 mL/day, or if recurrent episodes involve substantial amounts of blood ($>$100 mL/day) over days to weeks.[172] Although minor hemoptysis occurs relatively frequently, approximately 5% of patients with cystic fibrosis will have an episode that is massive. Indeed, massive hemoptysis is seen in older patients with more severe lung disease and portends a poorer outcome, with a 5-year survival rate of 35%.[173] The pathogenesis is related to the enlargement and tortuosity of the bronchial arteries and the multiple anastamoses that form between these vessels and the pulmonary arteries (Fig. 66-9).[157] Nonbronchial arteries may also form collaterals with the bronchial circulation or enter the lung through granulation tissue. Most episodes of major hemoptysis resolve spontaneously but sedation and the discontinuation of medications that impair coagulation should be initiated. Hemoptysis usually indicates deteriorating lung function and thus antibiotics may be used at this time to treat underlying infection.

Bronchial artery embolization has emerged as a highly successful nonsurgical intervention for the short-term control of hemoptysis. Several series have demonstrated that this technique is safe and effective for the control of massive hemoptysis[174,175] with success rates, defined as no repeat bleeding within 24 hours, approaching 95%. However, almost 50% of these patients require repeated embolization within 19 months.[174] Failure of embolization is mainly attributable to nonbronchial collaterals.[176] Bronchoscopy can be used to help with the preoperative localization of bleeding. Surgery with lobectomy may be life-saving for patients who fail embolization or for those patients with fulminant, massive hemoptysis. In this scenario, mortality is high, ranging up to 36%.[146]

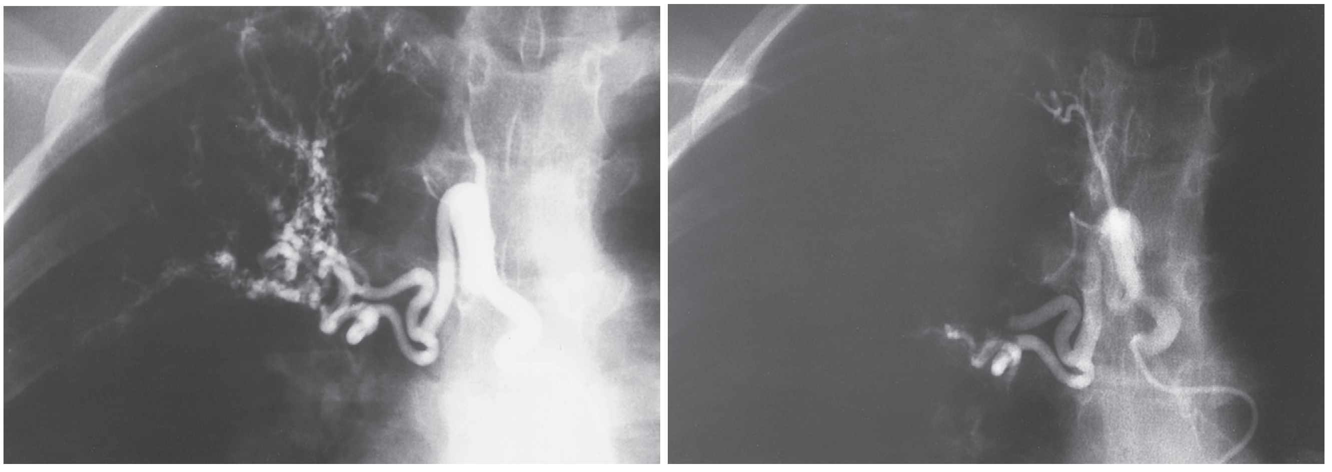
## COMPLICATIONS OF PNEUMONIA

### Pneumatocele

Pneumatoceles are small, thin-walled structures consisting of single or multiple air-filled cysts secondary to alveolar and bronchiolar necrosis. These abnormalities are seen frequently as a consequence of infection by *Staphylococcus aureus*, group A *Streptococcus*, and occasionally *Haemophilus influenzae*. Pneumatoceles secondary to *Staphylococcus aureus* infections may be identified early in the disease process and occur in up to 80% of patients.[177] Pneumothorax and pyopneumothorax are complications resulting from the rupture of pneumatoceles, with or without infection. These lesions can be difficult to distinguish from congenital cysts of the lung. However, pneumatoceles are prone to spontaneous resolution, whereas congenital abnormalities should not involute. Follow-up chest radiographs are required until the resolution of the pneumatocele. A CT scan may be useful in suspicious instances (Fig. 66-10).

### Lung Abscess

A pulmonary abscess develops when a localized infection in the lung parenchyma leads to necrosis and cavitation. It occurs much less frequently than pneumonia or empyema, with an estimated incidence of 0.7 per 100,000 admissions per year.[178] Classically, pulmonary abscesses were classified into primary (occurring in healthy children) or secondary



A B

**FIGURE 66-9** **A,** Arteriogram obtained to identify the cause of hemoptysis in a 10-year-old girl with cystic fibrosis. Note the tortuous bronchial artery. **B,** After successful Gelfoam embolization, the peripheral branches of the artery are not visualized.

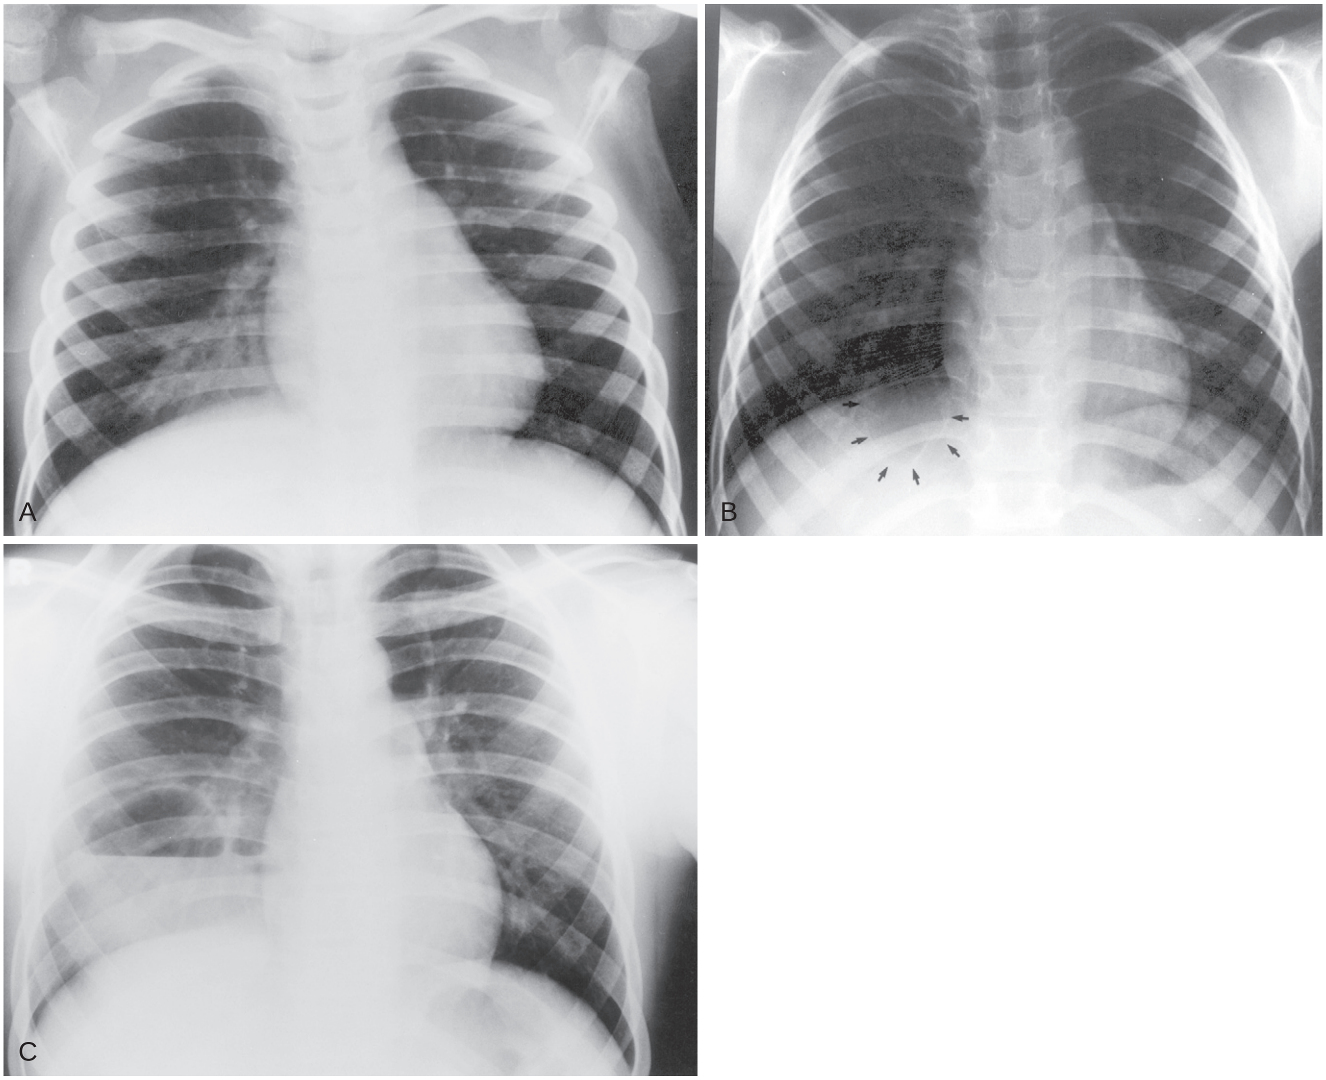


**FIGURE 66-10** **A,** A five-year-old child presented with a right lower lobe pneumonia that responded to intravenous antibiotics. **B,** During outpatient monitoring, small cysts were noted 6 weeks later and appeared to coalesce in a larger pneumatocele on this radiograph, taken 11 weeks after the initial study. Follow-up was recommended. **C,** At 14 years of age, the patient presented with a new episode of infection with a large air-fluid level and some smaller ones. Intravenous antibiotics were required for more than 2 weeks. Computed tomography (CT) confirmed the presence of three cysts. Six weeks later, a right lower lobectomy was performed, and microscopic examination confirmed a type I congenital cystic adenomatoid malformation.

(occurring in otherwise compromised children).[179] However, it is now clear that lung abscesses occur almost exclusively in areas of pneumonia.[180] When appropriate antibiotic therapy is administered early, the frequency of lung abscesses decreases considerably. Abscesses developing in immunocompromised, severely ill, or occasionally very young patients have recently become a more frequent problem. Occasionally, congenital bronchogenic or pulmonary cysts may become secondarily infected. These lesions may be indistinguishable from lung abscess on chest radiographs (Fig. 66-11, see Fig. 66-10, *C* ).

***History*** In the 17th century, Bonet described two patients whom he cured of lung abscess by external drainage.[181] In the 1930s, Neuhoff and Touroff[182] reported good results with one-stage surgical drainage of an acute putrid abscess of the lung. A two-stage procedure, the first step to induce pleural symphysis, was used by Welch[183] with a mortality rate of 40%. The treatment of lung abscess by resection in the early 1940s gave way to almost total reliance on antibiotics, which is still the approach now.[184]

***Pathogenesis*** The aspiration of gastric contents is a leading cause of chronic pneumonia and lung abscess in children, particularly in those with neurologic deficits.[178] Aspiration may occur acutely during trauma, anesthesia, epileptic seizures, or in those children with severe gastroesophageal reflux. Patients with repaired esophageal atresia or esophageal dysmotility are also at risk of aspiration.[184] Previously, common antecedents of lung abscess were the aspiration of foreign bodies, including blood or tissue following tonsillectomy.[184] Such abscesses are now infrequent, because they are prevented by prompt bronchoscopic removal[185] and by endotracheal intubation and pharyngeal packing, which protects against aspiration during operations on the oropharynx.

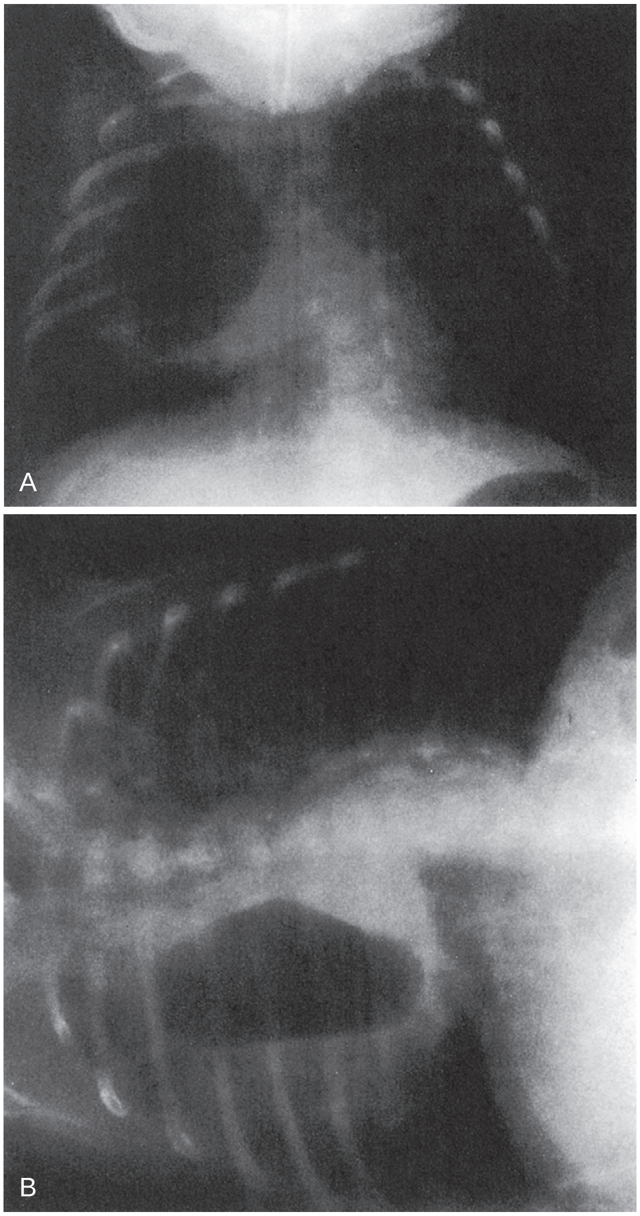

**FIGURE 66-11** Lung abscess following aspiration in an infant. **A,** A thick-walled cavity is present on the anteroposterior supine view. **B,** An air-fluid level is visible on the lateral decubitus view.

Lung abscess is an occasional complication of bacterial pneumonia and is much less frequent in the pediatric population than in adults. The most common causative organisms are anaerobes, followed by *Staphylococcus aureus*, *Pseudomonas*, *Streptococcus pneumoniae,* and occasionally *Haemophilus influenzae*. Other bacteria implicated in lung abscess include *Klebsiella*, *Escherichia coli*, *Peptostreptococci,* and *Peptococcus*.[186,187] Children with cellular or humoral immune deficiencies, either congenital or acquired, are occasionally unable to eradicate a pulmonary infection despite appropriate antibiotics, leading to inflammation, the breakdown of pulmonary parenchyma, and eventual abscess formation. Histologically, a lung abscess may be identified 18 to 36 hours after the inciting event but may only be apparent on chest radiographs after 7 days. When a lung abscess occurs in infants, an underlying congenital anomaly, such as a bronchogenic cyst or congenital cystic adenomatoid malformation, should be suspected (see Fig. 66-10).[188] These lesions require resection, but initial treatment with antibiotics with or without drainage is usually indicated.

The position of the child at the moment of aspiration determines the location of the lung abscess.[184] In supine patients, the superior segments of the lower lobes are most often involved. If the child is on the right side, the right upper lobe is at risk; if on the left side, the apical posterior segment of the left upper lobe may be the site. The upright child aspirates into basilar segments of the lower lobes. The distribution of lung abscesses in various lobes and segments in children is similar to that in adults. Lung abscesses often occur at the periphery of a segment or lobe, making them amenable to external drainage procedures (see later).

***Diagnosis*** The most common symptoms caused by lung abscess include fever, cough, chest pain, anorexia, productive sputum, weight loss, malaise, hemoptysis, and chills.[189] Purulent sputum may be easily obtained from older children to help with a bacteriologic diagnosis; younger patients usually swallow their secretions. Putrid sputum is characteristic of an anaerobic abscess. The affected area of the chest may be dull to percussion and have decreased breath sounds. Leukocytosis is common. Patients may also present with restrictive lung disease patterns resulting from the enlarging abscess or secondary to pleuritic chest pain.

The diagnosis of lung abscess may be established by chest radiographs, which show a cavity, commonly with an air-fluid level (see Fig. 66-11). An abscess should be distinguished from pneumatocele, a localized collection of intrapulmonary air that usually does not have an air-fluid level, and from empyema with an air-fluid level. However, computed tomography scans have become the most valuable radiologic investigation in the diagnosis and characterization of lung disease in complicated pneumonia, revealing pathology that may not be apparent on plain chest radiographs.[189]

***Treatment*** A specific bacteriologic diagnosis should be established before treatment whenever possible. Diagnostic bronchoscopy with direct aspiration of purulent fluid from the parent bronchus should be performed, except in those older children who are able to induce a satisfactory sputum sample. The needle aspiration of a peripheral abscess cavity under imaging guidance to isolate bacterial species and drain collections has been used with success.[190] Furthermore, isolation of the causative organism is possible with this technique even if patients are concurrently receiving antibiotic therapy.

The vast majority of lung abscesses may be treated effectively with appropriate intravenous antibiotic therapy. Penicillin is the antibiotic of choice because of its efficacy against streptococcal and anaerobic species. However, β-lactam resistance may be a problem, and thus clindamycin may be added to address this issue, as well as to cover against *Staphylococcus aureus* in children who are very ill.[191] Third-generation cephalosporins are also very effective. Intravenous antibiotics are recommended for 2 to 4 weeks, followed by oral antibiotics for a total treatment period of 6 to 8 weeks.[178]

Percutaneous catheter drainage of the abscess has become a standard part of the management scheme for children with lung abscesses over the last 20 years. It may be helpful in acutely ill children, particularly for those who experience rapid progression of the disease despite maximal antibiotic therapy.[178,192] Percutaneous drainage provides an opportunity to culture responsible organisms, effect ongoing drainage, and thus hasten recovery.[189] Complications related to percutaneous techniques occur occasionally and include pneumothorax, hemothorax, incomplete drainage, and bronchopleural fistulae.[193] Surgical resection of the lung abscess by segmental resection or lobectomy is recommended for the chronic, large, and thick-walled abscesses or for those few patients who do not respond to intensive antibiotic therapy or percutaneous drainage.[188,194] Other indications for resection include chronic abscesses lasting longer than 3 months, persistent significant hemoptysis, bronchial stenosis, significant bronchiectasis, and massive pulmonary necrosis. The overall outcome of children with lung abscess is very good. Mortality rates are low (approximately 5%) and usually occur in those with secondary abscesses.

## Empyema

***History*** Even during the ancient times of Hippocrates, Paul of Aegina, and Fabricus, empyema was a known complication that followed pulmonary infections and required external drainage for cure. In the 16th century, Paré manually evacuated a putrid hematoma from the pleural cavity of a French soldier.[181] Formal decortications were performed by Kuster in 1889 and Fowler in 1891.[195] Until the antibiotic era, discussions of therapy for empyema largely centered on the relative advantages of open drainage, various types of closed drainage, and the optimal time for the use of these measures.[196]

***Definition and Pathogenesis*** An empyema is the accumulation of purulent fluid in the pleural cavity and complicates pneumonia in 1 of 150 affected children.[197] It may also occur following trauma, neoplastic processes, intrathoracic esophageal perforation, or as a complication of intrathoracic surgery. Normally, the pleural membranes are permeable to liquid, and a small amount of fluid exists between the visceral and parietal pleura to minimize friction during respiration. When the adjacent lung is healthy, the pleural cavity is generally resistant to infection. Empyema, once established, exhibits three characteristic stages[198,199]: (1) an exudative or early stage when the fluid is thin and of low cellular content; (2) an intermediate or fibrinopurulent stage during which large numbers of polymorphonuclear cells and fibrin are deposited in the pleural space, progressively impairing lung expansion and leading to the formation of fluid loculations, and (3) a final stage or organizing empyema during which a thick exudate forms and fibroblasts invade the fibrinous peel. The empyema may be diffuse and involve the entire pleural space or it may be localized and encapsulated in an interlobar, diaphragmatic, or paramediastinal location.

Currently, the most common organisms in childhood empyema are *Streptococcus pneumoniae*, *Staphylococcus aureus,* and *Haemophilus influenzae*.[200] Other streptococci, mixed oral flora, and anaerobes have also been classically associated with the development of empyema. The changes in bacteriology are likely due to changing antibiotic resistance patterns. However, the incidence of empyema may be increasing,[197] and the virulence of the causative organisms appears to impact the natural course and, ultimately, the management of these patients.[201] Tuberculous empyema is much more rare than effusion and is associated with a high bacterial load within the pleural space. Mycobacterial resistance is a problem in this situation because of the poor pleural penetration of standard antitubercular agents.[202]

***Clinical Manifestations and Diagnosis*** The symptoms of empyema in a child include a short history of pulmonary infection, followed by respiratory distress, fever, and cough. Chest or shoulder pain coupled with abdominal pain, distension, and ileus may intensify the respiratory difficulty. The radiographic appearance often includes bilateral pulmonary involvement, with pneumatoceles occasionally identified within the lung. Haziness of a hemithorax may represent either pulmonary consolidation or pleural fluid. In the early exudative phase, the pleural fluid flows freely along the lateral chest wall on decubitus views (Fig. 66-12). In advanced empyema, the exudate is a solid mass of fibrin and does not move with changes in position. In the intermediate fibrinopurulent stage, loculations typically develop (see Fig. 66-12, *C*). Air-fluid levels within the loculations suggest the presence of anaerobes in the pleural contents. Thoracentesis may provide valuable information on the quality of pleural fluid. The progression to advanced-stage empyema may be suspected if the fluid demonstrates any of the following characteristics after diagnostic thoracentesis: (1) gross pus, (2) pH less than 7.0, (3) lactate dehydrogenase greater than 1000 U/mL, (4) glucose less than 40 mg/dL, and (5) bacteria visible on Gram stain.

***Treatment*** Primary therapy for empyema is the administration of high-dose intravenous antibiotics. Effective drainage of the pleural space will accelerate its resolution. Indeed, fluid that layers in the decubitus position on chest radiographs may be amenable to chest tube drainage alone. However, loculated fluid collections may not be sufficiently drained in such a manner, and the optimal management of these patients is still debated. The options for therapy include chest tube drainage alone, fibrinolytic therapy, and VATS.

There appears to be ample evidence demonstrating that both fibrinolytic therapy[203–205] and VATS[206–210] are superior to chest tube drainage alone for loculated empyema. Furthermore, there has been broad acceptance of the use of VATS as the first line of treatment.[197,206] In 2006, Sonnappa and colleagues[211] performed the first prospective randomized control trial, involving 60 children, that compared intrapleural urokinase with VATS. The authors found that the post-intervention length of stay for patients receiving urokinase (6 days, range 4 to 25 days) was similar to the length of stay for VATS patients (6 days, range 3 to 16 days). The failure rates were also similar between groups, with five in the urokinase group and four in the VATS group who were "rescued" by VATS or mini-thoracotomy, respectively. An important conclusion in favor of fibrinolytic therapy was that it was 25% less expensive than VATS. In 2009, St. Peter and colleagues[212] published a similar prospective trial involving 36 patients who were randomized to receive either recombinant tissue plasminogen activator or VATS as primary therapy for empyema. In this study, equivalent lengths of stay, post-therapy oxygen support, days until afebrile after intervention, and analgesia doses were noted

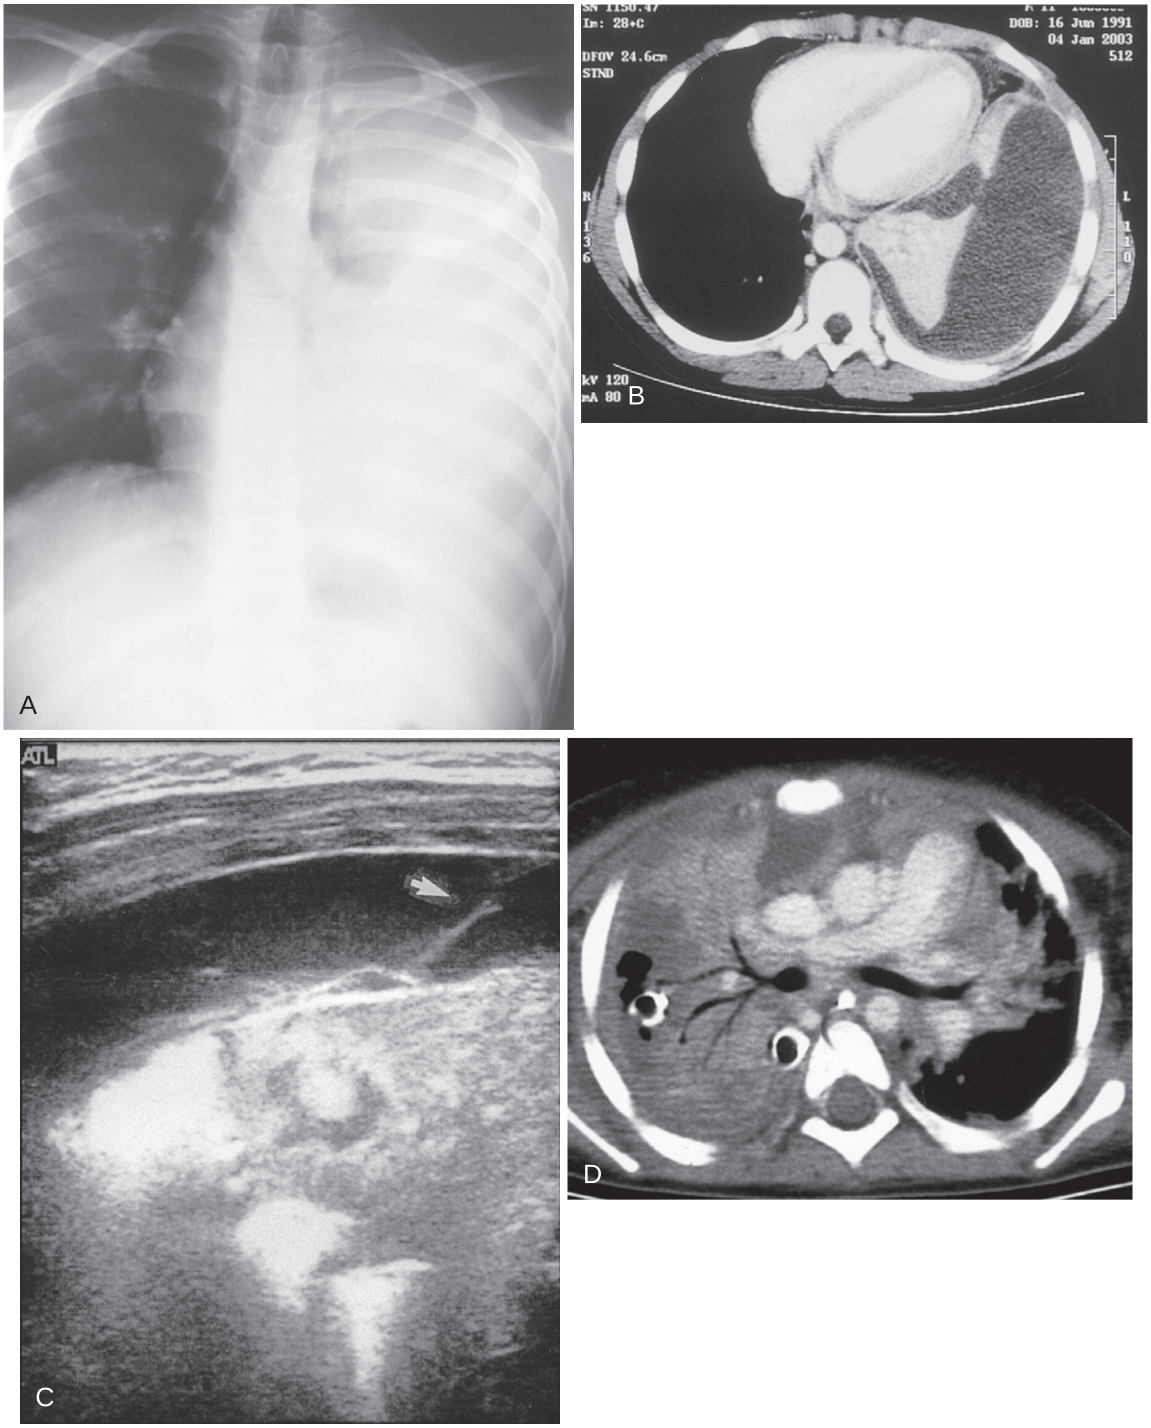

**FIGURE 66-12** **A** and **B,** An 11-year-old boy presented with left-sided pleuritic pain and fever. **A,** Chest radiograph shows a large left-sided effusion with mediastinal shift. **B,** Because of concern about an underlying malignancy, a computed tomography (CT) scan was obtained. This shows a large nonloculated fluid collection with a collapsed lower lobe; fluid can be seen in the fissure. A chest tube was inserted and drained 400 mL of serous fluid, with a lactate dehydrogenase level of 4,000 U/L, thus qualifying it as a fibrinopurulent empyema. There were no bacteria on Gram stain, but cultures grew *Streptococcus pneumoniae*. The patient improved with intravenous antibiotics, and the chest tube was removed 8 days later. **C** and **D,** A 3-year-old girl had a more fulminant course. Loculations *(arrow)* and debris in the pleural fluid were evident on ultrasonography in **C,** Despite early thoracoscopic drainage, she developed lung necrosis—seen on computed tomography with intravenous contrast in (**D**) with a persistent air leak, requiring 10 days in the intensive care unit and 1 month in hospital.

between the groups. The only significant difference was the 35% reduction in hospital charges in those receiving fibrinolysis. Interestingly, these two trials had almost identical study designs and produced results that were strikingly similar, especially with regard to the length of stay postintervention (6 days) and failure rates (16.6% in each trial) of fibrinolysis. Although some criticism has been voiced about the broad applicability of the results of these single-center trials to individual centers (i.e., placement of chest tubes at the bedside), and the rather long period of symptoms (10 days) before intervention,[213] which may have mitigated the benefit of early VATS, the current recommendations for primary therapy in loculated empyema appear to favor fibrinolysis. Importantly, however, the overall excellent outcomes of children with empyema, irrespective of the treatment modality, still complicate the debate regarding the “best” strategy to treat intermediate/advanced empyema and loculated parapneumonic effusions.

Treatment algorithms for pediatric patients with empyema are often institution specific and vary with local expertise and experience. Presently, based on the results of the two prospective randomized trials, St. Peter[212] has suggested an algorithm in which patients with empyema, diagnosed either by the presence of loculations on ultrasonography or greater than 10,000 white blood cells/μl in pleural fluid, should receive three daily doses of recombinant tissue plasminogen activator (4 mg in 40 mL saline) after the insertion of a small chest tube. Should drainage decrease in the absence of clinical improvement, imaging with ultrasonography or CT scan is indicated. In this context, the absence of pleural disease would require the continuation of antibiotics only, while persistent pleural disease would require rescue VATS. A slightly varied approach based on the interval of time from the onset of symptoms has been suggested by the American Pediatric Surgical Association (APSA) New Technology Committee.[213] This algorithm recommends chest tube drainage for simple effusions of less than 5 days duration. For patients with more than 5 days of symptoms, either fibrinolysis or VATS may be used. If symptoms persist more than 7 days after intervention, CT scans are recommended to determine the presence of pleural disease. As with the St. Peter algorithm, antibiotics are only required in the absence of pleural diseases, while persistent loculations are treated with VATS. If VATS is unsuccessful at any point, decortication by thoracotomy is recommended.

# Pediatric Spontaneous Pneumothorax

Primary spontaneous pneumothorax is defined as a pneumothorax occurring secondary to apical blebs (<2 cm) or bullae (>2 cm) without evidence of other lung pathology.[214,215] It can also occur in term neonates without any risk factors. In contrast, secondary spontaneous pneumothoraces occur in the context of underlying lung disease, such as cystic fibrosis or *Pneumocystis jirovecii* pneumonia. Other lung infections, bronchiolitis, asthma (even mild), connective tissue disorders, congenital cystic adenomatoid malformations, and traumatic lung contusions are other risk factors.[215–217] The incidence of primary spontaneous pneumothorax is estimated to be 7.4 to 18 per 100,000 boys and 1.2 to 6 per 100,000 girls in the United States.[218,219] Typically, the patient is a thin, lean adolescent who presents with an acute onset of ipsilateral pleuritic chest pain and nonproductive cough. Most patients are clinically stable upon initial assessment. However, a small number may present in fulminant distress, including hypotension and respiratory failure, secondary to a tension pneumothorax. Other clinical findings in patients with pneumothorax include tachypnea and tachycardia. Chest radiographs confirm the diagnosis and may identify underlying pathology within the lung. Expiratory films may be helpful to identify small pneumothoraces. Different methods are available to quantitate the size of the pneumothorax, because this factor is most likely to influence subsequent management. These include the Light,[220] the Rhea[221] and the Collins methods.[222] The Light method, using only a posteroanterior (PA) radiograph, has been endorsed by the British Thoracic Society,[223] but it is unclear exactly where the measurements should be taken. The Rhea method does possess standardized measurement points, but it requires both PA and lateral radiographs for calculation. The Collins method has been developed using helical CT scans of the chest, and like the Light method, can be calculated based on a single PA chest radiograph. However, like the Rhea method, it has not been validated for digital images. Furthermore, although the Collins method appears to be the most accurate, it needs further validation.[224] There are also differing definitions of “large” pneumothoraces. The British Thoracic Society describes these as greater than 2 cm of separation between the lung and the entire lateral chest wall, but this does not account for those located at the apex.[223] The American College of Chest Physicians,[225] however, describes large pneumothoraces as greater than 3 cm of apical distance but does not account for those pneumothoraces that are more equivalently distributed. A combination of both definitions likely seems appropriate.[224]

Patients who present with an acute pneumothorax require supplemental oxygen and intravenous access. For those few patients presenting with a tension pneumothorax, immediate needle decompression in the second intercostal space (midclavicular line) is necessary even before chest radiograph confirmation, followed by the prompt placement of a chest tube. A pneumothorax of less than 15% can often be managed by observation with or without supplemental oxygen, especially if the initial symptoms occurred more than 24 hours before presentation. Needle aspiration is emerging as a first-line therapy in adults with large, asymptomatic pneumothoraces or small symptomatic ones[224] and this strategy has been endorsed by the British Thoracic Society.[223] However, pediatric data are sparse,[224] and the Delphi Consensus Statement from the American College of Chest Physicians (2001) does not support the routine use of needle decompression in this instance.[225] Heimlich valves connected to the pleural drain allow for outpatient management of small pneumothoraces in compliant patients. Large pneumothoraces require the placement of a chest tube with underwater seal and drainage. An air leak that persists for more than 5 to 7 days may require further intervention, or at least confirmation that the chest tube in place is functioning properly.[226] For most young children (<8 years of age), and those with asthma as a predisposing factor, chest tube drainage is sufficient for treatment. However, adolescents with spontaneous pneumothorax have been reported to have a recurrence rate of up to 40% to 60%.[214,227] Interestingly, in one adult series, large drains were associated with a higher recurrence rate of pneumothorax

(33%) than either observation alone (17%) or small-bore chest tubes (6%).[228] In the end, symptomatology should direct further investigation and treatment. Computed tomography scans are more sensitive at detecting blebs and bullae than normal radiographs, but it is unclear if their routine use for spontaneous pneumothorax ultimately changes management. Some adult series have identified blebs and bullae in up to 56% to 88% of adults with spontaneous pneumothorax.[229,230] However, a recent series identified a much lower rate of blebs (28%), with none identified in the control group, in a series of 43 adolescents from 13 to 19 years of age.[231] These lesions were always located at the lung apices. This series also identified *contralateral* blebs and bullae in 78% of patients with pneumothorax. Furthermore, blebs and bullae are not to be confused with "apical lines," which occur in 56% of patients with pneumothorax and 28% of controls, and could represent normal variants in the apices of the lung.[231] Some authors advocate the use of computed tomography after the index presentation, while others wait for a recurrence before further investigation.[215,224] Ouanes-Berbes and colleagues[232] reported a 19% recurrence rate over 7 years in young adults (17 to 27 years of age) who had an incidence of blebs/bullae of 72%. However, there is still equipoise regarding the role of imaging, especially the indications for and timing of CT scans, in spontaneous pneumothorax.

The indications for surgical management include recurrence, persistent air leak, bilateral disease, and possibly the presence of large bullae. Video-assisted thoracoscopic surgery appears to be superior to standard thoracotomy with respect to postoperative pain and complications.[227,233] Transaxillary mini-thoracotomy is a viable alternative to VATS and has certain advantages, particularly in the context of poor visualization and the presence of dense adhesions.[215,234] For pleurodesis, thoracoscopic pleural abrasion is effective.[227,233] Talc poudrage has also been used with success, but some caution against it because of the small but clinically significant risk of respiratory distress associated with its use.[235] Apical pleurectomy can be easily performed through a transaxillary incision and is another effective method for pleurodesis, especially in the context of recurrence. For bilateral disease, both VATS and transaxillary mini-thoracotomy are effective and can be used as a single-stage operation.[215] Despite similar results in outcome, VATS has become more popular among surgeons for the treatment of spontaneous pneumothorax, even though some controversy persists. Recurrence rates in VATS have been linked to experience with this technique.[236] The overall recurrence rate of pediatric spontaneous pneumothorax treated nonoperatively approaches 50% to 60%,[224,237] but those managed operatively have recurrence rates between 6% to 9%.[214,238] For transaxillary mini-thoracotomy, the recurrence rate has been reported to be equivalent.[224] All in all, both VATS and transaxillary thoracotomy are effective in the treatment of spontaneous pneumothorax. Furthermore, the guidelines for the treatment of spontaneous pneumothorax are often extrapolated from adult series and randomized trials in the pediatric population are clearly warranted.

Pneumothoraces in patients with cystic fibrosis are more difficult to treat, because the air leak frequently persists. The use of a higher negative pressure (20 to 25 cm $H_2O$) may be helpful. If this fails, thoracoscopic talc poudrage[239] or other sclerosing agents[240] are required to achieve pleurodesis and prevent recurrence. Pleurectomy is usually avoided to facilitate pneumonectomy should lung transplantation become necessary.

# Intrathoracic Access and Procedures

## CHEST TUBE INSERTION IN THE NEWBORN FOR PNEUMOTHORAX

In preparation of chest tube insertion, the infant is placed in an oxygen hood or, if intubated, maintained on ventilator support, restrained, and monitored by pulse oximetry and electrocardiogram. A surgical headlight or an overhead light source of similar quality should be available. The procedure is performed with sterile technique (mask, cap, gown, and gloves). In addition to sterile instruments (scalpel, mosquito clamps, Adson forceps, needle holder, fine scissors) and drapes, 8- and 10-Fr catheters, a sterile connector, 3-0 and 4-0 nonabsorbable suture on curved swaged-on needles, and an infant-sized underwater seal drainage system should be readily available. The chest wall is prepared with chlorhexidine or an iodophor solution and draped with sterile towels. The skin is infiltrated with lidocaine through a 25-gauge needle placed lateral to the nipple in the anterior axillary line over the fourth rib. Injury to the nipple and underlying breast tissue should be avoided. A 3- to 4-mm incision is made with a No. 11 scalpel blade. A mosquito clamp is placed through the incision and used to spread the subcutaneous tissues. It is advanced upward over the rib and used to spread the intercostal muscles above the incision, which requires firm pressure, and then passed into the pleural cavity. This method produces a "tunnel" so that the entrance into the pleural cavity is superior to the level of the skin incision. Entry into the pleural space is heralded by reduced resistance and is usually followed by the sound of escaping air. The tip of the 8-Fr chest tube is placed in the end of the curved mosquito clamp, and the tube is advanced into the pleural cavity (Fig. 66-13). An alternative is to use a trocar inside the chest tube to guide the latter through the tunnel. With this technique, it is safer to withdraw the tip of the trocar by a few millimeters and to place a large clamp on the tube 5 cm proximal to the tip to avoid uncontrolled penetration and injury to the mediastinal structures. The tube is advanced superiorly and anteriorly 3 to 4 cm, being certain that all of the holes in the tube are intrapleural, yet avoiding a tube that is too far and kinks after reaching the mediastinum. The tube is then sutured in place with a 3-0 nonabsorbable purse-string suture. Povidone (Betadine) ointment is placed at the tube–skin interface, and the tube is secured. The connecting tube is attached to an underwater seal, and the water level is observed to ensure fluctuation with respiration. The system may be set at 10 cm of water of negative pressure if necessary, remembering that a high negative pressure will add to the positive pressure applied by a ventilator, and may lead to barotrauma. A disposable infant Pleur-evac system (Teleflex, Research Triangle Park, NC) is highly effective and easily managed in the neonatal intensive care unit (NICU).

A chest radiograph is obtained to determine the location of the tube, to ensure that all the holes are intrapleural, and to check that tube placement was effective in expanding the

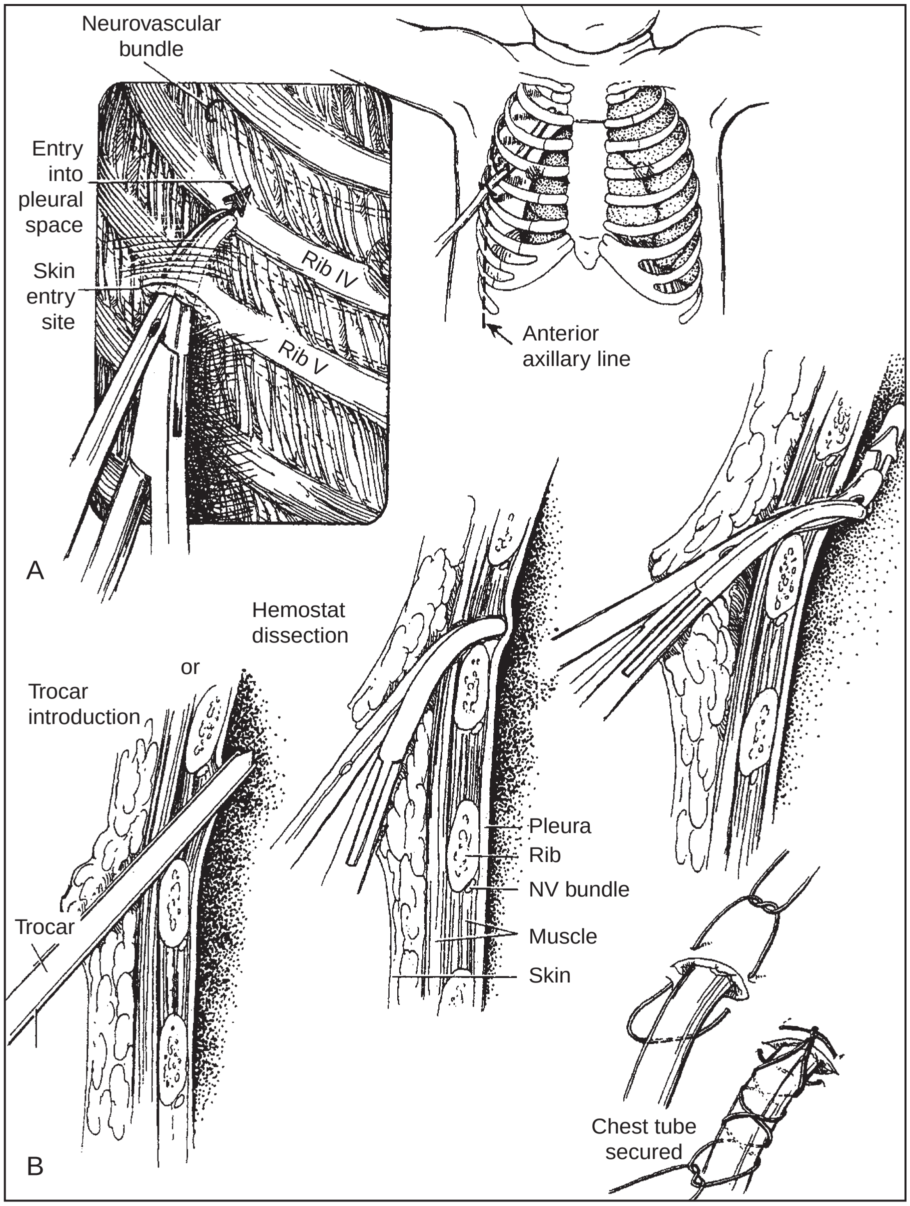

**FIGURE 66-13** Chest tube insertion in the newborn for pneumothorax. **A,** Preferably, a small hemostat is inserted through a small incision in the anterior or midaxillary line and is tunneled upward, entering the chest above the next rib. The chest tube is tunneled upward, entering the chest above the next rib. The chest tube is inserted and secured with a suture ligature. Several knots should be placed after each circumferential pass of the thread to avoid any slippage. **B,** A trocar can be used as an alternative method of tube insertion, as long as the trocar is withdrawn by a few millimeters within the tube; this technique allows easier guidance of the tube, for example, if it has to be placed posteriorly and inferiorly to drain an effusion.

collapsed lung. A lateral chest radiograph may be obtained to determine whether the tube is in an anterior or a posterior location. A superior and anteriorly placed tube most effectively evacuates pneumothorax. Excessive bubbling indicates a continued source of air leak from the injured lung, a bronchopulmonary fistula, or a leak in the system.

The most frequent complications related to chest tube insertion are (1) injury to the intercostal vessels during insertion and (2) lung perforation caused by the clamp or tube. If there is excessive bleeding and continued significant air leak, surgical correction is required. Injury to mediastinal lymphatic, venous, and nervous structures have also been described.

Kits are available that allow the Seldinger technique to be used to rapidly and safely place a small chest tube in infants. A needle is inserted in the pleural cavity and a guidewire passed. The needle is removed and a dilator passed over the wire, followed by a pigtail catheter.

## CHEST TUBE CARE AND REMOVAL

Following insertion for pneumothorax a chest tube usually drains little fluid after the air is evacuated. In babies who do not require mechanical ventilation, when there is no further bubbling in the water seal chamber and the lung is fully expanded for 24 to 48 hours, the suction, if used, is removed and the tube left only on an underwater seal. If the pneumothorax does not reaccumulate in 12 to 24 hours, it is probably safe to remove the tube. The tube should be removed rapidly and the tube site sealed with petroleum gauze dressing to prevent air from entering the chest. An additional chest radiograph is usually obtained to be sure that there is no recurrence of the pneumothorax. It is probably safer to leave the chest tube in place for longer periods if the infant requires mechanical ventilation, especially if high peak-inspiratory pressure and/or positive end-expiratory pressure are necessary.

## CHEST TUBE INSERTION IN OLDER CHILDREN

Pneumothorax in older children is usually encountered in patients with spontaneous rupture of a bleb, asthma, cystic fibrosis, and following blunt, or, occasionally, penetrating chest wall trauma. A tube thoracostomy is required in symptomatic patients. Chest tube insertion in older infants and children may also be required for pleural effusions from a variety of causes, including chylothorax, traumatic hemothorax, lymphoma, inflammation as a result of bacterial, fungal, and viral pneumonia, empyema, and other causes.

Insertion of a chest tube in these patients follows the same pattern of sterile techniques and preparation described in the management of neonates. Infants and toddlers can be premedicated with intravenous fentanyl (1 μg/kg) and midazolam (0.1 mg/kg) as part of a conscious sedation protocol. Alternatively, ketamine (1 mg/kg) with or without midazolam provides excellent analgesia and sedation while preserving respiration reflexes and cardiac parameters throughout the duration of the procedure. Children are kept in the supine position with a small roll under the affected hemithorax to elevate the area. The ipsilateral arm is positioned superiorly and laterally. The chest tube size is determined by the child's weight and whether the problem is a pneumothorax, a transudate, or an exudate (Table 66-1), although the recent trend has been to use smaller-caliber tubes, even for empyema drainage. After sterile preparation, a local anesthetic, and placement of a small skin incision, the appropriate-sized tube is inserted in the third or fourth interspace in the anterior to midaxillary line and positioned upward and anteriorly for pneumothorax. If the patient has an effusion, the location should be determined by correlating the physical examination (e.g., dullness to percussion and diminished tactile fremitus) with the findings on chest radiograph, ultrasonography, and/or chest computed tomography. A 20-gauge needle or angiocatheter may be inserted just at the level of transition of percussion sounds (from tympanic to dull) to locate the effusion. The chest tube can then be inserted as noted earlier and positioned inferiorly and posteriorly. The chest tube should not be placed below the level of the seventh rib to avoid injury to the spleen, liver, or diaphragm.

**TABLE 66-1**

| | Size (French) | | |
|---|---|---|---|
| *Patient Weight (kg)* | *Pneumothorax* | *Transudate* | *Exudate* |
| <3 | 8-10 | 8-10 | 10-12 |
| 3-8 | 10-12 | 10-12 | 12-16 |
| 8-15 | 12-16 | 12-16 | 16-20 |
| 16-40 | 16-20 | 16-20 | 20-28 |
| >40 | 20-24 | 24-28 | 28-36 |

## LUNG BIOPSY

Open lung biopsy is usually obtained early in the diagnostic evaluation of diffuse pulmonary disorders in children and is generally preferred to a percutaneous transthoracic needle biopsy for establishing the diagnosis. Needle lung biopsies are fairly reliable and accurate; however, pneumothorax or hemothorax occur in approximately one third of patients. Larger specimens are obtained by open lung biopsy for cultures and histologic study as well as special staining, and occasionally for electron microscopy. It is easier to avoid air leaks and to secure complete hemostasis with a wedge biopsy. Pneumothorax is prevented by the routine use of a chest tube. The mortality after surgery is rarely a result of the procedure; death, when it occurs, is almost always caused by the patient's underlying disease. A tissue diagnosis is established in almost all patients after open or thoracoscopic lung biopsy and influences subsequent therapy in greater than 90%.[130] The preoperative diagnosis is confirmed in approximately 60% of patients and corrected in greater than 35%. Moreover, the differential diagnosis is often between infectious, neoplastic, or inflammatory processes, such as bronchiolitis obliterans with organizing pneumonia (BOOP) or lymphoid interstitial pneumonitis. Because the latter require tissue for diagnosis and are treated with steroids, a lung biopsy is essential to confirm diagnosis (Fig. 66-14, see Fig. 66-6).

Children who must undergo lung biopsy may be poor risks for surgery and anesthesia. They are often immunosuppressed with spreading pulmonary infiltrates and impending respiratory

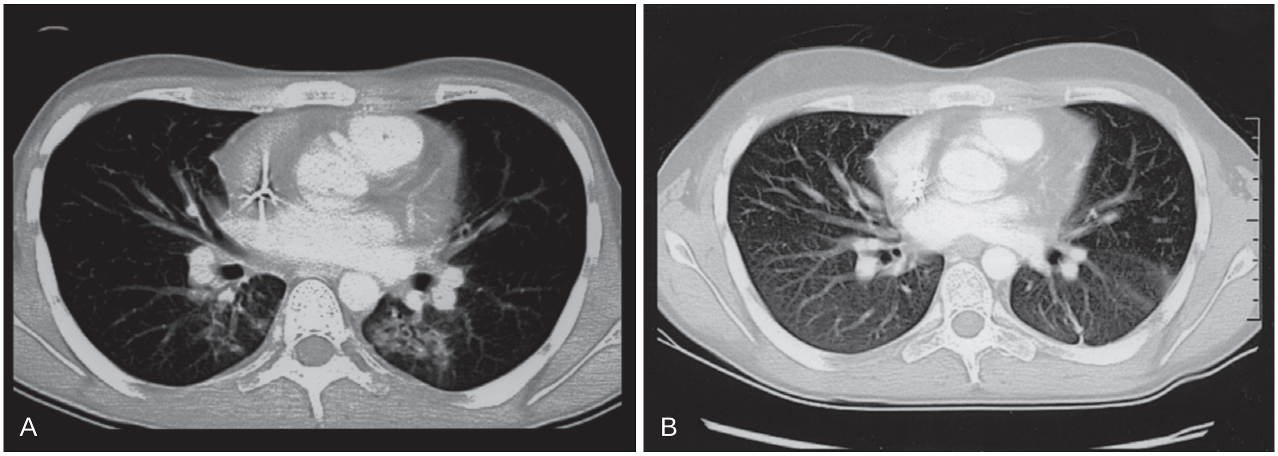

**FIGURE 66-14** A 17-year-old child with stage IV Hodgkin disease underwent radiotherapy and autologous bone marrow transplantation. **A,** On routine surveillance computed tomography, bilateral focal airspace disease was seen, mostly in the superior segments of the lower lobes. Lung biopsy revealed bronchiolitis obliterans. He was treated with steroids, and a repeat scan 3 months later (**B**) showed a near-complete resolution.

failure. Biopsy should be performed early, when indicated, rather than after respiratory failure has supervened and the child is dependent on a ventilator. However, even for patients with persisting or undiagnosed respiratory failure, lung biopsy still leads to significant changes in management despite a higher incidence of complications, mainly as air leak (45%). Careful preoperative review of chest roentgenograms is essential to identify the optimum site for biopsy; sometimes two different areas should be biopsied, one heavily infiltrated and the other less involved. Preoperative discussion with the pathologist is invaluable. A small anterior thoracotomy incision with the biopsy performed using a stapler device is safe and expeditious; in smaller children, a Lahey clamp allows an adequate biopsy specimen through a smaller incision, especially if the lung parenchyma is stiff and cannot be brought out through the incision (Fig. 66-15). Alternatively, a transaxillary incision may provide adequate access to lung tissue desired for lung biopsy. In experienced hands, there is minimal mortality or morbidity from open lung biopsy, in spite of the patient population. In patients large enough to allow the use of endoscopic stapling devices, lung biopsy can also be performed by thoracoscopy, with similar risks and complications to the open procedures.

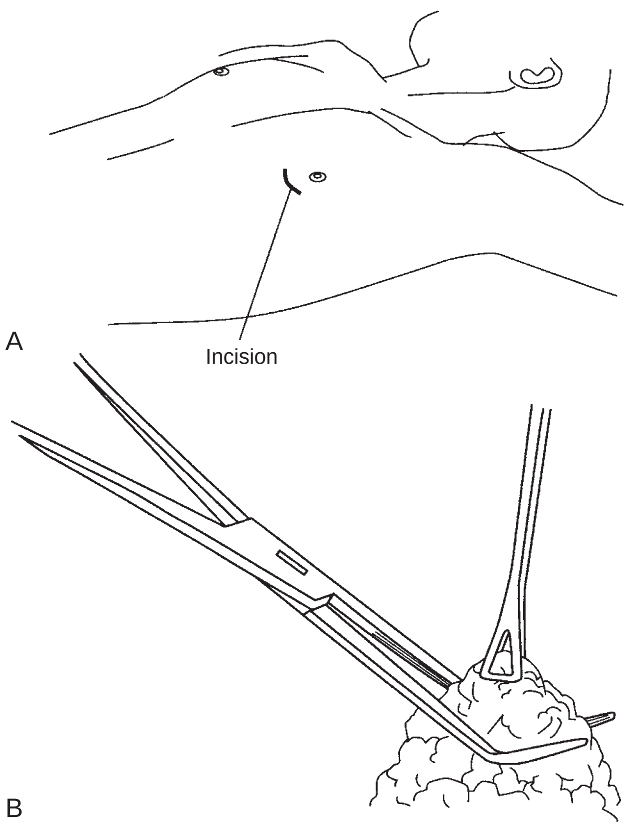

FIGURE 66-15 **A,** An open lung biopsy can be done with minimal morbidity using a small anterior thoracotomy. **B,** The lingula can be grasped easily and provides an adequate specimen in patients with diffuse lung infiltrate; in small children (or when a stiff lung cannot be brought outside the chest wall) a Lahey clamp is used to obtain the biopsy specimen instead of a linear stapler. After the lung tissue above the Lahey clamp is cut sharply with a scalpel, a continuous U suture is passed underneath the clamp, the clamp is released, and the suture is tightened and brought back as a simple continuous stitch. This provides excellent hemostasis and prevents air leaks.

# Chylothorax

The escape of chyle into the mediastinum from a defective thoracic duct, and thence into one or both pleural spaces, is a well-described entity. Historical perspectives on chylothorax and its management include the evolution of the knowledge of anatomy and physiology of the thoracic duct, the development of the science of nutrition, and progress in thoracic surgery. Of note, in 1937, Blalock reported that the experimental occlusion of the superior vena cava could produce chylothorax, which was prevented by prior ligation of the thoracic duct.[241] A decade later, Lampson was the first to use this treatment clinically.[242] Considerations of therapy focus on causative factors and include dietary modification and octreotide to decrease thoracic duct flow; thoracentesis and/or thoracostomy drainage to relieve respiratory embarrassment and promote pleural sealing; and surgical ligation of the disrupted duct, pleurodesis, or pleuroperitoneal shunting when conservative measures fail.

## ETIOLOGY

Effusion of chylous fluid into the thorax may occur spontaneously in newborns and has usually been attributed to congenital abnormalities of the thoracic duct or trauma from delivery.[243] However, the occurrence of chylothorax in most cases cannot be related to the type of labor or delivery, and lymphatic effusions may be discovered prenatally.[244,245] Chylothorax is the leading cause of pleural effusions in neonates.[246]

Chylothorax in older children is rarely spontaneous and occurs almost invariably after trauma or cardiothoracic surgery, with the latter having an incidence of 0.85% to 6.6%.[247–249] Some patients with thoracic lymphangioma may also present in this older age group (Fig. 66-16).[250] Operative injury may be in part a result of anatomic variations of the thoracic duct. Trauma leading to hyperextension of the spine with rupture of the duct from stretching has been reported with high diving, wrestling, and other such

FIGURE 66-16 Chest radiograph of 4-year-old girl with bilateral extensive lymphangioma and chylothorax. Note hazy appearance of fluid and major compression of the left lung.

activities.[247] Chylothorax has also been observed in "nonaccidental trauma" and mistaken for spontaneous chylothorax.[251] Extensive bouts of coughing may also lead to thoracic duct rupture, which is particularly vulnerable when full following a fatty meal. Neoplasms, particularly lymphomas and neuroblastomas, have occasionally been noted to cause obstruction of the thoracic duct. Lymphangiomatosis or diffuse lymphangiectasia (such as seen in Gorham disease and other syndromes) may produce chylous effusion in the pleural space and peritoneal cavity. Other causes include mediastinal inflammation, increased central venous pressure, subclavian vein or superior vena caval thrombosis, and misplaced central venous catheters.[247]

## ANATOMY AND PATHOPHYSIOLOGY

The thoracic duct develops from outgrowths of the jugular lymphatic sacs and the cisterna chyli. During embryonic life, bilateral thoracic lymphatic channels are present, each attached in the neck to the corresponding jugular sac. As development progresses, the upper third of the right duct and the lower two thirds of the left duct involute and close. The wide variation in the final anatomic structure of the main ductal system attests to the multiple communications of the small vessels comprising the lymphatic system. The thoracic duct originates in the abdomen at the cisterna chyli located over the second lumbar vertebra (Fig. 66-17). The duct extends into the thorax through the aortic hiatus and then passes upward into the posterior mediastinum on the right before shifting toward the left at the level of the fifth thoracic vertebra. It then ascends posterior to the aortic arch and into the posterior neck to the junction of the subclavian and internal jugular veins.

Many variations are present in the entire ductal system, and the typical course of the thoracic duct is present in only approximately 35% to 50% of individuals.[252,253] The most common variations are a double system originating from the cisterna or a multiple ductal pattern at the level of the diaphragm. In the chest, a rich collateral system originates from intercostal spaces, the posterior mediastinum, and visceral lymphatics, which communicate freely with the main duct through collecting trunks.

The thoracic duct contains smooth muscle in the wall that is capable of contracting with sufficient force to propel lymph upward toward the jugular venous junction at a rate of 50 to 200 mL/hour.[254] The rate of lymph flow in the thoracic duct varies widely and relates to the volume of fat ingestion, scar tissue in the mediastinum, presence of portal hypertension, and other factors. The flow of chyle superiorly into the subclavian vein is enhanced by the presence of valves in the thoracic duct, portal pressure, and the differential gradient between the negative intrapleural pressure and the positive intra-abdominal pressure.[241,255] Conversely, increasing the intrathoracic pressure through the use of positive end-expiratory pressure has been shown to decrease the flow of chyle by half in the thoracic duct.

The chyle contained in the thoracic duct conveys approximately three fourths of the ingested fat from the intestine to the systemic circulation. The fat content of chyle varies from 0.4 to 6.0 g/dL.[247] The large fat molecules absorbed from the intestinal lacteals flow through the cisterna chyli and superiorly through the thoracic duct.[256] Total protein content of thoracic duct lymph is also high. Nutritional complications were a major source of mortality from chylothorax in the era preceding parental nutrition. Other than nutrients, the thoracic duct carries white blood cells, primarily lymphocytes (T cells)—approximately 2,000 to 20,000 cells/mL. Eosinophils are also present in higher proportion than in circulating blood. Loss of lymphocytes through a thoracic duct fistula may lead to an immunocompromised state[255]; in fact, external drainage of the thoracic duct was used as an adjunct to immunosuppression in the early era of organ transplantation. Chyle appears to have a bacteriostatic property, which accounts for the rare occurrence of infection complicating chylothorax.

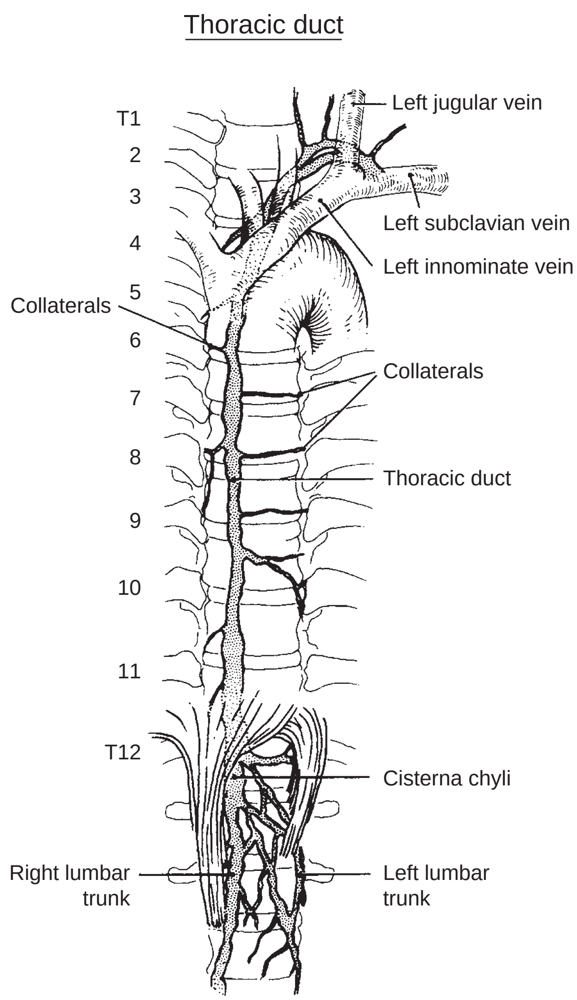

**FIGURE 66-17** Schematic representation of most common anatomic arrangement of the thoracic duct. (From DeMeester R, Lafontaine E: The pleura. In Sabiston DC, Spencer FC (eds): Gibbon's Surgery of the Chest, ed 4. Philadelphia, WB Saunders, 1983. Reprinted with permission.)

## CLINICAL MANIFESTATIONS

Birth trauma was formerly thought to be the cause of many neonatal chylothoraces, but the increasing use of prenatal ultrasonography has changed this perspective. Noniatrogenic chylothorax occurring in young children is usually related to congenital anomalies of the chyliferous vessels, cisterna chyli, or the thoracic duct itself. Most of these chylothoraces result from intrapleural leakage from dilated and thin-walled intercostal, diaphragmatic, or accessory mediastinal lymphatics. When there is lymphatic

overload, these alternate lymphatics may dilate considerably to eventually become transudative lymphatic varices. In other cases, subpleural lymphatics may rupture into the pleural cavity, as in certain cardiac anomalies (e.g., total anomalous pulmonary venous return).

The accumulation of chyle in the pleural space from a thoracic duct leak may occur rapidly and produce pressure on other structures in the chest, causing acute respiratory distress, dyspnea, and cyanosis with tachypnea. In the fetus, a pleural effusion may be secondary to generalized hydrops but a primary lymphatic effusion (idiopathic, secondary to subpleural lymphangiectasia, pulmonary sequestration or associated with syndromes, such as Down, Turner, and Noonan) can cause mediastinal shift and result in hydrops or lead to pulmonary hypoplasia.[244,245] Postnatally, the effects of chylothorax and the prolonged loss of chyle may include malnutrition, hypoproteinemia, fluid and electrolyte imbalance, metabolic acidosis, and immunodeficiency.[257]

In a neonate, symptoms of respiratory embarrassment observed in combination with a pleural effusion strongly suggest chylothorax. The involved side presents characteristic findings of intrapleural fluid with respiratory lag, dullness on percussion, diminished breath sounds, and shift of the mediastinum. Fever is not common. Chest roentgenograms typically show massive fluid effusion in the ipsilateral chest with pulmonary compression and mediastinal shift. Bilateral effusions may also occur. Aspiration of the pleural effusion reveals a clear straw-colored fluid in the fasting patient, which becomes milky after feedings. Analysis of the chyle generally reveals a total fat content of more than 400 mg/dL (or triglyceride level greater than 110 mg/dL) and a protein content of more than 5 g/dL. In a fetus or a fasting neonate, the most useful and simple test is to perform a complete cell count and differential on the fluid; when lymphocytes exceed 80% or 90% of the white blood cells, a lymphatic effusion is confirmed; the differential can be compared with that obtained from the blood count, where lymphocytes rarely represent more than 70% of white blood cells.

Most cases of traumatic chylothorax develop after thoracic operations, in particular, surgery for congenital heart disease.[247] Injury to the thoracic duct in the left chest is also common during secondary thoracotomies for correction of lesions in the descending aorta or esophagus just inferior to the arch. If lymphatic drainage is noted at operation, the proximal and distal ends of the thoracic duct should be ligated.[258] A period of days or weeks may elapse between trauma or surgery and the development of a symptomatic chylothorax.

As chyle accumulates in the pleural space from a thoracic duct leak, progressively more pronounced respiratory symptoms develop as pulmonary compression becomes more severe. Dyspnea, tachypnea, and, eventually, arterial desaturation with cyanosis can develop. Nutritional deficiency is a late manifestation of chyle depletion and occurs when dietary intake is insufficient to replace the thoracic duct fluid loss.

## THERAPY

Whereas small quantities of short-chain fatty acids are absorbed through the portal venous circulation, 80% to 90% of all fat absorbed from the gut is transported by way of the thoracic duct in the form of chylomicrons. Thus feedings restricted to medium- or short-chain triglycerides theoretically result in reduced lymph flow in the thoracic duct and may enhance spontaneous healing of a thoracic duct fistula.[247] However, it has been shown that any enteral feeding, even with clear fluids, significantly increases thoracic duct flow.[259] Therefore for patients who experience large chylous fluid losses, withholding oral feedings and providing total parenteral nutrition (TPN) is preferred as the initial treatment.[249] For patients who are already on mechanical ventilation, the addition of positive end-expiratory pressure can further decrease the lymphatic flow. First described by Ulibarri and colleagues in 1991,[260] somatostatin, or its analog octreotide, has been found useful in treatment of pediatric chylothorax in several reports.[261–264] These agents decrease gastric, pancreatic, and intestinal secretions and have become an important tool in the management of pancreatic and intestinal fistulae. Because of its short half-life, somatostatin requires a continuous intravenous infusion,[265] while the synthetic analog octreotide can be given subcutaneously every 8 hours, starting at a dose of 10 to 20 μg/kg/day.[262] Octreotide infusions may also be used, with dose ranges between 0.5 μg/kg/hour to 50 μg/kg/hour.[266] It has also been used as a rescue after failed surgery,[261] and even as the first-line treatment without diet modification.[266] The response to octreotide has been observed as early as 2 days after the initiation of therapy. In a recent systematic review by Roehr and colleagues,[266] patients given a continuous infusion of octreotide had a median time of treatment of 7 days compared with 17 days for those patients receiving it subcutaneously. If nonoperative management is effective, enteral intake should be reinstituted first with medium-chain triglycerides, followed by a normal diet for age after 2 weeks. Cultures of chylous fluid are rarely positive and providing long-term antibiotics during the full course of chest tube drainage is not considered necessary.

Thoracentesis is used for diagnosis and may be sufficient to relieve spontaneous chylothorax in occasional infants with the dietary measures described. However, chest tube drainage will be necessary for the majority. Further, drainage allows for daily quantification of the chyle leak and promotes pulmonary reexpansion, which may enhance healing. Chylothorax in newborns usually ceases spontaneously,[244] but octreotide has also been shown to be effective.[267] Because identifying the actual site of the fluid leak is difficult, surgery is often deferred for several weeks. Similarly, most cases of traumatic injury to the thoracic duct can be managed successfully by chest tube drainage and replacement of the protein and fat loss.[258] If drainage persists in quantities beyond the tolerance of the infant or child and shows no evidence of diminishing, or if it persists after 2 to 3 weeks without decreasing, ligation of the thoracic duct on the side of the effusion may be necessary. Standard contrast lymphangiography has been abandoned, but lymphoscintigraphy using technetium-99m colloid or other markers may be helpful in identifying the site of the fistula, because it is more technically feasible in children and does not expose them to radiation.[268,269]

Occasionally, the chylous fluid may enter the pericardial sac and cause chylopericardial tamponade, in which case pericardiocentesis should provide immediate relief.[258] Although bilateral spontaneous chylothorax in newborns is uncommon, it can produce fatal respiratory distress unless recognized and drained promptly.

When chylothorax remains resistant despite prolonged chest tube drainage and TPN, thoracotomy or thoracoscopy

on the ipsilateral side may be necessary. The decision whether to continue with conservative management or to undertake surgical intervention should be based on the nature of the underlying disorder, the duration of the leak, the daily volume of fluid drainage, and the severity of nutritional and/or immunologic depletion. Several authors have suggested that patients in whom the chest tube drains more than 100 mL/year of age/day or 10 mL/kg/day, without slowing down after 10 to 20 days, should undergo surgery.[258,259,269a] Although this is not an absolute indication, one should remember that the loss of lymphocytes can lead to overwhelming bacterial or fungal infections, and explains the majority of deaths from chylothorax in the current era.[270] Others suggest that persistent drainage for more than 3 weeks despite maximal medical therapy is another indication for surgical intervention. The identification of the thoracic duct and the fistula may be facilitated by the ingestion of 60 mL of table cream 30 minutes before surgery. When identified, the draining lymphatic vessel should be suture ligated above and below the leak with reinforcement by a pleural or intercostal muscle flap. Meticulous dissection of the thoracic duct with isolation of the fistula is often not feasible. When a leak cannot be identified with certainty, or when multiple leaks originate from the mediastinum, ligation of all the tissues surrounding the aorta at the level of the hiatus provides the best results. Pleurectomy is another option. Fibrin glue and argon-beam coagulation have also been used as an adjunct for ill-defined areas of leakage or incompletely resected lymphangiomas.[271]

Thoracoscopy has been used in larger patients to avoid thoracotomy.[272,273] The leak, if visualized, can be ligated, clipped, or sealed with fibrin glue. If the leak cannot be identified, pleurodesis can be accomplished with talc or other sclerotic agents under direct vision through the thoracoscope, but this technique should be used cautiously in infancy because of the potential consequences on lung and chest wall growth. If there is concomitant chylopericardium, a pericardial window can be fashioned. Because thoracoscopy is less invasive, some surgeons advocate early intervention, as early as 5 to 10 days. This approach may be indicated in conditions where the failure rate of conservative management is higher, such as superior vena cava thrombosis or problems associated with increased central venous pressures.

Pleuroperitoneal shunts have been used for refractory chylothorax in which a leak has not been identified and in those patients who do not respond to initial nonoperative management, especially if they have a higher operative risk.[274–276] This approach has been used with occasional success both in patients with congenital anomalies of the thoracic duct or lymphangiomas, or in patients who have persistent drainage after cardiac surgery.[277] A Denver double-valve shunt system is the type most commonly used; it may be implanted under local anesthesia and allows the patient or parent to pump the valve to achieve decompression of the pleural fluid into the abdominal cavity, where it is reabsorbed. An externalized pumping chamber was found to be superior in smaller babies.[275] It may offer the least invasive treatment for neonates or infants who develop a refractory chylothorax after surgery for complex cardiac malformations, as long as right heart pressures are less than 25 cm $H_2O$.

Overall, most patients with chylothorax can be cured with conservative measures, nutritional support, and occasional operative intervention. Patients with diffuse lymphatic malformations remain a challenge.

# Mediastinal Infections

## ACUTE MEDIASTINITIS

Acute mediastinitis occurs as a result of contamination and/or soilage of the mediastinal space secondary to the trauma or perforation of either the trachea or esophagus. Furthermore, mediastinitis can develop from a descending retropharyngeal or cervical abscess[278] or the rupture of suppurative mediastinal lymph nodes. Infection within the mediastinum can disseminate quickly, because this space contains no anatomic barriers to the spread of infection. Clinically, acute mediastinitis is heralded by high fever, chest pain, dyspnea, cyanosis, marked tachycardia as well as a significant leukocytosis. In neonates, the signs and symptoms may be subtle, including lethargy, fever, apnea, temperature instability, and leukopenia. The management of mediastinitis includes hemodynamic support, the prompt administration of intravenous antibiotics, and mediastinal drainage. Drainage may be particularly important in the context of a mediastinal abscess or continued leak/contamination from a perforated esophagus. Cervical, transthoracic, retropleural, or anterior approaches may be used to facilitate drainage, depending upon the location of abscess or leakage.

## INFECTIONS AFTER MEDIAN STERNOTOMY

Although the incidence of sternal wound and mediastinal infections after median sternotomy is low, these infections can have devastating implications on the postoperative course of these patients. In adult series, sternal wound infections have been shown to occur in up to 20% of patients, while the incidence of mediastinitis ranges from 1% to 3%.[279] Barker and colleagues noted an incidence of mediastinitis of 0.3% when reviewing 30,078 pediatric cardiac cases from 48 centers.[280] The most common infective organisms included *Staphylococcus* species, including methicillin-resistant organisms.[281] Other organisms included *Pseudomonas* and *Candida*. Deep sternal infections may also be caused by gram-negative enteric flora and anaerobes. Several risk factors for the development of poststernotomy mediastinitis in children have been identified and include young age, perioperative interventions, the use of parenteral nutrition, preoperative admission greater than 1 day, and long aortic cross-clamp and cardiopulmonary bypass times.[280,282,283]

The early identification and aggressive treatment of mediastinal infections is required. Clinically, patients present with local erythema, fluctuance, purulent drainage, sternal instability, fever, and leukocytosis. These features may only be apparent after the first postoperative week and even after discharge. CT and gallium scanning has been useful in identifying deep sternal infections as well as sternal osteomyelitis. Controversy still exists regarding the optimal modalities that may be used to treat mediastinitis in sternotomy patients. Classic management strategies, including local debridement, wound packing, and antibiotic irrigation have evolved to the liberal use of omental and rotational muscle flaps.[284] More recently, vacuum-assisted closure has been used with success in the pediatric population.[285,286] The results with all techniques have generally been good, but the early identification of infection and an aggressive approach to the management of sternal

wound complications is strongly recommended to prevent morbidity and mortality.[280]

## GRANULOMATOUS AND SCLEROSING MEDIASTINITIS

This invasive and compressive process results from the enlargement of mediastinal and hilar lymph nodes secondary to tuberculosis or fungal diseases such as histoplasmosis.[287] These lesions may mimic anterior mediastinal masses, and thus malignancy must also be included as part of the differential diagnosis.[288] In a classical review of 180 cases, Schowengerdt demonstrated that ongoing enlargement or suppuration of these lymph nodes would lead to the compression, invasion, and fibrosis of mediastinal structures.[289] The superior vena cava syndrome and pulmonary vascular and bronchial obstruction have also been ascribed to this process. CT and MRI are often used to fully delineate the extent of disease, but biopsy is often required to confirm the diagnosis.[290,291] The course of this disease is generally mild and may be treated medically. Symptoms related to the compression of mediastinal structures usually subside with control of the underlying tubercular or fungal infection.

CHAPTER 67

# Esophagoscopy and Diagnostic Techniques

Harry Lindahl

## History

The first person to perform esophagoscopy was Kussmaul in 1870, who used a hollow rigid tube with a reflected light for illumination. Mikulicz introduced the gastroscope in 1881. His instrument consisted of several small optical units coupled with articulated joints. In 1897 Kelling invented a flexible metal esophagoscope, and in 1898 he invented a gastroscope, the lower third of which could be flexed to 45 degrees. In 1936 Schindler worked with Wolf, an optical physicist and manufacturer, to design a semiflexible gastroscope that incorporated a rubber finger at the working end.[1]

Hirschowirz and colleagues developed flexible fiberglass gastroscopes in 1958 for endoscopy of the upper gastrointestinal tract. For more than 15 years flexible video endoscopes have surpassed the use of fiber endoscopes. Video endoscopes are at present available from major manufacturers in sizes enabling upper gastrointestinal endoscopy even in small premature infants.[1]

## Evaluation of Esophageal Anatomy and Function

### RADIOGRAPHIC IMAGING

Esophageal length, diameter, and contour are best evaluated by radiographic imaging with intraluminal barium. Whenever esophageal perforation is suspected, however, a water-soluble iso-osmotic contrast medium such as Omnipaque (Amersham Health, Buckinghamshire, UK) is preferred over barium. The possibility of leaking barium into the mediastinum through an esophageal perforation should be avoided.

### ESOPHAGOSCOPY

Direct visualization and mucosal biopsy through an esophagoscope are the only accurate means of evaluating mucosal changes in the esophagus. The normal esophageal mucosa has a flat, shiny surface with a pattern of fine vessels.

With slight air insufflation, the point of diaphragmatic closure is easily identified at the lower end, and the junction between the flat esophageal and the more reddish and velvety gastric mucosa is normally below the level of diaphragmatic closure. This gastroesophageal junction forms an undulating circle that is usually easy to identify.

Mucosal biopsy is necessary to evaluate submucosal and subtle surface changes. Advanced degrees of inflammation are obvious by visual inspection, and the deeper changes can often be inferred.

### PRESSURE MONITORING

Intraluminal recording of esophageal pressure dynamics is currently the most accurate way to evaluate esophageal motility. Observation of peristalsis during radiographic contrast study is less reproducible and certainly less quantifiable, although information about coordination of peristalsis, esophageal spasm, and completely uncoordinated esophageal contractions is easily seen radiographically. Early pressure recording techniques used intraesophageal balloons. Water-perfused catheters with multiple pressure recording ports that are pulled back through the length of the esophagus during the recording have supplanted this technique. More sophisticated techniques incorporate circular ports to calculate radial pressure vectors during the pullback.[2]

Manometry has been applied much less widely in infants and children. Patient cooperation is required for a good study. Infants and children seldom tolerate esophageal-pressure recording probes without sedation, and the sedation itself may alter interpretation of the study results. Moreover, the motility disorders identified by manometry in adults are much less common in children. Finally, data from motility studies in children, with the exception of the few with achalasia, have seldom produced significant changes in surgical management.[3]

### EIGHTEEN TO 24-HOUR pH MONITORING

Reflux of gastric acid into the esophagus is thought to be the most common cause of esophageal inflammation, and evaluation of the presence and severity of reflux esophagitis is the

most common reason for esophagoscopy in children. In situations in which some quantification of reflux is important, the 24-hour esophageal pH study is suggested.[4] Several authors have described the technical aspects of performing esophageal pH studies in children.[5,6] Normal values for infants and children have also been documented.[7,8] However, pH monitoring only measures acid reflux, and one study has demonstrated a 30% discordance between two consecutive 24-hour pH measurements.[9]

### MULTICHANNEL ESOPHAGEAL IMPEDANCE MONITORING

Multichannel esophageal impedance monitoring is able to detect nonacid reflux. It increases diagnostic accuracy when combined with pH monitoring, compared with pH monitoring alone. In modern equipment, the impedance transducers are built into the same catheter as the pH transducers, and both measurements can be performed simultaneously.[10]

### BILE REFLUX DETECTION

Reflux of bile into the esophagus has been implicated as a synergistic factor in the development of reflux esophagitis,[11] and convincing data suggest that bile, combined with acid reflux, is the critical factor in the development of Barrett mucosal dysplasia in the lower esophagus.[12]

Esophageal bile detection is difficult and uncertain with pH monitoring because the mixture of acid with alkaline bile is often recorded in the neutral range by pH monitoring. The presence of bile and acid reflux is thus masked unless bile acids are measured directly from gastric aspirates. Technical improvements have allowed the direct and continuous measurement of bile in the esophagus independent of pH.[13]

## Indications and Applications of Esophagoscopy

Esophagoscopy is performed for either diagnostic or therapeutic indications. For diagnostic endoscopy the flexible adequate-size video endoscope is superior. For some therapeutic procedures the open-tube rigid esophagoscope still has its advantages. Esophagoscopy is an unpleasant procedure and should preferably be performed in children under general anesthesia with endotracheal intubation. Therapeutic esophagoscopy should always be performed under general anesthesia with endotracheal intubation. In units where safe anesthesia cannot be guaranteed, therapeutic esophagoscopy should not be done.

### DIAGNOSTIC EVALUATION

#### Suspicion of Gastroesophageal Reflux

The suspicion of gastroesophageal reflux is probably the most common cause of diagnostic esophagoscopy in children. The examination is performed to evaluate the presence or severity of reflux esophagitis. However, inflammation of the esophageal mucosa and submucosa is not reliably diagnosed endoscopically in the absence of mucosal ulcerations or erosions. The macroscopic appearance of the esophageal mucosa is difficult to interpret, and therefore the diagnosis and grading of esophagitis depend on mucosal biopsy.[14]

The more advanced degrees of esophagitis are easily recognized. Normally, a fine vascular pattern can be seen just below the mucosal surface (Fig. 67-1). Loss of this superficial vascular pattern, along with erythema, erosions, ulcerations, or nodularity, is associated with varying degrees of biopsy-proven esophagitis. Additional signs of esophagitis include mucosal bleeding on contact, white plaques of various configurations surrounded by an erythematous border, and a cobblestone appearance of the mucosa. Narrowing of the lumen caused by stricture is a complication of long-standing untreated severe esophagitis.

Esophagoscopy for suspicion of gastroesophageal reflux must include gastroduodenoscopy to evaluate possible gastric mucosal lesions and to rule out pyloric or duodenal obstruction. Retrograde view of the cardia gives information of hiatal hernia and the angle of His, which are factors affecting gastroesophageal reflux (Fig. 67-2).

#### Dysphagia

Dysphagia may be associated with esophagitis, esophageal foreign body, congenital or acquired stricture, congenital malformations, benign tumors, structural disease of the esophageal wall, or functional disorders. Endoscopic evaluation gives information of anatomic defects (e.g., stricture) but nothing of functional disorders.

#### Corrosive Injury

Indications for esophagoscopy after caustic ingestion are controversial in children. Also, the preferred timing of endoscopy varies. I prefer to perform esophagoscopy within 24 hours of ingestion of caustic liquid in symptomatic patients. Patients without symptoms, that is, those who can swallow without difficulties and pain, do not need endoscopy.

Flexible endoscopes instead of rigid instruments should be used to assess the severity of mucosal injury. In severe cases,

FIGURE 67-1 Normal cardia of a 7-month-old boy as seen from above. Normal esophageal mucosa: A pattern of fine vessels can be seen under the mucosa.

FIGURE 67-2 Cardia of a 10-year-old boy with portal vein thrombosis 3 months after a successful Rex shunt. The His angle is normal. Submucous veins are still prominent after 10 years of portal vein hypertension.

even in older children, the use of a neonatal video endoscope of 5 to 6 mm in diameter can be useful because it causes less trauma than a larger instrument. Endoscopy should always be performed with complete visual control. The instrument must never be pushed blindly forward because this may cause esophageal perforation, especially in cases with full-thickness injury. Circumferential damage is not a contraindication of passing the endoscope, provided it can be done in full visual control. In circular damage it is advisable to pass a silicone tube to the stomach because this enables enteral feeding and also assists dilatation of the following stricture.

The diagnosis of full-thickness injury cannot be made with endoscopy. It is a clinical diagnosis, in which the knowledge of the nature and amount of ingested material, the patient's clinical condition, and the laboratory parameters are more important than endoscopic findings.

### Upper Gastrointestinal Bleeding

Upper gastrointestinal bleeding is rare in children. Severe esophagitis, variceal bleeding, Mallory-Weiss lesion, and bleeding from mucosal lesions of the stomach or duodenum are the causes. The best way to diagnose these is with upper gastrointestinal endoscopy.

Endoscopy for acute upper gastrointestinal hemorrhage is technically demanding and should only be performed by an experienced endoscopist. Bleeding from esophageal varices can be anticipated from a palpable large spleen. The cause can be either portal vein thrombosis or liver cirrhosis, which in children is usually caused by biliary atresia. If variceal bleeding is suspected, preparation for acute sclerotherapy or ligation of the varices should be made.

Severe esophagitis causing significant blood loss is rare but easily detected in endoscopy. Mallory-Weiss tear occurs even in neonates and is best seen in inversion endoscopy from the stomach side of the cardia. Often Mallory-Weiss tear appears as a local hematoma in the cardia, which hides the actual tear.

### Trauma

The most common cause of esophageal disruption is iatrogenic. Most often it results from esophageal dilatation or other therapeutic instrumentation.[15] If the dilatation is performed under endoscopic control, the perforation is usually easily diagnosed in the same endoscopy.

Compression injuries to the chest more commonly disrupt the airway, but an air-filled esophagus may also be disrupted. In these cases esophagography with water-soluble contrast medium provides the best approach to diagnosis of esophageal perforation if the patient is conscious and a swallowing study can be performed. Flexible esophagoscopy can identify major tears or complete disruption, but a small crack in the wall after stricture dilatation may not be apparent without contrast radiographic imaging.

### Anatomic Abnormalities

Anatomic abnormalities of the esophagus such as congenital stenoses, cartilaginous rings in the esophageal wall, leiomyomas, and cystic duplications are usually first identified radiographically and then confirmed endoscopically. The unyielding, ribbed esophageal wall associated with cartilaginous rings is striking to view with a flexible scope. Tracheoesophageal fistulas are best seen with tracheoscopy and are usually invisible from the esophageal side. Figure 67-3, *A* shows the anastomotic stricture of a patient after esophageal atresia repair.

### Follow-up of Congenital Upper Gastrointestinal Anomalies

Operated congenital upper gastrointestinal anomalies such as esophageal atresia carry a significant risk of late esophageal pathology. Complications of gastroesophageal reflux, esophagitis, gastric metaplasia, and even adenocarcinoma have been reported. Many of the patients are asymptomatic, even when harboring gastric metaplasia. To prevent irreversible premalignant mucosal changes, routine follow-up esophagoscopy of corrected upper gastrointestinal anomalies should be considered.[16–19]

## THERAPEUTIC APPLICATIONS

### Stricture Dilatation

Balloon dilatation with or without a guidewire and with either fluoroscopic or endoscopic control is the treatment of choice for strictures. Localized anastomotic strictures are commonly managed with balloon dilatation either under fluoroscopic control or using direct endoscopic visualization. Long or tight and tortuous strictures require the passage of a guidewire either endoscopically or under fluoroscopic control.

### Balloon Dilatation with Fluoroscopic Control

The dilating balloon is passed over a small slippery wire, which is positioned through the esophagus and into the stomach by fluoroscopy. In simple, not too tight strictures a soft-tipped balloon without a guidewire can also be used. The balloon is then filled with water-soluble contrast agent so that the waistlike indentation on the balloon can be visualized under fluoroscopy as the stricture is stretched.

This technique offers the advantage of direct visualization during dilatation, and the radial forces generated during

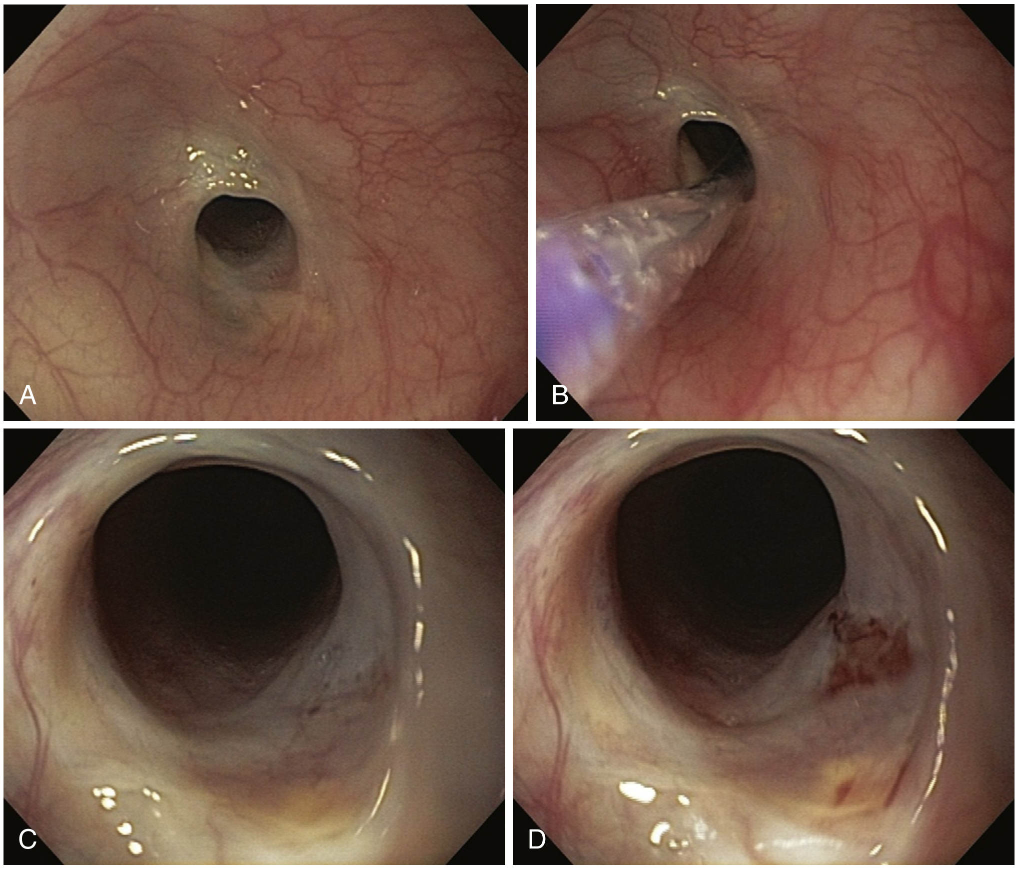

**FIGURE 67-3** Anastomotic stricture of a 5-month-old infant with esophageal atresia undergoing a fourth session of endoscopic balloon dilatation. **A,** The 5.6-mm flexible gastroscope could not pass beyond the stricture. **B,** The balloon dilator is passed over a guidewire through the instrument channel. **C,** Minimal petechiae after 8-mm dilatation. **D,** Superficial mucosal tear after 9-mm balloon dilation; the 5.6-mm endoscope could now pass. Note the yellowish plaque at 5 o'clock, caused by residual triamcinolone injected at the previous dilatation session. (Courtesy Dominique Lévesque, MD, pediatric gastroenterologist, McGill University Health Center.) *(See Expert Consult site for color version.)*

dilatation are thought to be safer and more localized than the shearing forces generated by longitudinal tapered dilators.[20]

### Balloon Dilatation with Direct Endoscopic Visualization

The balloon dilatator can also be introduced with endoscopic control. Small-caliber dilatators fit the endoscope working channel and can be directly pushed into the stricture. Larger caliber balloons usually require separate passing of the guidewire through the working channel of the scope into the stricture. After that, the endoscope is removed and the dilator is passed over the wire as in fluoroscopic-assisted dilatation. In simple strictures a soft-tipped dilatator without a guidewire can be passed blindly through the stricture. The dilatation procedure can be inspected if the endoscope is passed beside the dilator to have a direct view of the stricture. The advantage of this method is that the extent of inflammation can be assessed and biopsy can be done, balloon dilatation can be monitored through the flexible esophagoscope, and any cracking or mucosal damage can be evaluated after the balloon is withdrawn (Fig. 67-3).

### Dilatation with a Guidewire Left in Situ

In difficult strictures requiring multiple dilatations this technique is helpful. A gastrostomy is required. A guidewire is passed from the upper esophagus through the flexible scope into the stomach. Through the gastrostomy opening, the intragastric portion is then recovered with an endoscope or blindly using a nerve hook. With the use of this guidewire, balloon dilators can be pushed to the stricture either from below or from above. After dilatation the guidewire can be replaced with a nasogastric tube, which is tied to the gastrostomy tube. In the next session the nasogastric tube can be used to lead the guidewire from the nose through the gastrostomy, making repeated dilatations easy and safe. An alternative method is to leave a long No. 2 silk in situ between dilatations. The silk is initially tied to the guidewire at the gastrostomy site and withdrawn out through the mouth. A feeding tube is placed through the nose, and its tip is retrieved from the mouth using a laryngoscope and Magill forceps. The silk is tied to the feeding tube, which is used to guide it out of a nostril. The long silk is then taped loosely behind the ear, down the neck and chest, and tied to its gastric end, thereby making a long continuous loop. The gastrostomy tube is replaced, and the silk remains in situ with minimal discomfort and cannot be dislodged accidentally. At the next session, the silk is cut, the gastric end can be tied into a loop to assist retrograde dilatations with Tucker bougies or used to pull a guidewire through the stricture to allow balloon dilatation.

### Gastrostomy Tube or Button Insertion

Flexible gastroscopy is an essential component of the retrograde "pull" technique for percutaneous placement of gastrostomy tubes or gastrostomy buttons.[21] Details of the technique

are well described in the supply kits for these devices. The final position of the flared end in the stomach should be monitored by direct inspection through the gastroscope to make certain the gastric wall is pulled up snugly against the parietal peritoneum. Previous upper-abdominal surgery is a relative contraindication to endoscopic placement of gastrostomy devices because adhesions may prevent apposition of the stomach with the anterior abdominal wall when it is filled with air through the gastroscope. Tubes have actually traversed the colon or small bowel en route to the stomach because of adhesions limiting direct contact between the stomach and parietal peritoneum.[22]

I prefer to make the first tube or button change with endoscopic control to ensure that the end of the tube or button is inside the stomach. Separation of the stomach and anterior peritoneum has happened, resulting in feeding into the peritoneal cavity, which is a potentially lethal complication.[23] Because endoscopy requires general anesthesia in infants and toddlers, others prefer to delay the first tube change for at least 4 months and ensure correct placement at the time of tube change by confirming return of gastric contents before feedings are resumed.

### Foreign-Body Removal

Effective management of esophageal foreign bodies requires familiarity and skill in the use of several different extraction techniques.

Many esophageal foreign bodies that are not sharp and not embedded in the mucosa as a result of long-term residence can be removed with a contrast medium-filled balloon catheter under fluoroscopic control. Coins account for most of these problems. In a series of 415 cases, 76% were caused by coins; the catheter removal technique was successful in 91%.[24] Foreign bodies that are stuck at the cricopharyngeus sphincter can often be removed using a long-bladed laryngoscope and Magill forceps.[25] There are also other minimally invasive techniques for removing coins.[26] Esophagoscopic removal is considered necessary when the foreign body seems embedded, has sharp points or corners, or is soft and fragmented and may present a risk for aspiration during balloon extraction. However, depending on the experience of the unit, esophagoscopic removal using an open channeled esophagoscope can also be used in simple coin removals.

Impacted organic matter is best removed using the rigid open-channel esophagoscope. Large extraction forceps can be introduced through the rigid scope, allowing several passes of the instrument without removal of the scope sheath with each fragment. Large, sharp objects are also more safely manipulated into the protecting sheath of the open-channel scope. This prevents contact with the esophageal wall during extraction of the foreign body and scope as a unit. In all extractions with the open-channel esophagoscope, the use of optical forceps from a rigid pediatric bronchoscope can be helpful because it provides a magnified view.

Small, embedded objects can sometimes be handled with the flexible scope and the appropriate alligator, cup, or tack forceps or various grasping wires or baskets. Open safety pins pointing upward are easily extracted by grasping the spring loop with a tack forceps, passing the entire pin into the stomach for a turnaround, and then extracting the pin with the open point downward as it is removed as a unit with the scope.

### Injection Sclerotherapy

Injection sclerotherapy for esophageal varices is done with the flexible esophagoscope and the flexible needle injector. We have used intravariceal injection with 3% sodium tetradecyl sulfate. The injection volume has been 0.5 to 1 mL per varicose vein, with a total volume of 2 to 3 mL per session. In about 30 years of experience I have seen one complication associated with the sclerosant. There has been no need for blood transfusions because of the injection. There are few randomized controlled trials of the effect of injection sclerotherapy. In a series of 100 children with varices, randomized for prophylactic sclerotherapy, good elimination of varices was achieved in the sclerotherapy group, but this did not improve survival.[27]

Endoscopic variceal ligation with small rubber bands has been developed as an alternative to endoscopic variceal sclerosis, and the effectiveness and complication rates for the two techniques were similar in a randomized trial in adults.[28] Ligation of varices is gaining popularity also in the pediatric age group.[29,30]

### Intraluminal Laser Therapy

Intraluminal laser ablation of esophageal lesions is used in adults.[31] Flexible optical fibers for cutting, sclerosing, or ablating lesions are available for passage through the instrument channel of a fiberscope, but clinical applications in infants and children are currently so rare that most pediatric surgical units do not maintain the necessary equipment or expertise. Endoscopic laser applications can be a possibility for future development.

# Instrumentation

## FLEXIBLE ENDOSCOPY

The flexible video end-viewing gastroscope is the instrument of choice for esophagoscopy in infants and children. Excellent videoscopes in pediatric sizes are now available from several major manufacturers of endoscopic equipment. For routine diagnostic and therapeutic applications, the endoscopes are equipped with at least one channel for suction and instrumentation. The gastroscopes also include positive-pressure insufflation and the capability to flush and clear the lens without withdrawal of the scope. Four-way directional controls for the viewing tip are standard. The video picture can be recorded, and both paper and digital pictures can be obtained with modern equipment. The external diameter of most pediatric videoscopes with these features ranges from 6 to 9 mm.

Guidelines for sterilization of fiberscopes are now fairly rigid. Automatic sterilizers are available from the manufacturers to assist cleaning and decontamination. Accessory instrumentation for passage through the long working channel of the scopes includes various biopsy and foreign-body forceps, graspers, baskets, flexible injectors, magnets, diathermy loops, and laser optical fibers.

## RIGID, OPEN-CHANNEL ENDOSCOPY

The use of a rigid, open-channel instrument in the esophagus still has a few specific indications. The large working channel of the open, rigid scope allows safe removal of large, sharp,

pointed foreign bodies because the sharp edges of the foreign body can be partially drawn into the scope for protection during withdrawal. Large organic foreign bodies are also more easily removed.

## Patient Preparation, Sedation, and Pain Control

Even flexible esophagoscopy is an unpleasant procedure in children. Therefore I prefer general anesthesia with airway intubation. It provides a more controlled and, in many cases, a safer environment for esophagoscopy than sedation. General anesthesia is mandatory in children for the management of foreign-body extraction, stricture dilatation, injection sclerotherapy, or variceal ligation. It might seem that general anesthesia would involve increased risk, but the reverse is usually the case. Intravenous sedation and a forceful endoscopy in an agitated or uncooperative child without airway control can invite disaster from respiratory depression and cardiovascular collapse. Aspiration is also an increased risk in procedures such as injection sclerotherapy or evaluation of acute bleeding, in which irrigation fluid or blood may reflux back into an unprotected airway. General anesthesia minimizes psychic trauma, increases the safety of the manipulation, and makes endoscopy much easier for the surgeon.

I have no personal experience with esophagoscopy under conscious sedation without general anesthesia. However, some clinicians still use this approach. The usual agents for intravenous sedation include a short-acting central nervous system depressant of the benzodiazepine class combined with a narcotic. Dosages are titrated to effect, within predetermined limits. A topical anesthetic spray of the hypopharynx is helpful before introduction of the endoscope. Continuous monitoring of heart rate and oxygen saturation and intermittent monitoring of blood pressure during the procedure and for an appropriate interval afterward are mandatory. Oxygen, bag, mask, and an intravenous narcotic antagonist should be available at the bedside during the procedure. Esophagoscopy under sedation should only be performed in facilities that are equipped for resuscitation and cardiorespiratory support.

Some cooperative teenagers can undergo endoscopy without sedation, using only topical anesthetic spray of the pharynx. In selected patients this provides better cooperation than endoscopy under sedation.

## Technical Considerations

Before use, all equipment must be checked to ensure that it is in working order. The lens focus on the flexible endoscope must also be adjusted before insertion, and the video endoscope must be white balanced. The control element of the flexible scope is held in the notch between thumb and fingers of the left hand. The upward-pointing second and third fingers operate the suction and insufflation controls, and the fourth and fifth fingers stabilize the endoscope. The left thumb is used to control the north and south movement, and the right hand stabilizes the distal scope at the mouth, controls insertion, and provides lateral movement by rotational changes. Fine adjustments in east and west orientation of the tip can be made with the lateral adjustment control wheel. To protect the flexible scope, a mouthpiece is inserted between the anterior teeth.

### FLEXIBLE ENDOSCOPY WITH GENERAL ANESTHESIA

Flexible videoendoscopy under general anesthesia is simpler in every respect except for insertion of the scope through the cricopharyngeus. The anesthetized patient does not swallow, either voluntarily or involuntarily. The patient is placed supine, and the endoscopist stands at the head of the patient on the right side of the table. Alternatively, the patient may be placed in lateral decubitus. The endoscope is passed under visual control behind the larynx to the esophagus. If the larynx lies tightly against the back wall of the hypopharynx, the anesthetist can be asked to gently lift the angle of the jaw. A small jet of air can be introduced from the level of the pyriform sinus to open the cricopharyngeus. The tip of the endoscope is then advanced under vision into the orifice that comes into view. Once through the cricopharyngeus, the endoscope is adjusted so that the lumen of the esophagus is straight ahead. Observations are made during advancement and withdrawal of the endoscope. In evaluation of esophagitis or caustic injury, it is important to record the condition of the mucosa before the endoscope has passed over it.

### FLEXIBLE ENDOSCOPY WITH INTRAVENOUS SEDATION OR WITHOUT SEDATION

Intravenous sedation rarely provides total cooperation of the child undergoing endoscopy. The examination must be comprehensive but brief. This requires gentleness, precise manipulation, no unnecessary or false maneuvers, and considerable experience on the part of the endoscopist.

In larger patients without sedation and those only lightly sedated, the introduction of the endoscope is best performed when the patient is sitting. After the introduction of the endoscope through the cricopharyngeus sphincter, the patient is usually placed in the left lateral position with the head slightly extended. A smooth introduction greatly reduces fear of and resistance to the procedure. Many endoscopists prefer blind intubation of the cricopharyngeus, accomplished by pressing the tongue forward with the index and middle fingers of the left hand while the right hand advances the scope during a swallow. However, introduction under direct vision through the scope offers more precise placement. A swallow can sometimes be initiated in a child by squirting water into the pharynx through the lens-washing system.

### RIGID ENDOSCOPY WITH OPEN-CHANNEL VIEWING

Rigid endoscopy in a child should always involve general intubation anesthesia to minimize trauma and the risk for perforation. The supine position, with the neck forward and the head extended, is satisfactory for most examinations.

The open-channel rigid esophagoscope is introduced under direct vision into the back of the pharynx with the lip of the beveled portion anterior. This lip is then used to elevate the larynx gently and to open the cricopharyngeus.

The patient's mandible and maxilla are supported with the endoscopist's left hand; the thumb and index finger hold the esophagoscope as if holding a billiard cue. The right hand manipulates the scope as it would a cue. The scope should not be advanced unless the lumen of the pharynx or esophagus is clearly visualized straight ahead. If the cricopharyngeus does not open up with elevation by the lip of the scope against the posterior portion of the larynx, the esophageal lumen should be identified by passage of a soft suction catheter through the scope as a lumen finder. The scope is then passed over this catheter into the upper esophagus under direct vision. A view of the esophageal lumen should be maintained as the scope is advanced through the gastroesophageal junction into the stomach. More detailed inspection can then be obtained as the scope is withdrawn.

## Complications

Esophagoscopy involves risks associated with sedation or anesthesia in addition to the risk for direct instrumental perforation of the pharynx, esophagus, or stomach. Drug reactions, tracheobronchial aspiration, and hypoxic brain damage are all potential and almost entirely preventable complications associated with upper gastrointestinal endoscopy. Instrumental perforation should be entirely preventable; unfortunately, this complication still occurs.

Before flexible endoscopy, the more common sites for perforation involved the posterior pharynx in children who were restrained and were examined while awake. Esophagoscopy associated with the dilatation of tight strictures still carries a greater risk for perforation than does a purely diagnostic procedure, but reliable figures on the incidence of instrumental perforation are not available for children. Even for simple diagnosis, the risk for perforation in the presence of severe esophagitis, whether from reflux or from caustic ingestion, must be greater than that in a patient with an esophagus that is not inflamed. The predominant use of flexible instruments in recent years is a major factor in reducing and almost eliminating instrumental perforation in children. As long as a magnified view of the esophageal lumen is maintained throughout the procedure, perforation remains unlikely.

During the 16-year period 1994-2009 there were 9155 esophagoscopies or upper gastrointestinal endoscopies performed by pediatric surgeons in Helsinki University Children's Hospital. Esophageal dilatation was performed in 539 sessions. There were two perforations, both related to dilatation of anastomotic stricture after esophageal atresia repair. Both required surgical correction. There was no mortality associated with the perforations, but in one patient several operations were required to preserve the patient's esophagus. During the same period, esophagoscopy and extraction of esophageal foreign body were performed on 174 patients and sclerotherapy of esophageal varices was performed in 197 sessions. There was one esophageal perforation after injection sclerotherapy. There were no esophageal perforations or other complications needing treatment associated with diagnostic esophagoscopies.

CHAPTER 68

# Esophageal Rupture and Perforation

Thomas R. Weber

Boerhaave's classic postmortem description of a patient, Baron Wassenaer, is recognized to be the first report of a case of spontaneous, postemetic esophageal rupture. In 1952 Fryfogle[1] reported spontaneous rupture of the esophagus in a neonate that was successfully repaired surgically. In 1968 Eklof and colleagues[2] first emphasized iatrogenic perforation of the cervical esophagus by catheters in the newborn. These authors suggested that nonsurgical therapy might be appropriate in many cases.

## Classification and Incidence

Abnormal communications of the esophagus into the pleural cavity, mediastinum, or peritoneal cavity are classified as either esophageal rupture or esophageal perforation. Esophageal rupture is also labeled spontaneous perforation, Boerhaave syndrome, effort perforation, and esophageal apoplexy. In these conditions, no instrumentation or intubation of the esophagus has occurred, thus implying that an intrinsic anatomic abnormality or dysfunction is present within the esophageal wall.[3–8] A recently recognized clinical entity, eosinophilic esophagitis has been the cause of spontaneous esophageal rupture in several studies.[9,10] Esophageal perforation, on the other hand, is produced by the introduction of an object into esophageal lumen. These lesions are traumatic and, in many cases, result from diagnostic or therapeutic manipulation.[11–17] Esophageal perforation can also be caused by the ingestion of foreign bodies[18,19] and caustic substances or by blunt and penetrating trauma.[20,21] Spontaneous rupture of the esophagus in neonates and infants is rare and accounts for 4% of all reported cases.[14] In contrast, iatrogenic perforation of the upper part of the esophagus by attempted passage of a nasogastric or endotracheal tube is not uncommon and probably occurs more frequently than reported in the literature.[15,22] In addition, esophageal perforation complicates 0.4% to 1.2% of esophagoscopy and esophageal dilatation procedures,[16] thus making this an important risk factor in the use of these procedures.

## Clinical Findings

Neonatal spontaneous esophageal rupture occurs most frequently in full-term babies after uncomplicated pregnancies. Respiratory distress with cyanosis may be present immediately or may be delayed for several hours.[6] Respiratory distress is caused by a pneumothorax that is usually located on the right side and in which tension may rapidly develop. The predilection for neonatal Boerhaave syndrome to be manifested as a right-sided pneumothorax, as opposed to the left pleural cavity (most commonly found in adults), is explained by the close adherence of the aorta to the left side of the esophagus in infants. This adherence provides additional support to that side of the esophagus.[23] If the perforation remains undiagnosed, respiratory distress usually worsens with the first feeding. Vomiting, coughing, choking episodes, and mild hematemesis have been observed in several cases. Thoracentesis or tube thoracostomy may reveal serosanguineous or grossly bloody pleural fluid or the contents of previous feedings.[24] Formula promptly appears if feeding is again attempted.[25]

In contrast, esophageal perforation is most frequently associated with difficulty passing a nasogastric tube in premature infants (63% of cases).[15,22] At least 75% of patients with perforation have difficulty swallowing, characterized by drooling, increased oral secretions, and feeding problems. In older children, severe pleuritic or substernal pain is the hallmark of perforation as a result of esophagoscopy or dilatation procedures. Fever, often high, and rapid, toxic progression to shock may occur in any age group but seems to be more prevalent in older children after mediastinal or free pleural perforation. Subcutaneous emphysema, often present in adults with esophageal perforation, is rare in infants unless massive pneumomediastinum occurs.

## Diagnosis

The early diagnosis of esophageal rupture or perforation is indicated by clinical findings and confirmed by radiographic procedures. The typical appearance of spontaneous rupture or extensive traumatic injury of the esophagus includes

right-sided tension pneumothorax or hydropneumothorax on an upright radiograph or pneumomediastinum (Fig. 68-1). Plain chest radiographs in children with iatrogenic catheter perforation frequently show malpositioning of a nasogastric tube, usually into the right pleural cavity (Fig. 68-2). In other cases the perforating tube may be located in a submucosal or mediastinal position and cause the formation of a "pseudodiverticulum" of the esophagus. In cases of perforation caused by esophageal dilatation, pneumomediastinum or left chest pneumothorax is frequently present (Fig. 68-3). A lateral chest radiograph may be necessary to demonstrate mediastinal air early. Premature infants with iatrogenic perforation are often initially suspected of having esophageal atresia, but the nasogastric or orogastric tube returns blood-tinged secretions and the tube is displaced away from the midline on chest radiograph.[15,26]

In all cases of esophageal perforation, esophagography is necessary to establish the diagnosis, localize the perforation, and direct therapy.[13] If perforation of the upper part of the esophagus by a nasogastric tube is suspected, the tube can be left in place and a small amount of water-soluble contrast injected through it. If the tube has been removed or if the perforation was suspected after other procedures such as laryngoscopy or endotracheal intubation, esophagography may be performed by carefully injecting soluble contrast material into the upper part of the esophagus through a small tube. Patients with suspected lower esophageal perforation secondary to instrumentation frequently show extravasation of contrast into the pleural space or mediastinum during esophagography. If questions remain after water-soluble contrast esophagography or if anatomic definition is inadequate, the study may be repeated with barium. However, most surgeons consider extravasation of barium into the thorax undesirable. Computed tomography with oral contrast offers another option.[13] Esophagoscopy offers no diagnostic advantages and may actually enlarge the perforation, thus making subsequent repair more difficult.

Patients with swallowed foreign bodies stuck in the esophagus present with drooling, dysphagia, and occasionally chest pain. If the foreign body is not visible on plain radiographs, contrast esophagography is indicated. Prompt removal of all esophageal foreign bodies, especially button batteries, is essential before perforation occurs; these patients are at risk for mediastinitis, but most importantly, aorto-esophageal fistula formation.[32]

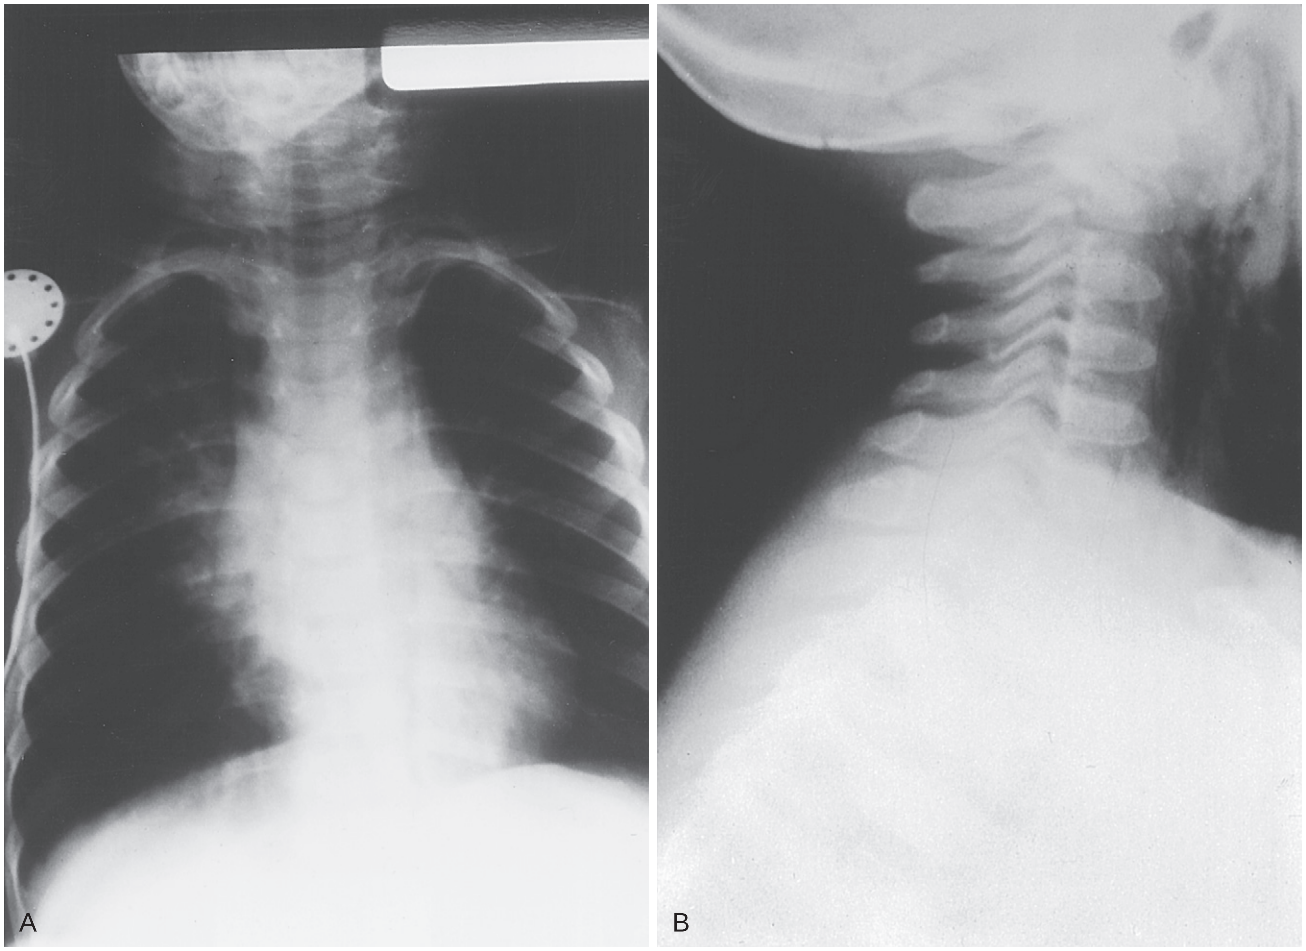

**FIGURE 68-1** **A,** The esophagus was injured when the patient fell while holding a pencil in his mouth. Note the large amount of mediastinal air on each side of the mediastinum. **B,** Air is also seen in the soft tissues of the neck, indicative of injury to the cervical esophagus. Lateral views are particularly helpful for demonstration of air in the neck or chest.

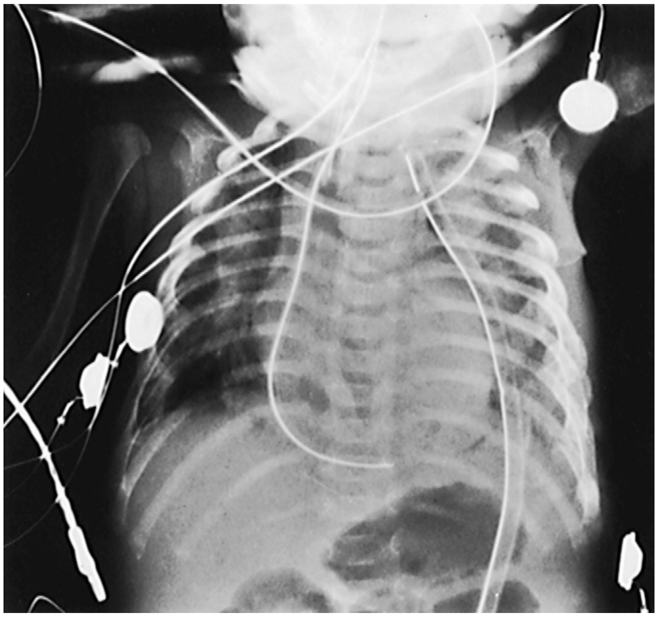

**FIGURE 68-2** Upper esophageal perforation in a premature infant. Note the position of the presumed nasogastric tube in the right side of the chest. The tube was withdrawn, and nonsurgical therapy resulted in complete recovery.

**FIGURE 68-3** This collection of gas in the mediastinum behind the heart occurred 1 hour after an esophageal dilatation procedure. Subsequent esophagography demonstrated distal esophageal perforation.

## Treatment

The decision about the most appropriate therapy after the diagnosis of esophageal rupture and perforation depends on the site of perforation, whether the perforation is free or contained, the interval from injury to diagnosis, and the systemic response to injury.[27,28] Spontaneous rupture not related to instrumentation usually results in substantial contamination of the mediastinum or pleural space and elicits a severe systemic response of fever, sepsis, pleuritic pain, and occasionally shock. This group of patients needs rapid preoperative preparation including intravenous fluids, antibiotics, thoracentesis, tube thoracostomy (if pneumothorax or hydrothorax is present), and cessation of oral intake. Esophagography should be performed to define the location of the perforation, followed immediately by thoracotomy, irrigation of the pleural space, and suture or patch of the laceration if it can be found. Flexible esophagoscopy during the exploration may help localize the perforation. A flap of pleura or pericardium can also be used to reinforce the esophageal closure.[29] Placement of several large chest tubes completes the procedure.

Free pleural perforation secondary to instrumentation should be managed in an identical manner. Because most of these latter perforations are diagnosed early, little reaction is generally present and primary repair of the perforation or esophageal resection with primary anastomosis is usually possible. The pleural cavity should be generously irrigated and drained with one or two chest tubes. Ancillary procedures such as diverting or tube cervical esophagostomy, esophageal division without anastomosis, gastrostomy, and feeding jejunostomy also have a role in selected cases. These techniques, however, have not been used extensively in children. In addition, stenting techniques have been used in a few cases[30] and may be useful in highly selected children. A more conservative approach, without chest tube drainage or surgical repair, has been advocated,[31] but most authors would not recommend such an approach.

In general, upper esophageal perforation caused by attempted placement of a nasogastric or endotracheal tube can be managed nonsurgically.[15,31] These perforations may affect the mediastinum only or may extend into the pleural space (usually the right side). The perforating tube should be withdrawn, a new nasogastric tube should be inserted under fluoroscopic guidance, and contrast should be injected to confirm placement of the tube in the stomach. A chest tube is placed if a pneumothorax is present. The infant is given broad-spectrum antibiotics and intravenous nutrition, and oral feedings are withheld. After several days, feedings through the nasogastric tube may be started. If gastroesophageal reflux occurs, the nasogastric tube can be advanced through the pylorus so that duodenal feedings can be initiated. If sepsis occurs at any time during nonsurgical therapy, formation of a mediastinal abscess must be suspected. Computed tomography of the chest should be done and surgical drainage performed.

Regardless of the therapy used, contrast esophagography is performed 7 to 10 days after injury or repair. If the perforation has completely healed, the chest or mediastinal tubes are removed and oral feeding is resumed. If extravasation is observed, continued conservative therapy generally results in healing within another 7 to 10 days. Persistent esophageal fistula is unusual and suggests distal esophageal or gastric outlet obstruction.

## Results of Therapy

Because of the rarity of spontaneous esophageal rupture in childhood, it is difficult to assess the success of surgical repair. In a review of 13 patients, Aaronson and colleagues[3] noted that 3 patients treated by chest tube drainage alone

died, whereas 7 of 8 infants treated by thoracotomy and suture repair survived. Late stricture was occasionally encountered at the site of the repair; this complication responded well to dilatation. Other case reports have emphasized the uniform mortality with nonsurgical therapy[12] and the satisfying results obtained with thoracotomy and repair.[4] Similar results can be expected with aggressive surgical repair of esophageal perforation secondary to instrumentation and foreign bodies in which the perforation has entered the pleural space.

Many authors advocate the use of nonsurgical therapy for upper esophageal perforations.[2,7,14,15,17,28,31] When selectively applied to infants with no systemic symptoms of perforation, the survival rate approaches 100%. This is usually the case when the perforation is submucosal or well contained in the mediastinum, the so-called pseudodiverticulum of the esophagus. When free perforation into a pleural space has occurred, conservative therapy can still be used if the baby does not appear ill; however, vital signs must be monitored closely and thoracotomy performed if signs of sepsis appear.

CHAPTER 69

# Congenital Anomalies of the Esophagus

Carroll M. Harmon and Arnold G. Coran

## Historical Background

The documented history of esophageal atresia (EA) began in the year 1670 with William Durston's published description of "A Narrative of a Monstrous Birth in Plymouth . . ." in which he described a blind-ending upper esophageal pouch in the right infant of a set of female thoracopagus-conjoined twins.[1] The first description of EA with the typical form of tracheoesophageal fistula (EA-TEF) appeared in 1697 in the fifth edition of Thomas Gibson's *The Anatomy of Humane Bodies Epitomized*.[2] Isolated case reports of EA-TEF surfaced in the nineteenth century including one by Thomas Hill in 1840. Published in the *Boston Medical and Surgical Journal*, this report described an infant with EA-TEF and associated rectal agenesis with a rectourinary fistula.[3] In 1861 Harald Hirschsprung of Copenhagen reported 4 cases of his own and collected 10 cases of EA and distal TEF from the literature.[4] In 1880 Morell Mackenzie,[5] another prominent medical figure of the nineteenth century, reported 57 cases of congenital esophageal malformation with 37 examples of tracheal or bronchial esophageal fistula. He also discussed at length the embryology, pathology, and clinical diagnosis of these anomalies including a description of associated anomalies such as spina bifida, horseshoe kidney, and imperforate anus. E. D. Plass, an instructor in obstetrics at Johns Hopkins University, surveyed the literature in 1919 and reported 136 verifiable cases of EA including 92 with an associated TEF.[6] By 1931, Rosenthal had collected data on 255 patients[7] and indicated, as Ladd emphasized in 1944,[8] "that atresia of the esophagus is a much more frequent anomaly than it has usually been considered to be."

The history of the surgical treatment of EA-TEF is remarkable and covers 270 years linking the first description and the first survivor. In 1869 Timothy Holmes of London, the author of *Surgical Management of Children's Diseases,* was the first to suggest the possibility of a surgical esophageal anastomosis in infants who had EA without TEF; however, he added that "the attempt ought not, I think, be made."[9] The first operative attempt to correct EA without TEF was undertaken in 1888 by Charles Steele of London, and his report titled "Case of Deficient Oesophagus" was published in the journal *Lancet.*[10] Using chloroform anesthesia, Steele performed a gastrotomy and attempted to perforate through what he suspected was an esophageal membrane by pushing a long, slender steel probe through the gastrotomy site and up the lower esophageal pouch into the upper pouch, which was simultaneously pushed down with a bougie.[10] The attempt was unsuccessful, and at autopsy, the esophagus was found "to terminate above and below in blind rounded ends an inch and a half apart and there was no cord or connection between the parts."[10] In 1899 Hoffman performed the first permanent gastrostomy in an infant with EA.[11] In 1913 H. M. Richter of Chicago described two infants with EA-TEF, on whom he operated without success. Despite his results, Richter was optimistic about the eventual success of primary esophageal repair and stated, "I do not wish to dismiss the idea of immediate union of the two ends of the esophagus."[12] In the same year, however, J. Brennemann, a prominent pediatrician working in Chicago with Richter, referred to the fatal outcome of the two infants who underwent attempted surgical repair by stating that "the physician who, after making his diagnosis of congenital atresia of the esophagus, decides to let his little patient die undisturbed can amply justify his course."[13] Despite Richter's optimism, primary esophageal anastomosis and a myriad of other operations continued to fail; the mortality rate for EA remained 100%. In a 1925 textbook of thoracic surgery, Lilienthal proposed that operative treatment might include "division of the tracheoesophageal fistula and 'anastomosis' of the atretic esophagus by tying each pouch over a rubber tube stent."[14] In 1936 Mims Gage and Alton Oschner of New Orleans, Louisiana, proposed early transabdominal ligation of the cardiac end of the esophagus and gastrostomy with early secondary cervical esophagostomy.[15] Like Richter, they noted that "the ideal operation would be the separation of the esophagus from the trachea and an end-to-end anastomosis of the upper to the lower segment."[15] They added that "such an extensive intrathoracic procedure is not justified in a newborn infant, however, and the operation would always be finished as a postmortem procedure."

The first published report of a case of EA-TEF treated by fistula ligation and primary esophageal anastomosis was presented by Robert Shaw of Dallas, Texas. Shaw performed the operation on September 25, 1938, and reported it in

December 1939.[16] In his report, Shaw referred to a personal communication from Paul C. Samson, who had also performed "an operation very similar" to the one Shaw described. Samson's patient died 12 hours after the operation. Shaw's patient died on the twelfth day after the operation, apparently as the result of a transfusion reaction. Shaw performed the operation without knowing that Thomas Lanman in Boston had performed four primary esophageal repairs for EA-TEF between January 2, 1936, and July 27, 1937, with the use of an extrapleural approach.[17] In November 1940, Lanman reported these 4 cases, 1 other case of primary esophageal repair, and 27 other cases of EA seen at Boston Children's Hospital between September 1929 and February 1940. All 32 patients in the series died. However, Lanman's fourth patient treated by fistula ligation and primary esophageal repair lived 9 days and at autopsy was found to have died of overhydration, not of mediastinitis or pneumonia. Remarkably, Lanman summarized: "In spite of the fatal outcome in all the 30 operative cases, it is felt that considerable progress along rational lines is being made. The successful operative treatment of a patient with this anomaly is only a question of time."

According to Humphreys and Ferrer,[18] the first survivor of congenital atresia of the esophagus without TEF was a boy born in New York on February 16, 1935. The patient was initially treated by gastrostomy alone, with his "first thoracic operation performed in 1946."[18] The first survivors of EA-TEF were a boy born in Minnesota on November 26, 1939, and a girl born in Massachusetts on the next day. After many failures in caring for infants with EA, N. Logan Leven of the University of Minnesota performed a gastrostomy on a 2500-g male infant with EA-TEF on November 29, 1939. After a failed attempt to close the TEF bronchoscopically with a coagulation electrode, extrapleural ligation of the fistula was accomplished on January 5, 1940. When the infant's weight increased to 4630 g, a cervical esophagostomy was performed on March 27, 1940. The child thrived, and Leven proposed that a subsequent antethoracic esophagoplasty be performed to reestablish continuity of the gastrointestinal tract. In Boston, William Ladd performed a gastrostomy on a female infant on November 28, 1939; on March 15, 1940, he closed the TEF and created a cervical esophagostomy. Although both these patients survived, esophagogastric continuity was achieved only after multiple operations to create an anterior skin-lined thoracic neoesophagus.

In 1935 Cameron Haight began caring for infants with EA at the University of Michigan (Fig. 69-1). His first patient was managed unsuccessfully by a gastrostomy alone. In 1939 Haight attempted his first primary repair of EA, which was unsuccessful. Four subsequent attempts at primary repair also failed; however, on March 15, 1941, the first successful primary repair of EA was performed. The infant girl was an "unusually robust" 12-day-old child who weighed 8 lb, 4 oz and had been transferred from Marquette, Mich., to the care of the Chief of Pediatrics, Harry A. Towsley. Dr. Towsley, in turn, consulted Dr. Haight.

The first successful primary repair of EA-TEF was accomplished by using a left extrapleural approach with fistula ligation and a single-layered esophageal anastomosis. An anastomotic leak developed on postoperative day 6 but was managed without surgical intervention. A stricture later developed at the anastomosis and responded to a single dilation. Drs. Haight and Towsley presented this case in February 1942 at the Central Surgical Association meeting in Chicago and published the report in 1943.[19] In 1943 Haight revised his procedure to a right extrapleural approach because he believed that better exposure of the distal segment was obtained from this side. He also moved to a modified two-layer, "telescoping" anastomosis in the hope of decreasing the risk for leak. Between 1939 and 1969, Dr. Haight cared for more than 284 infants with EA and reported a 52% overall survival rate.[20] After Haight's first success in 1941, reports of survival after direct esophageal anastomosis were sporadic; however, many centers soon began reporting series of successes. One interesting report by Longmire in 1947 describes four consecutive successful primary esophageal anastomoses including success in a baby who weighed only 1.4 kg.[21]

**FIGURE 69-1** Cameron Haight, MD, performed the first successful primary repair of esophageal atresia with a tracheoesophageal fistula on March 15, 1941.

The history of attempts to classify EA reflects differences in the terminology, but not in the types of anomalies encountered. In 1929 E. C. Vogt, a radiologist, recognized and classified the types of anomalies.[22] With the success of operative repair, many other anatomic classifications were proposed. In 1944 Ladd introduced a numeric form of classification that consisted of five types with Roman numerals.[8] Gross altered the numeric system in 1953 to an alphabetic system that is still frequently used (Fig. 69-2).[23] In 1962 Swenson returned to a numeric classification and used Arabic numbers instead of Roman numerals.[24] In a 1976 report, Kluth published a complete listing of all described variations of EA including 10 separate classes and additional subclasses.[25]

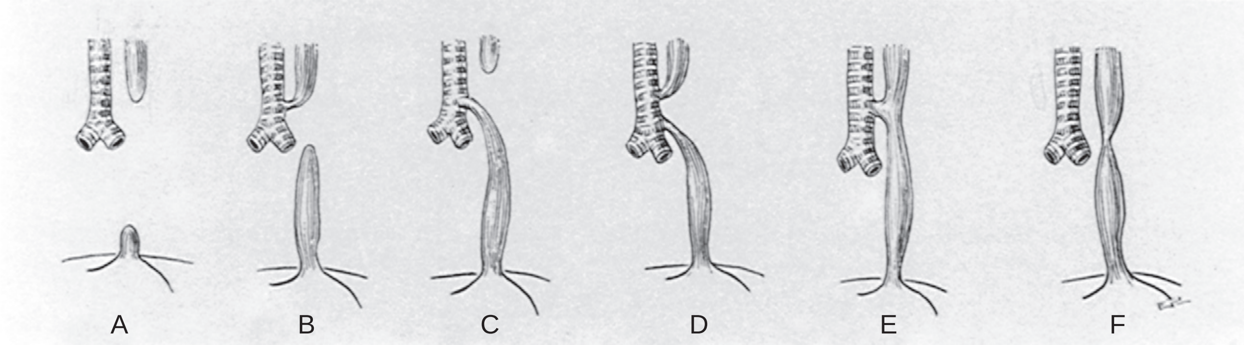

**FIGURE 69-2** Gross classification of anatomic patterns of esophageal atresia. **A,** Esophageal atresia without a tracheoesophageal fistula. This malformation is almost invariably associated with a "long gap." **B,** Atresia with a proximal tracheoesophageal fistula. It is an uncommon anomaly; the abdomen is airless, and the diagnosis may be missed unless contrast studies or endoscopy is performed. **C,** Esophageal atresia with a distal tracheoesophageal fistula, the most frequently encountered form of esophageal anomaly. **D,** Atresia with a double (proximal and distal) fistula. Though rare, this form is found more often than originally thought. **E,** Tracheoesophageal fistula without atresia (H-type fistula). This anomaly may be missed in the newborn period because swallowing is possible. It is associated with recurrent cough, pneumonia, and abdominal distention. **F,** Esophageal stenosis. (From Gross RE: Surgery of Infancy and Childhood. Philadelphia, WB Saunders, 1953.)

**TABLE 69-1**
**Waterston Risk Groups and Current Survival Figures**

| *Group* | *Survival (%)* | *Waterston Classification* |
|---|---|---|
| A | 100 | Birth weight > 2500 g and otherwise healthy |
| B | 85 | Birth weight 2000-2500 g and well or higher weight with moderate associated anomalies (noncardiac anomalies plus patent ductus arteriosus, ventricular septal defect, and atrial septal defect) |
| C | 65 | Birth weight < 2000 g or higher with severe associated cardiac anomalies |

In addition to anatomic classifications, in 1962 D. J. Waterston, R. E. Bonham Carter, and Eoin Aberdeen of the Hospital for Sick Children in London developed a classification system related to risk factors in infants with EA.[26] This risk stratification allowed comparison of case outcomes over time and between hospitals. The use of this classification scheme—which was based on birth weight, the presence of pneumonia, and associated congenital anomalies—allowed the identification of factors that predicted survival and guided operative treatment. This approach to the classification of EA anomalies has been an important contribution to the care of these infants (Table 69-1).

# Embryology

The pathogenesis of congenital EA malformations remains unknown. Although many theories have been offered to explain the etiology of EA, EA-TEF, and TEF, no single unifying theory has been proposed that addresses all the variations seen with this group of anomalies. The pathogenesis is heterogeneous and multifactorial and involves multiple genes and complex gene-environment interactions. In addition, about half of the cases of EA are isolated and the other half are associated with other malformations.

A clear understanding of the pathogenesis of the EA malformation is hindered by the fact that normal foregut embryology is still obscure. Wilhelm His, Sr., the founder of human embryology, was the first to describe normal development of the respiratory system.[27] He believed that division of the foregut was the result of fusion of invaginating lateral longitudinal ridges that created a septum dividing the foregut into a dorsal digestive tract and a ventral respiratory system. Formation of the so-called tracheoesophageal septum is believed to begin caudally and end cranially.[7] Many of the theories concerning the pathogenesis of EA malformations have been based on this description.[7,28–31] However, several investigators have more recently found little evidence to support this theory of normal foregut separation and development. Reinvestigation of human specimens from the Collection of Embryos at the Carnegie Institute suggests that ingrowth of lateral foregut wall ridges and cranial development of a tracheoesophageal septum do not occur in the human embryo.[32,33] In addition, Kluth and colleagues[34] studied staged chicken embryos via scanning electron microscopy in an attempt to clarify normal foregut development. In this model they also found no evidence of lateral ridges or an epithelial tracheoesophageal septum.

A summary of the major theories to explain the embryopathology of the foregut has recently been presented by Kluth and Fiegel.[35] Theories of foregut occlusion and failure of recanalization of the intestinal lumen have been historically prominent in discussions regarding the pathogenesis of intestinal atresias including EA.[36,37]

Overwhelming proliferation of esophageal epithelium may play a role in the development of rare membranous EA, but it falls short as a comprehensive theory of typical EA malformations.[25] Another theory has been put forth by Cozzi and colleagues[38,39] and others[40] in which it is suggested that EA is a component of cephalic neurocristopathy. The observation that there is a clear association of neural crest-implicated cardiovascular anomalies (aortic arch, conotruncal and membranous ventricular septal defects), as well as thymic, thyroid, parathyroid, and facial malformations with EA, as seen with the DiGeorge syndrome, suggests that the pathogenesis of EA may be related to defective pharyngeal arch development.

An animal model in which Adriamycin is used as a teratogen and results in embryos with a variety of malformations, including EA and TEF, has been described and promises to provide new insight into EA pathogenesis.[41,42] Merei and Hutson have used this model to develop a theory suggesting that the primitive foregut develops into the trachea, with

subsequent EA-TEF anomalies.[43] Gittes has recently used this model, as well as human TEF tissue samples, to investigate the molecular mechanisms that may play a role in the pathogenesis of EA-TEF. He has proposed that the distal fistula tract and esophagus are of respiratory origin and that defects in lung morphogenesis account for this aspect of the EA-TEF anomaly.[44,45] Insight into the pathogenesis of EA-TEF will also come from a clearer understanding of the genetics of this and associated conditions. More than 50% of cases of EA-TEF are associated with other anomalies, and up to 10% of cases are found in specific chromosomal or single-gene disorders. Chromosomal abnormalities associated with EA-TEF include DiGeorge syndrome; full trisomies (21, 13, and 18); Opitz syndrome; and 13q, 17q, and 16q24 deletions.[46] Single-gene mutation examples include MYCN (Feingold syndrome), CHD7 (CHARGE syndrome), SOX2 (AEG syndrome), GL13 (Pallister-Hall syndrome), MID1 (Opitz G syndrome), and FANCA (Fanconia anemia).[46]

Recent insights into the genetics involved in VACTERL association will also provide new information into the etiology of EA-TEF. For example, the VACTERL-hydrocephalus association is related to mutations in the following genes: FANCC, FANCD1 and 2, FACCG, FANCB, and PTEN. In addition to VACTERL associations, EA-TEF is also increased in several other conditions such as Goldenhar syndrome and Martinez-Frias syndrome.[47] The development of rat and mouse models of EA has recently allowed the parallel study of both normal and abnormal embryogenesis. As discussed earlier, controversies persist, but the fundamental morphogenetic process appears to be a rearrangement of the proximal foregut into separate respiratory (ventral) and gastrointestinal (dorsal) tubes. This process depends on the precise temporal and spatial pattern of expression of a number of foregut patterning genes. Disturbance of this pattern disrupts foregut separation and underlies the development of tracheoesophageal malformations.[48] Specific murine models of EA-TEF have suggested a number of important genes related to pathogenesis that are mostly in developmental pathways including vitamin A effectors, retinoic acid receptors α and β (Rarα and Rarβ), sonic hedgehog pathway effectors (Shh, Gli2, Gli3, Foxf1), and other homeobox containing transcription factors (Hoxc4, Ttf-1, Pcsk5).[46] As suggested by the Adriamycin rat model for EA-TEF, environmental teratogens have also been implicated in the pathogenesis of EA ± TEF. EA has occurred in infants born to mothers with prolonged exposure to contraceptive pills[49] and exposure to progesterone and estrogen during a pregnancy.[50] In addition, EA has been reported in some infants of hyperthyroid[51] and diabetic mothers and after intrauterine exposure to thalidomide and diethylstibestrol.[46,52]

Many studies have described transverse and vertical familial cases of all varieties of EA. Empirical risk figures based on the literature to date give a 0.5% to 2% recurrent risk in siblings of one affected child; the risk increases to 20% if more than one sibling is affected.[53] The empiric risk for a child born to an affected parent is 3% to 4%.[53]

## Epidemiology

The reported incidence of EA, with or without TEF (EA ± TEF), is 1:3500 live-born infants; however, it varies geographically from 1 in 2440 births in Finland[54] to 1 in 4500 births in the United States[55] and Australia.[56] According to data from the California Birth Defects Monitoring Program database, from 1983 to 1988 the total prevalence of EA, EA-TEF, and TEF alone was reported to be 2.82 per 10,000 live births and stillbirths.[57] In Europe, the prevalence rate of EA-TEF during 1980 to 1988 was 2.86 per 10,000 births, although this rate appeared to be decreasing over time.[58] In this European study, 62% of infants with EA-TEF were male, whereas the California database found that male-to-female ratios varied considerably between types of EA-TEF defects, with ratios of 2.29 for TEF alone, 1.44 for EA-TEF, and 1.33 for EA alone.[57] Mothers of white ethnicity have a higher (>60%) prevalence of EA-TEF and TEF than nonwhite populations do.[59,60] An increased risk for EA-TEF with a first pregnancy,[59] as well as increasing maternal age,[57] have been reported (twofold increased risk for women 35 to 40 years old and threefold increase for those older than age 40).[60]

The rate of multiple births is high for each type of EA-TEF anomaly (TEF, 3.7%; EA-TEF, 4.9%; and EA alone, 8.8% in a control population).[57] In addition, EA, along with other congenital anomalies, is significantly increased in the offspring of in vitro fertilization patients (OR 3.65:CI 2/53-5/26).[61]

## Associated Anomalies

The early disturbance in organogenesis that results in EA deformities, whatever the exact cause, also affects other organ systems. Other congenital anomalies are frequently associated with EA, and the associated anomaly often significantly alters treatment and affects survival. Numerous reports have suggested that between 50% and 70% of infants with EA have at least one associated congenital malformation. The anomalies are most common in cases of EA without TEF and are least common in cases of H-type TEF.[62] About half of all EA-TEF-associated malformations can be classified as part of a recognizable malformation syndrome such as chromosomal, VACTERL, CHARGE, Fanconi anemia, Opitz G, and Goldenhar. The other 50% of patients with associated malformations are considered as “nonsyndromic” with multiple congenital anomalies. In a recent study from France, these malformations included cardiovascular system (24%), urogenital (21%), digestive (21%), musculoskeletal (14%), and central nervous system (7%).[63]

Considering reports over recent decades, cardiovascular anomalies occur most frequently (11% to 49%),[39,64–66] followed by genitourinary (24%),[67] gastrointestinal (24%),[68] and musculoskeletal (13% to 22%)[69,70] anomalies (Table 69-2). Associated neurologic anomalies include neural tube defects (2.3%), hydrocephalus (5.2%), holoprosencephaly (2.3%), and anophthalmia or microphthalmos (3.7%).[59] Other reported associated anomalies include choanal atresia (5.2%), facial cleft (7.2%), abdominal wall defects (4.3%), and diaphragmatic hernia (2.9%).[59] One report suggests that the incidence of certain associated anomalies may vary by world region in that genitourinary anomalies were found in 26% of a European cohort of patients versus only 4% of an Asian cohort.[70]

Complex cardiac deformities may account for most of the deaths associated with EA malformations. The relative risk for death in infants with EA malformations associated with a major cardiac anomaly is reported to be 3.47 (95% confidence interval [CI], 1.51 to 7.96).[65,71] In a series of 153 patients

**TABLE 69-2**

**Incidence of Associated Anomalies**

| | |
|---|---|
| Cardiovascular | ≈24% |
| Genitourinary | ≈21% |
| Gastrointestinal | ≈21% |
| Musculoskeletal | ≈14% |
| Central nervous system | ≈7% |
| VACTERL association | ≈20% |
| Overall incidence | 50%-70% |

VACTERL, vertebral, anorectal, cardiac, tracheoesophageal, renal, and limb abnormalities.

with EA, Leonard and colleagues reported that the 1-year survival rate of infants with congenital heart disease (CHD) was 67% versus 95% in those without CHD.[66] Interestingly, these authors concluded that although CHD is associated with higher mortality in EA patients, it is not the direct cause of it.[66] The most common single defects identified are ventricular septal defects (19%), which have reportedly been associated with a mortality rate of 16%[72] and atrial septal defects (20%).[64] Other common cardiac anomalies include the tetralogy of Fallot (5%) and patent ductus arteriosus (13%).[64] Coarctation of the aorta is found in 1% to 4% of infants with EA malformations.[64,73] A descending aorta on the right side has been reported in 4% of infants with EA.[64]

Some gastrointestinal anomalies associated with EA ± TEF are anorectal malformations (14%),[64] duodenal atresia (2%),[64] intestinal malrotation (4%),[74] ileal atresia, annular pancreas, and pyloric stenosis. Genitourinary defects are varied and include renal agenesis or hypoplasia (1%), hypospadias, undescended testes, cystic renal disease, hydronephrosis, vesicoureteral reflux, ureteric duplication, ureteropelvic and vesicoureteral obstruction, urachal anomalies, ambiguous genitalia, and cloacal or bladder exstrophy.[59,75,76] Typical musculoskeletal malformations include limb (15%) and vertebral (17%) anomalies.[64]

In 1973 Quan and Smith,[77] suggested a broad spectrum of associated malformations that are associated with EA malformations. They arranged this association into the acronym VATER: vertebral defects, anal atresia, tracheoesophageal fistula, esophageal atresia, and renal defects. Opitz defined the term "association" as the idiopathic occurrence of multiple congenital anomalies during blastogenesis.[47,77] Affected patients have no family history of malformations, no recognizable teratogen is involved, and no chromosomal abnormality is observed. As the phenotype expanded, the acronym was changed to the VACTERL association, which includes vertebral, anorectal, cardiac, tracheoesophageal, renal, and limb abnormalities.[78] The incidence of the VACTERL association in the EA population is approximately 20%.[65] Infants specifically with EA-TEF frequently have VACTERL anomalies (vertebral, 17%; anal, 12%; cardiac, 20%; renal, 16%; limb, 10%), as well as other midline defects (cleft lip and palate, 2%; sacral dysgenesis, 2%; urogenital anomalies, 5%).[79] The "renal" category should include urinary tract anomalies such as megalourethra, urethral duplication, urethral valves, stricture, and hypospadias. It generally requires a minimum of three of the components to qualify as a "VACTERL patient." Recently, the VACTERL-H association has been described and includes congenital hydrocephalus.[77,80] Infants with EA malformations in association with the VACTERL association have a high mortality rate. Iuchtman and colleagues[81] analyzed the results of 46 infants born with EA and features of the VACTERL association among 313 patients with EA, TEF, or both. In this series, the mortality rate was 24%. Cardiovascular anomalies were present in 78% of the patients and were the principal cause of death. More recently, Driver and colleagues reported that the relative risk for mortality in patients with VACTERL associations was 2.54 (95% CI, 1.14 to 4.86).[65]

EA malformations are increasingly being described in association with other polytopic defects, sequences, syndromes, and associations. Some of these include Down syndrome[82]; the DiGeorge sequence[83]; the polysplenia sequence; Holt-Oram syndrome; the Pierre Robin sequence[53]; Feingold syndrome[84]; Fanconi syndrome; Townes-Brock syndrome; Bartsocas-Papas syndrome; McKusick-Kaufman syndrome[53,85–88]; the CHARGE association (coloboma, heart defects, atresia choanae, developmental retardation, genital hypoplasia, and ear deformities)[89]; and the schisis association (omphalocele, neural tube defects, cleft lip and palate, and genital hypoplasia).[90,91] Other serious or lethal associations are trisomy 18, cerebral hypoplasia, and Potter syndrome (bilateral renal agenesis).[92,93] In addition to the well-described anomalies associated with EA just discussed, many recent reports describe significant malformations and associated conditions that may become more frequently recognized. Unilateral pulmonary agenesis associated with EA-TEF is a rare condition; only 37 cases have been reported since 1874.[94–100] Usui and colleagues[101] reported a 47% incidence of tracheobronchial abnormalities such as ectopic or absent right upper lobe bronchus, congenital bronchial stenosis, and a decreased ratio of circumferential cartilaginous trachea to membranous trachea; these abnormalities could play an important role in such respiratory conditions as tracheomalacia and atelectasis associated with EA.[101] Several reports also suggest that EA is associated with abnormalities in vagal innervation that are not related to surgical intervention to repair the esophageal defect.[102]

# Classification

As noted previously, numerous classification schemes have been proposed and used to describe EA. The most useful and practical classifications are perhaps simple anatomic descriptions, even though many institutions and surgeons still use the Gross classification. It is important to note, however, that there are many variations to the fairly straightforward anatomic descriptions given in Table 69-3. In 1976 Kluth[35] summarized and diagrammed many of the anatomic variants not described by the many classifications mentioned here.

Waterston's 1962 classification was based on risk factors (see Table 69-1). The classification affected the surgical care of these patients. Infants in the "good"-risk category (A) were

**TABLE 69-3**

**Incidence of Various Esophageal Atresia—Tracheoesophageal Fistula Anomalies**

| | |
|---|---|
| 1. Esophageal atresia with a distal tracheoesophageal fistula | 84% |
| 2. Esophageal atresia without tracheoesophageal fistula | 6% |
| 3. Tracheoesophageal fistula without esophageal atresia | 4% |
| 4. Esophageal atresia with a fistula to both pouches | 1% |
| 5. Esophageal atresia with a proximal tracheoesophageal fistula | 5% |

typically treated with immediate operative repair, "moderate"-risk infants (B) were managed by delayed repair, and "high"-risk infants (C) were treated by staged repair. Although the Waterston classification continues to be used to compare results between centers, many investigators have questioned its current validity in caring for these infants.[68,92,103] With modern neonatal critical care, more low-birth-weight infants are surviving and more treatment options are available for infants with multiple congenital anomalies. As a result, a search for modern criteria for survival has produced several new classification schemes.

In 1989 Randolph and colleagues[103] suggested a refinement in Waterston's classification on the basis of the overall physiologic status of an infant with EA. According to a report analyzing the results of 39 infants managed with the physiologic status criteria, more and earlier primary repairs were performed, and excellent survival rates were maintained in stable infants in comparison with 87 infants previously managed by using Waterston's criteria.[103]

Other prognostic classifications have recently been proposed. Poenaru and colleagues[92] suggested that only severe pulmonary dysfunction with a preoperative mechanical ventilation requirement and severe associated anomalies were independent predictors of survival. Brown and Tam[104] suggested that the measured length of the esophageal gap provides a method of classification to predict morbidity and long-term outcome. In a review of 357 cases of EA treated at the Hospital for Sick Children on Great Ormond Street in London between 1980 and 1992, Spitz and colleagues[93] found that birth weight and major cardiac disease were important predictors of survival. The Spitz classification is currently the system most commonly used.[65,105] Okamoto and colleagues[196] recently suggested a revision to the Spitz classification (Table 69-4). Using receiver-operating characteristic (ROC) curves to compare the two classifications, these authors suggest that as overall care of low- and very-low-birth-weight infants improves, the cardiac anomalies play an increasing role in assessing prognosis for infants with EA.

## Diagnosis and Clinical Findings

Unlike many congenital pediatric surgical problems, prenatal EA is not commonly diagnosed. Prenatal detection of EA by ultrasonography relies on the finding of a small or absent stomach bubble and associated maternal polyhydramnios.[106] However, with these criteria, the predictive value of prenatal ultrasonography in the diagnosis of EA is only 20% to 40%.[107,108] The ultrasonographic finding of an esophageal pouch in the middle of the fetal neck in association with polyhydramnios and a small stomach may increase the accuracy of prenatal diagnosis of EA.[109,110] A recent report suggests that real-time fetal magnetic resonance imaging may be a useful adjunct in the prenatal diagnosis of EA anomalies suspected on ultrasound.[111]

Most infants with EA are symptomatic in the first few hours of life. The earliest clinical sign of EA is usually excessive salivation that results from pooling of secretions in the pharynx. Typically, the first feeding is followed by regurgitation, choking, and coughing. Other features are cyanosis with or without feeding, respiratory distress, inability to swallow, and inability to pass a feeding or suction catheter through the mouth or nose into the stomach. If a distal fistula is present, the abdomen distends as inspired air passes through the fistula into the stomach. Pulmonary compromise can become significant as gastric fluid refluxes through the TEF, spills into the trachea and lungs, and subsequently leads to chemical pneumonitis. As the abdomen distends with air, the diaphragms (the principal muscles of respiration in the newborn) elevate and pulmonary status worsens. Aspiration of saliva from the upper pouch into the trachea further exacerbates the pulmonary compromise.

The diagnosis of EA can be confirmed by passing a firm catheter through the mouth into the esophagus to the point at which resistance is met. A few milliliters of air can be injected through the tube and used as a contrast agent to distend the upper esophageal pouch as frontal and lateral films are obtained (Fig. 69-3). A flexible catheter such as a feeding tube will often curl up in the upper pouch, also suggesting the diagnosis of EA (Fig. 69-4). If necessary, 0.5 to 1.0 mL of diluted barium can be used as a contrast agent and injected into the upper pouch to confirm the diagnosis (Fig. 69-5). Under carefully controlled fluorography, barium may also detect a proximal TEF; in the usual circumstance of a portable film performed in the neonatal unit, however, barium identified in the tracheobronchial tree is more likely to represent contrast aspirated through the larynx rather than through a proximal TEF. A very small or short upper blind pouch may also suggest the presence of a proximal TEF. Air in the stomach and bowel confirms the presence of a distal TEF. Absence of air in the abdomen typically represents isolated EA without distal TEF (Fig. 69-6), but the presence or absence of a proximal TEF must be confirmed by bronchoscopy. The incidence of proximal TEF is much higher than thought in the past. However, it is possible to have absence of intestinal air in the circumstance of a narrow or occluded distal fistula, which is identified at the time of operation.[112,113] The diagnosis of TEF without EA is more difficult and requires a high index of suspicion on the basis of clinical symptoms. The diagnosis is often delayed, and investigations are triggered by repeated coughing or choking during feedings, often with pulmonary infiltrates on chest radiograph suggesting aspiration. The diagnosis can be made by barium esophagography in the prone position (Fig. 69-7); however, bronchoscopy with or without esophagoscopy is often required to confirm the diagnosis.

**TABLE 69-4**
**Okamoto modification of the Spitz Classification: Predictors of Survival in Cases of Esophageal Atresia**

| *Class* | *Description* | *Risk* | *Survival* |
|---|---|---|---|
| Class I | No major cardiac anomaly, BW $\geq$ 2000 g | Low | 100% |
| Class II | No major cardiac anomaly, BW $<$ 2000 g | Moderate | 81% |
| Class III | Major cardiac anomaly, BW $\geq$ 2000 g | Relatively high | 72% |
| Class IV | Major cardiac anomaly, BW $<$ 2000 g | High | 27% |

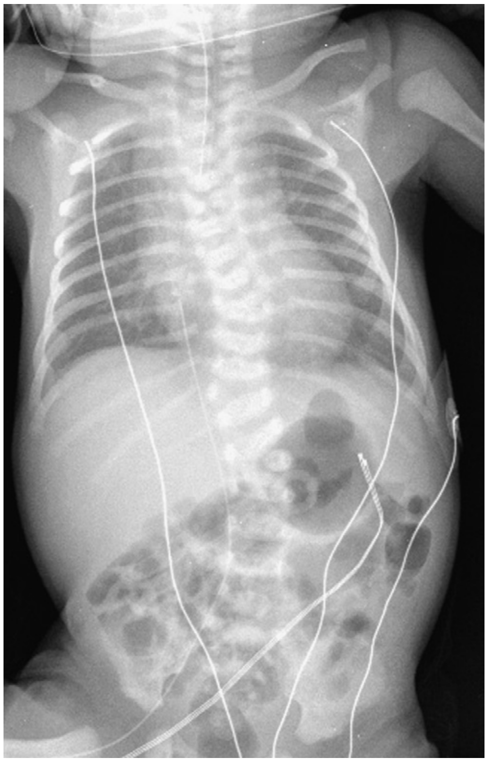

FIGURE 69-3 Upper esophageal atresia pouch with air. Also note vertebral anomalies.

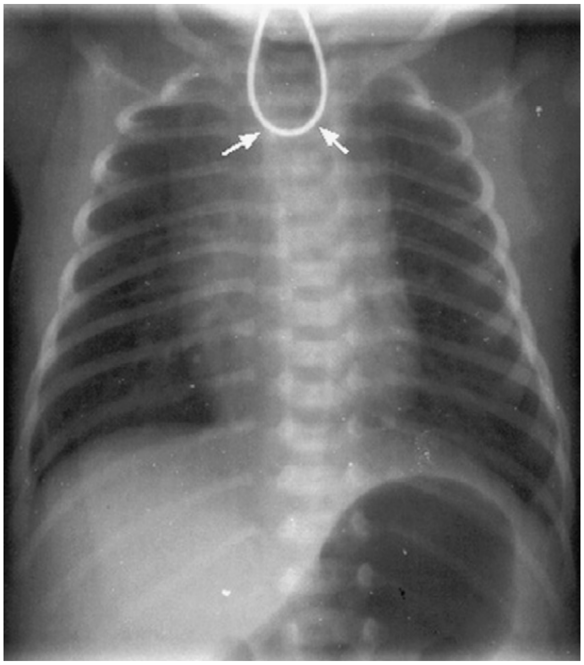

FIGURE 69-4 Upper esophageal atresia pouch with coiled feeding tube.

As previously discussed, the incidence of recognizable congenital defects associated with EA is between 50% and 70%. The clinical evidence of these other anomalies should, therefore, be considered in the diagnostic evaluation for EA. In addition to a physical examination focused on seeking known associated defects (such as those of the VACTERL association), additional testing usually includes echocardiography, renal ultrasonography, and chromosomal analysis. In fact, it is not unusual for the finding of an anorectal malformation, for example, to precede the clinical signs and symptoms of a concomitant EA.

## Preoperative Treatment

Pneumonitis from aspiration of upper pouch secretions and reflux of gastric acid through the TEF causing worsening respiratory distress is the most critical preoperative problem for an infant with EA-TEF. Immediate management includes measures to prevent further aspiration and treatment of pneumonitis. A sump catheter should be positioned in the upper esophageal pouch to continuously aspirate saliva under low-pressure suction. The double-lumen Replogle type of catheter is best for this purpose because the perforations along the side of the catheter are located only near the tip, which minimizes the possibility of suctioning oxygenated air away from the larynx. The infant should be positioned to minimize reflux of gastric fluid up through the TEF. An upright sitting position has traditionally been advocated, but some authors argue that the head-up, prone position is most effective at minimizing reflux. Broad-spectrum antibiotic coverage and pulmonary physiotherapy are also initiated. Intravenous fluid therapy with 10% dextrose and hypotonic saline should be started to maintain fluid, electrolyte, and glucose balance. Vitamin K analogue should also be administered before surgery. Routine endotracheal intubation should be avoided because of the risk for gastric perforation and worsening respiratory distress as the abdomen becomes distended from ventilation through the TEF.

## Operative Repair

The operative approach to an infant with EA depends greatly on the specific type of anomaly present and the occurrence of associated anomalies.

### ESOPHAGEAL ATRESIA WITH DISTAL TRACHEOESOPHAGEAL FISTULA

Emergent operation for EA with distal TEF is seldom necessary, and a period of 24 to 48 hours between diagnosis and operation permits full assessment of the infant and treatment of pulmonary insufficiency including atelectasis and pneumonitis. In most infants, open thoracotomy or thoracoscopic division of the fistula with primary anastomosis of the esophagus is possible and is the operative procedure of choice.

For the open approach, the infant is usually positioned for a standard right posterolateral thoracotomy, with the right arm extended above the head and the head slightly flexed. If a right-sided aortic arch (2.5%) is identified on a preoperative echocardiogram, a left-sided thoracotomy is preferred; however, a double aortic arch is not unusual and makes a left thoracic approach difficult as well.[114] A curved skin incision is made around the lower border of the scapula and extends from the anterior axillary line posteriorly to the paravertebral region (Fig. 69-8). Subcutaneous tissue and chest wall muscles are divided using electrocautery; this allows elevation of the scapula and identification of the fourth intercostal space.

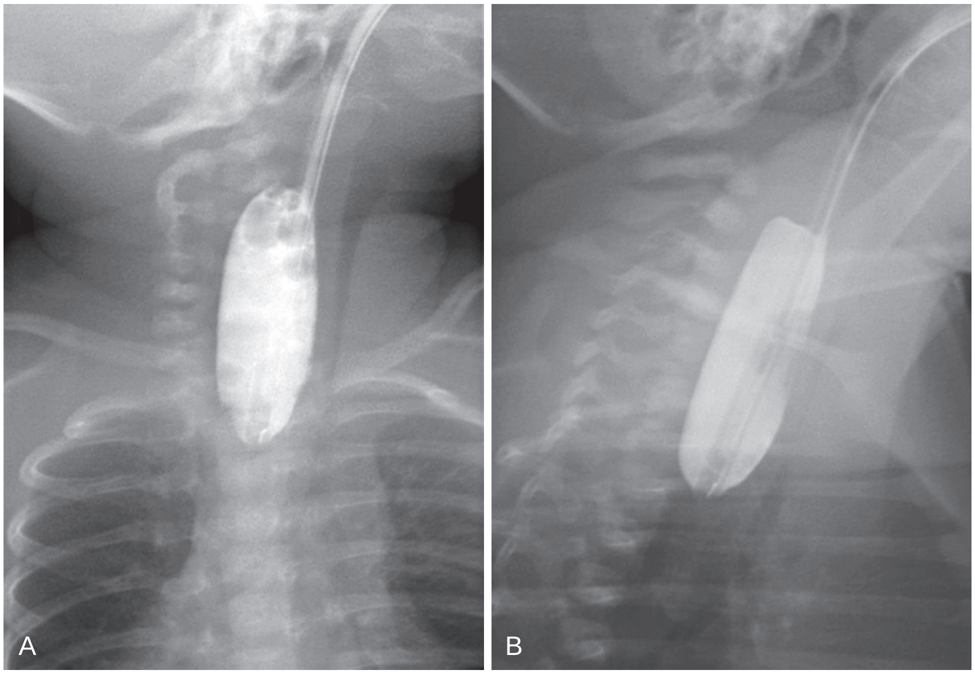

**FIGURE 69-5** The upper esophageal pouch is outlined by 0.5 to 1 mL of thin barium in the frontal **(A)** and lateral **(B)** projections.

**FIGURE 69-6** Absence of intestinal air suggests isolated esophageal atresia without tracheoesophageal fistula. Also note vertebral anomalies.

**FIGURE 69-7** An H-type tracheoesophageal fistula is shown as contrast is injected through a nasoesophageal tube. Contrast is noted passing from the esophagus, through the fistula (*arrow*), and filling the upper part of the trachea and larynx.

Some surgeons advocate a muscle-sparing thoracotomy using an approach between the latissimus dorsi and the serratus anterior muscles in an attempt to minimize postoperative shoulder function morbidity.[115,116] The thorax is entered through the fourth intercostal space by dividing the intercostal muscles, with care taken to avoid incising the pleura. Most pediatric surgeons continue to advocate the extrapleural approach for EA-TEF repair because a substantial anastomotic leak does not result in empyema but merely causes an esophagocutaneous fistula, which typically closes in 1 to 2 weeks. Surgeons who use the transpleural route argue that the operative time is shorter and, with current antibiotic options, the risk for empyema after a leak is minimal. With the extrapleural approach, the pleura are gently pushed away from the chest

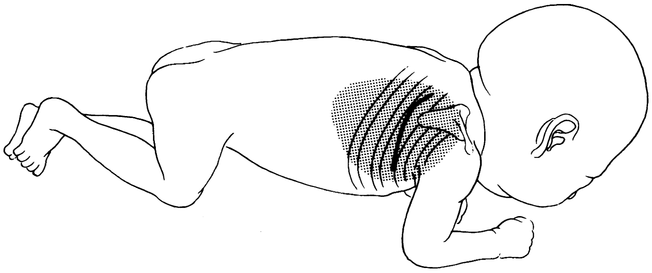

**FIGURE 69-8** Positioning of an infant for repair of esophageal atresia with or without a tracheoesophageal fistula. The thorax is entered.

wall; this in turn allows insertion of a rib-spreading retractor. Moist pledgets, tissue applicators, or gauze can be used to dissect the pleura anteromedially as the rib spreader is sequentially opened (Fig. 69-9). With further retropleural dissection, the azygos vein is exposed and may be divided between ties as the lung and pleura are gently retracted medially. When the posterior mediastinum is exposed, the upper pouch, distal TEF, trachea, and vagus nerve are identified. The lower part of the esophagus is dissected circumferentially at the level of the fistula, and every effort is made to preserve the vagal fibers that supply the distal portion of the esophagus. Traction on a heavy silk suture, tape, or vessel loop passed around the distal end of the esophagus controls gas flow through the fistula into the stomach and allows meticulous dissection and exposure for fistula closure (Fig. 69-10). The latter can be performed with 5-0 or 6-0 permanent or absorbable suture placed in interrupted fashion (Fig. 69-11). Because occasional intratracheal granuloma has occurred with permanent sutures, we recently chose to close the fistula with absorbable suture such as polydioxanone (Fig. 69-12). It is important to leave 1 to 2 mm of esophagus on the tracheal end of the fistula to minimize the risk for postoperative tracheal stricture, while not leaving an excessive amount that would act as a tracheal diverticulum. The air-tightness of the tracheal closure can be tested by filling the thoracic cavity with warm saline and watching for bubbles with positive-pressure ventilation.

A small tube should be passed through the distal end of the esophagus to ensure that the lumen is adequate and open and to aspirate air distending the stomach. Occasionally,

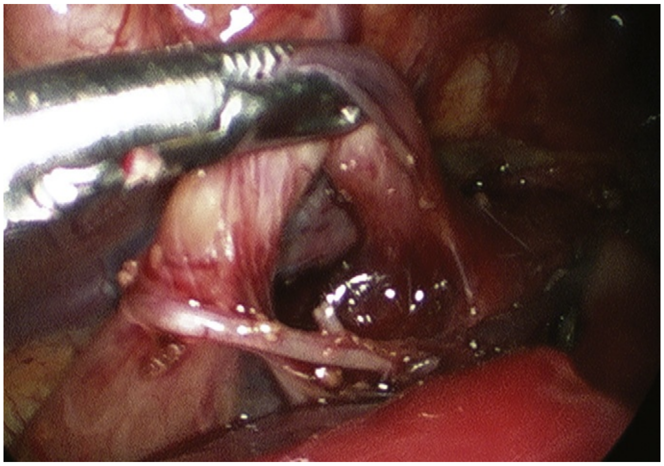

**FIGURE 69-10** Distal esophageal pouch mobilization up to the tracheoesophageal fistula at the tracheal bifurcation. Note the clear view of vagal branches. *(See Expert Consult site for color version.)*

a congenital distal esophageal stricture will be encountered. Two fine stay sutures on the distal esophageal opening allow gentle traction for dissection. The extent of distal mobilization should be minimized to avoid damaging vagal branches and the segmental blood supply. However, distal mobilization should be undertaken if it is necessary to ensure a primary low-tension anastomosis. Identification of the proximal esophageal pouch can be facilitated if the anesthesiologist gently pushes on a suction catheter, which is passed through the mouth into the upper pouch. A traction suture can be placed through the tip of the pouch, and even through the suction catheter, to assist in proximal dissection and avoid the trauma caused by repeatedly applying forceps to the proximal pouch. Mobilization of the upper pouch should be sufficient to bring the upper pouch down to the distal esophageal segment. This usually necessitates dissection up to the thoracic inlet (Fig. 69-13). Extensive circumferential dissection of the proximal pouch also allows for identification of an undiagnosed proximal TEF. Because the cervical blood supply to the proximal part of the esophagus is excellent, this type of extensive dissection does not run a significant risk for ischemic injury. Great care must be taken during the dissection between

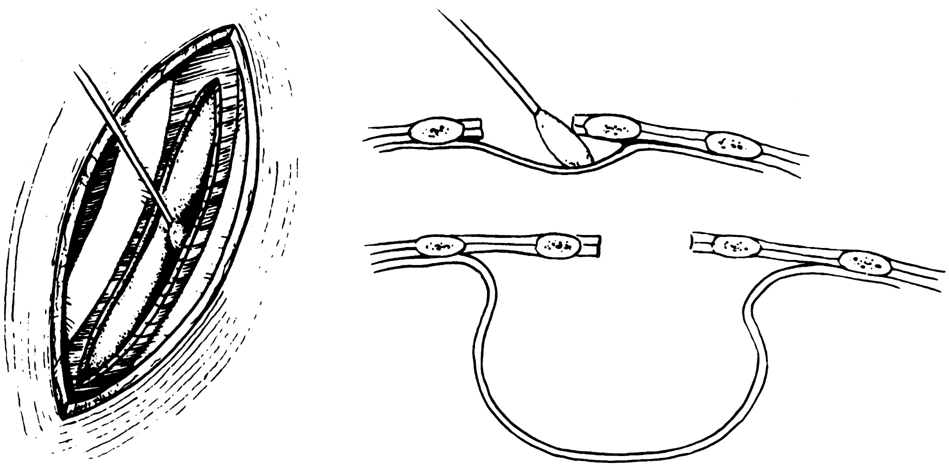

**FIGURE 69-9** Extrapleural dissection is facilitated by using moistened tissue applicators or pledgets to push the parietal pleura away from the chest wall and subsequently away from the posterior mediastinum.

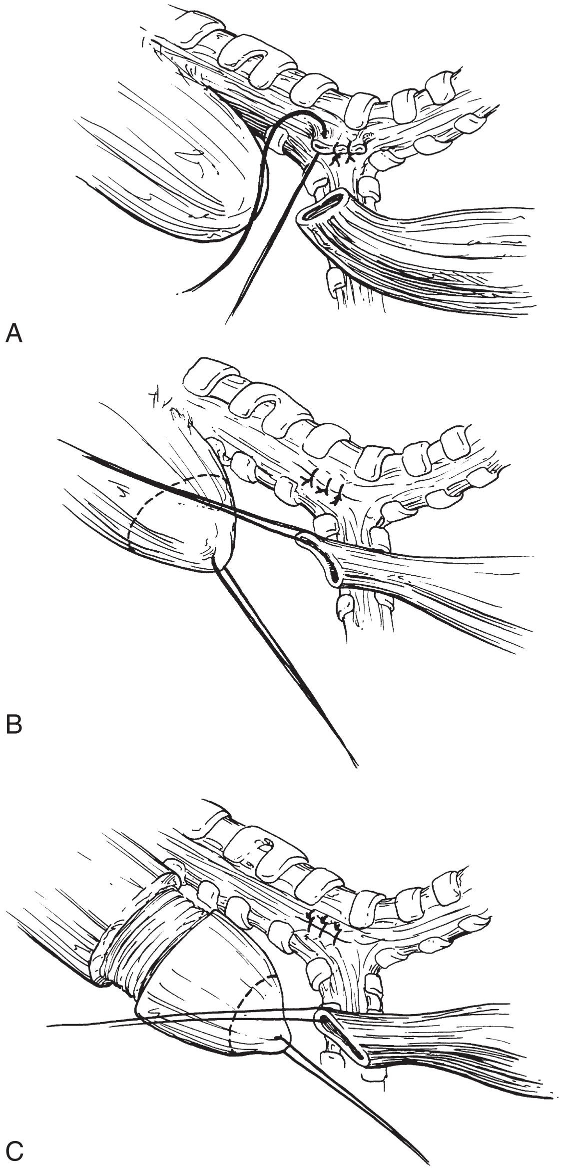

FIGURE 69-11 **A,** The opening of the tracheoesophageal fistula is closed with 5-0 or 6-0 nonabsorbable suture. **B,** The feasibility of primary anastomosis between the two esophageal segments is being assessed. **C,** A proximal esophagomyotomy being used to gain additional length. the esophagus and the membranous trachea, however, to avoid inadvertently opening the trachea. Unfortunately, the more extensive the proximal dissection, the greater the likelihood of disturbance to vagal branches.

The tip of the upper esophageal pouch is excised or simply opened and stretched at its lowest point to a diameter corresponding to the distal esophageal lumen. Traction sutures are placed opposite each other, and an end-to-end anastomosis is begun by placing interrupted 5-0 or 6-0 sutures in the back wall with the knots tied on the inside of the lumen; great care should be taken to include full-thickness esophageal wall including the mucosa and muscularis (Fig. 69-14). The upper pouch mucosa often retracts and can easily be missed if the surgeon is not vigilant. Unless the two ends of the esophagus are very close, it is best to insert the entire back row of sutures before tying them. A small feeding tube can then be passed and advanced across the anastomosis into the stomach to ensure distal esophageal patency and the potential for early postoperative enteral feeding if desired. The anterior layer of the anastomosis is then completed over the tube, with the knots tied on the outside (Fig. 69-15). The effect of the type of suture material used in the esophageal anastomosis on subsequent stricture formation has been a point of debate. In a review of patients in whom anastomotic strictures developed, Chittmittrapap and colleagues[117] reported a statistically significant increased rate of stricture when braided silk was used versus polypropylene or polyglycolic acid suture.

Once the anastomosis is complete, the position of the tube should be confirmed if it is to remain in place for postoperative gastric decompression and feeding. A chest tube or closed suction drain is usually placed in the retropleural space and secured to the lateral chest wall by a loose absorbable suture. The drain should be placed away from the anastomosis. Some surgeons leave no chest tube or drain in the chest after a retropleural dissection.[118]

In infants with EA and distal TEF, another technique for handling the fistula and uniting the esophageal ends is the end-to-side anastomosis developed by Sulamaa and colleagues[119] and championed by Duhamel and others.[109,120,121] With this technique, a single ligature is used to ligate the

fistula; the upper pouch is mobilized down to the lower esophageal segment, and a wide, oblique, end-to-side anastomosis is performed. Because of concern for recurrent TEF formation, this method has not been widely accepted. In a review from a center where both techniques were used, Poenaru and colleagues identified end-to-side anastomosis as a significant risk factor for mortality, specifically because of recurrent TEF, but noted a lower rate of gastroesophageal reflux (GER).[122]

In another series of 68 infants treated with this technique, Touloukian and colleagues[121] reported a TEF recurrence rate of 7%, a rate similar to or lower than that seen in large series of end-to-end reconstructions. In addition, the rate of other complications such as stricture (5%), anastomotic leak (8%), and GER (6%) was lower than in most other series using end-to-end esophageal reconstruction.

Thoracoscopic repair of EA-TEF is being adopted more widely. This technique typically uses three 2.5- to 5-mm transpleural access trocars, an angled telescope, a video camera, and small-diameter (2.5 to 5 mm) instruments to identify and ligate the TEF (often with a 5-mm clip), mobilize the proximal esophageal pouch, and perform an end-to-end esophagoesophagostomy in a fashion that is similar to the open thoracotomy approach (see Figs. 69-10, 69-12, 69-13, 69-15, and 69-16). Advocates of this approach have suggested that benefits include superior visualization, improved cosmesis, and elimination of the morbidity of neonatal thoracotomy including scoliosis, winged scapula, chronic pain, shoulder weakness, chest wall asymmetry, and maldevelopment.[123,123a] However, the thoracoscopic EA-TEF repair is technically demanding and requires advanced endosurgical skills. The thoracoscopic end-to-end esophageal anastomosis is technically challenging because of limited working space, lack of articulation at the end of the instruments (the needle driver in particular), and the necessity of tying sutures under tension.[123]

Particular attention must be given to infants with EA and a large distal TEF with severe respiratory distress syndrome. Under these circumstances, preoperative endotracheal intubation is often necessary. However, high-pressure ventilation may worsen lung ventilation and abdominal distention as inspired air is diverted through the TEF into the stomach, thus exacerbating respiratory compromise. Affected infants may require emergency surgical intervention to stabilize the pulmonary status and avoid gastric perforation, which is typically fatal in these circumstances.

Several operative approaches have been described to manage this problem including gastric division,[124] banding of the gastroesophageal junction,[125] and positioning the tip of the endotracheal tube below the fistulous orifice.[126] The latter technique may be dangerous if not combined with fiberoptic bronchoscopy to locate the TEF; a fistula at or close to the carina precludes the safe use of this technique, and inadvertent intubation through a large fistula may be fatal.[127] Bronchoscopic placement of a Fogarty balloon catheter through the fistula has been successfully used to ablate the flow of ventilated air through the fistula.[128] This approach may be used to stabilize a rapidly deteriorating infant; however, concern has been raised about potential technical difficulties with this approach and problems with injury to the distal end of the esophagus in which the balloon is inflated.[129] Emergency gastrostomy to decompress the air-filled stomach

and small bowel has also been used in this situation. This approach, however, places the infant at risk for pulmonary collapse because each ventilator breath volume bypasses the lung by preferentially passing through the TEF and escaping via the low-resistance gastrostomy tube. The use of a gastrostomy tube with an underwater seal may increase air resistance and decrease runoff through the fistula. A small balloon catheter passed through the gastrostomy into the lower esophagus can provide excellent palliation for days to weeks.[129a]

Emergent thoracotomy and fistula division in an infant with severe respiratory distress syndrome who requires high-pressure ventilation is generally the best approach; in a premature baby, the decision to operate should be made early because the hyaline membrane disease will worsen in the first 24 to 36 hours and will make the lungs even less compliant. In many circumstances, the infant remarkably improves after emergency fistula ligation; this improved condition may allow primary repair of the esophagus and thus eliminates the need for a second operation.

## LONG-GAP ESOPHAGEAL ATRESIA

Occasionally in infants with EA-TEF, the upper pouch is high and the distance between the upper and lower esophageal segments limits the ability to easily complete end-to-end esophagoesophagostomy with acceptable tension. The same is true for most neonates with isolated EA because the lower esophagus is not "attached" to the trachea. Although much has been said and written about the subject, there is no precise definition of "long-gap" EA. What is amenable to primary anastomosis by some surgeons may be considered "long gap," "very long gap," or "ultralong gap" by others. In addition, measurement of gap length can be biased by the method used to measure the distance between the proximal and distal ends of the esophagus. Some reports describe preoperative measurement of the gap by inserting a radiopaque tube or bougie into the upper pouch and placing contrast or a flexible endoscope into the distal pouch through a previously placed gastrostomy tube.[130,131] Other definitions of gap length are based on intraoperative measurements obtained before or after mobilization of the proximal pouch and, on occasion, the proximal and distal pouches. These variations on the method of determining gap length contribute to the confusion and debate about how long is long.[132]

In the case of isolated EA, in which a "long gap" is expected, most pediatric surgeons would proceed with the operative placement of a gastrostomy tube, a period of observation, and an attempted delayed primary repair. It is well documented that during the first several months of life, the gap between the two ends of the esophagus tends to lessen because of spontaneous growth, possibly related in part to reflux of bolus gastric feedings into the lower esophagus, which makes primary repair more feasible.[133,134] In addition, many preoperative mechanical techniques have been described as a means to facilitate narrowing of the esophageal gap. The most commonly used method is that of upper pouch bougienage, in which a weighted bougie is passed through the mouth into the upper pouch, with forward pressure applied daily or twice daily for 6 to 12 weeks before attempting delayed primary repair.[135] The use of preoperative upper and lower pouch bougienage to decrease gap length has also been described,[136] but some of the early proponents have abandoned this technique.[136a] In 1975 Hendren and Hale[137,138] reported using an electromagnetic field to pull together metallic "bullets" placed in the two ends of the esophagus in order to shorten the gap.

Other innovative operative techniques designed to narrow the long gap before attempted surgical esophageal anastomoses have been advocated. In 1971 Rehbein and Schweder[139] described the use of a nylon thread bridging the gap between the two ends of the esophagus and attached to silver olives[136] residing within each lumen. The olives were pushed toward each other over time until the two ends of the esophagus pressed together and created a fistula. Shafer and David[140] used a similar technique to create a fistula between the two ends of the esophagus by simply approximating the two ends of the mobilized esophagus with tacking sutures, then placing a bridging silk suture. A modification of this technique has recently been reported successful in five infants.[141] Another method that facilitates esophageal lengthening is the multistaged, extrathoracic elongation technique of Kimura, in which the upper part of the esophagus is mobilized and initially brought out as an end cervical esophagostomy. Every 2 to 3 weeks, the esophagus and its cutaneous stoma are surgically mobilized and translocated down the anterior chest wall until enough length is achieved to perform an end-to-end esophageal anastomosis.[142,143] Foker has described a novel technique in which traction sutures on both the proximal and distal esophageal pouches exit through the chest wall and are serially pulled in opposite directions until the pouches approximate (Fig. 69-17). The external traction technique is reported to induce esophageal growth and expedite approximation of the pouches, thus allowing for earlier primary repair (10 to 14 days).[144,145] Internal traction sutures have also been used to promote esophageal growth in cases where the gap is such that an initial anastomosis would perhaps be under too much tension. Successful thoracoscopic esophageal elongation for long-gap EA has also been reported.[146] There is also a report of using the Kimura technique for proximal pouch lengthening and the Foker technique for distal pouch lengthening.[147]

In addition to preoperative attempts to elongate the esophagus, many intraoperative techniques have been used to establish a primary esophageal anastomosis, either at an initial operation in the newborn period or at the time of a delayed operation after the elongation methods previously described have been used. Bagolan advocates using the "Foker traction" principle intraoperatively, finding that significant length can be obtained after 20 to 30 minutes of traction on the esophageal ends.[147a] Livaditis and colleagues[148,149] described the use of a circular myotomy of the upper part of the esophagus to decrease the tension on an end-to-end esophageal anastomosis in a piglet model of EA and, in 1973, reported the clinical use of this technique to lengthen the upper esophageal segment in order to allow for a primary anastomosis in an infant with long-gap EA (see Fig. 69-11).[150] Since that time, proximal esophageal circular myotomy to lengthen the upper esophageal pouch and achieve a primary anastomosis in long-gap EA has been widely used. The use of balloon catheters or cuffed endotracheal tubes inflated in the upper esophageal pouch to facilitate mobilization and subsequent circular myotomy seems to be a useful modification of this method.[151–154] We have occasionally made an additional right cervical incision to mobilize the upper esophageal pouch up and out of the neck and perform a more proximal second or third circular myotomy.[132]

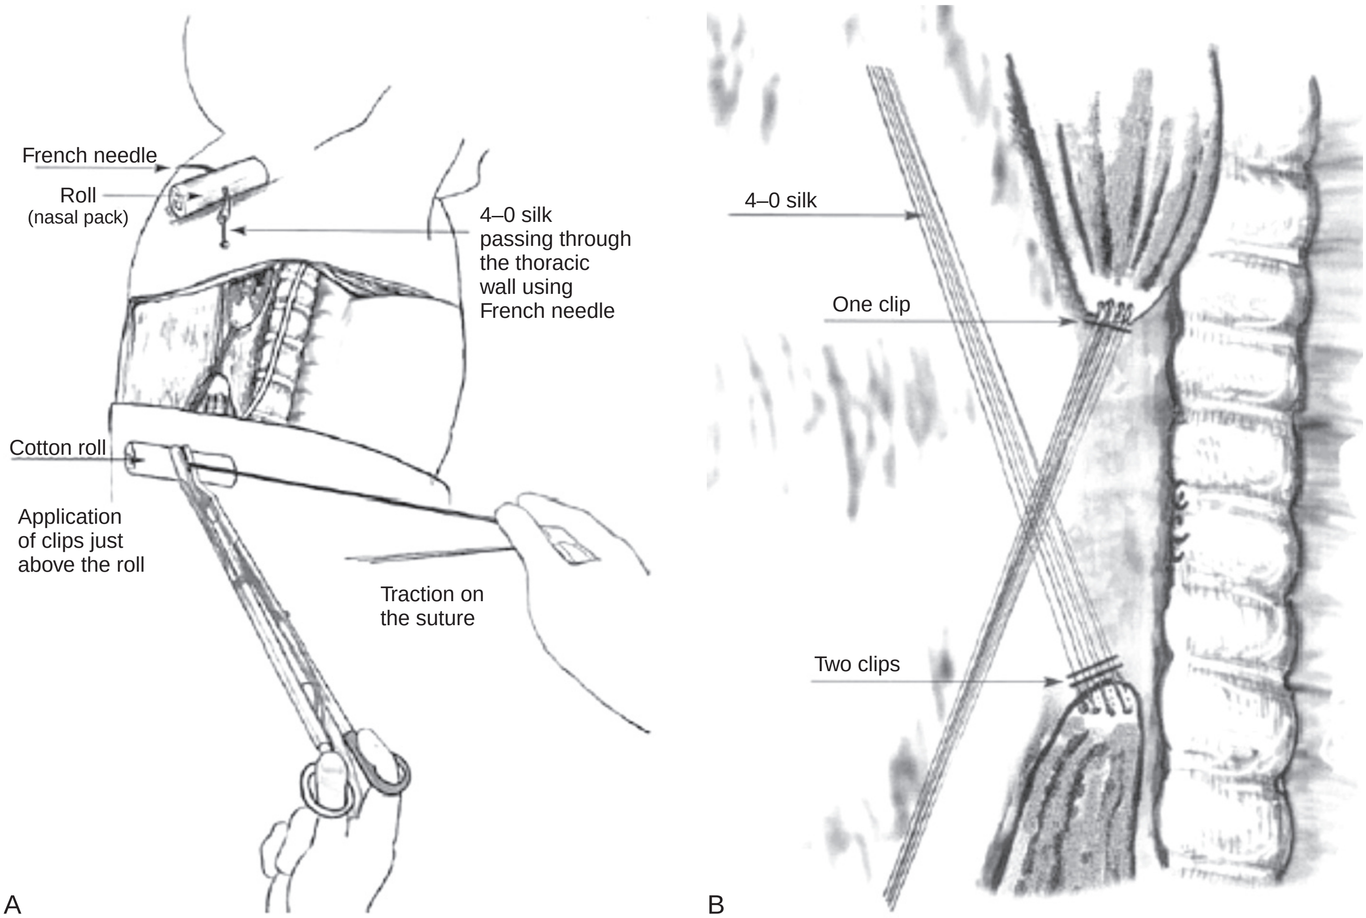

**FIGURE 69-17** Foker technique for lengthening the upper and lower esophageal pouches by external traction sutures. **A,** External view of crossed traction sutures and bolsters. **B,** Internal view. (From Foker JE, Linden BC, Boyle EM Jr, et al: Development of a true primary repair for the full spectrum of esophageal atresia. Ann Surg 1997;226:533.)

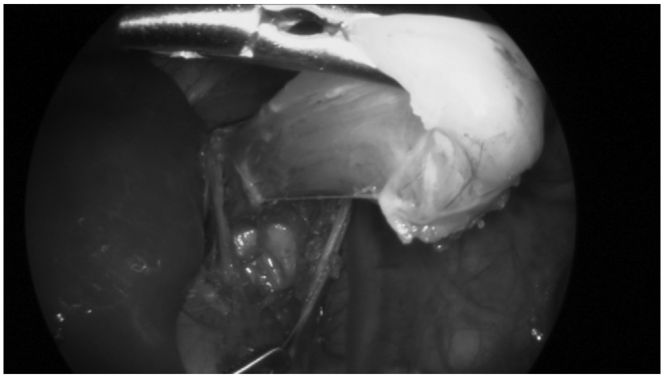
However, significant complications of circular myotomy have been described and have created a debate among surgeons regarding its safety. Complications include esophageal leak, impaction of food particles in the myotomized segment,[155] and mild ballooning of the myotomized segment. Severe ballooning resulting in an esophageal pseudodiverticulum has been reported to be a potentially serious complication. Several reports have noted the formation of a pseudodiverticulum with a distal anastomotic stricture, as might be expected.[152,155,156] If the stricture is not treated, the pseudodiverticulum can enlarge so much that it causes complications such as dysphagia and life-threatening respiratory obstruction.[156]

Several reports have suggested the use of a distal esophageal pouch circular myotomy in addition to proximal myotomy to achieve a primary esophageal anastomosis.[157,158] Many technical modifications have been suggested to minimize the risk for potential serious complications from circular myotomy. The use of a spiral upper pouch myotomy with oblique suture closure of the muscular layer has been advocated as a technique that minimizes the chance of diverticulum formation and, theoretically, improves motility.[159,160] Another method used to elongate the upper pouch involves the creation of a full-thickness anterior flap of the upper pouch wall as described by Gough; when folded distally, the flap can be rolled into a tube and attached to the lower esophageal segment.[161] In 1989 Bar-Maor and colleagues[162] emphasized the technical details of this method to elongate the upper pouch. Davenport and Bianchi[163] reported good follow-up results in 25 infants with EA treated by this method over a 5-year period. Variations of this technique have been described and consist of the creation of a 5-mm posterior flap[164] or anterior esophageal flap,[165] followed by an end-to-end oblique anastomosis with a spatulated distal esophagus.

At the time of attempted initial or delayed primary repair, the esophageal segments sometimes do not reach together even though one or more of the methods just presented have been tried. Several additional techniques have been described to facilitate an esophageal anastomosis. Despite the long-held opinion that the blood supply to the distal end of the esophagus is tenuous and may be compromised by mobilization, many surgeons have found that the distal esophagus can be, and often is, mobilized to facilitate a primary anastomosis (Fig. 69-18).[166] We have successfully achieved primary end-to-end esophageal anastomosis by completely mobilizing the distal esophagus down to and even through the esophageal hiatus of the diaphragm. With this approach, some of the fundus of the stomach can be brought up into the chest to facilitate anastomosis.[132]

Taking this concept further, Schärli described a combined abdominal and thoracic procedure in which distal esophageal elongation was achieved by ligation and division of the left gastric artery, transverse or diagonal division of the lesser



FIGURES 69-18 Aggressive mobilization of distal esophageal pouch in a case of isolated esophageal atresia.

curvature of the stomach, and mobilization of the gastric cardia and upper fundus into the chest to achieve primary esophageal anastomosis.[167,168] A partial fundoplication is recommended to treat the anticipated GER. Not surprisingly, postoperative GER has been reported to be a significant problem after this procedure.[169] By use of a similar approach, a Collis gastroplasty with Nissen fundoplication has also been described as a means of lengthening the distal end of the esophagus to avoid esophageal replacement.[170,171]

In addition to the surgical techniques used to facilitate saving the native esophagus as the conduit of choice for the repair of long-gap EA, the use of postoperative head flexion, paralysis, and mechanical ventilatory support has been strongly advocated by some to minimize the risk for anastomotic disruption when the esophageal anastomosis is under substantial tension.[68,136,172,173]

The rationale for this approach is the prevention of disruptive force at the anastomotic site by flexion of the neck and paralysis of the striated muscles in the proximal part of the esophagus.[136,174]

## ESOPHAGEAL REPLACEMENT

For an extensive discussion of esophageal replacement, see Chapter 71. Despite the many methods and innovations developed to achieve esophageal continuity in infants with EA, the esophagus may need to be replaced if these methods fail. Numerous operative procedures have been described for esophageal replacement in infants with EA, as well as children with caustic injury.

The choice of esophageal substitute depends on many factors. Colon replacement, or ileocolon, has been widely practiced for many years as a method of esophageal replacement. Either the right or left colon can be placed substernally or behind the hilum of the lung on the right or left side. Vagotomy and a gastric drainage procedure are typically performed to avoid stricture or ulceration at the cologastric anastomosis. Several complications occur after colonic interposition including cervical anastomotic leak (30% to 50% of cases), stricture, and intrathoracic redundant colon with stasis, gastric reflux, respiratory problems, and diarrhea. Some surgeons favor a reversed gastric tube as a substitute; in this procedure, a tubularized portion of the greater curvature is brought up to the cervical esophagus in the substernal or retrohilar position. Complications are similar to those described for colonic interposition. A modified gastric tube has also been described in which a portion of the greater curve is fashioned into a "free" tube graft based on the right gastroepiploic artery.[175] The jejunum has also been used for esophageal replacement both in a Roux-en-Y fashion and as a free graft with microvascular anastomosis.[176]

Gastric transposition has more recently become a well-established and successful esophageal substitute in infants with EA.[136,177,178] Spitz and colleagues[40] have reported good to excellent outcomes in 90% of 138 infants and children with EA in whom this method of replacement was used (age at operation ranged from 7 days to 17 years).[179] The survival rate was 95.4%, the incidence of anastomotic leak was 12%, the incidence of strictures requiring dilation was 20%, and there was no deterioration in function over a 10-year follow-up. A recent review by one of us (AGC) reports excellent outcomes in more than 110 infants treated with gastric transposition for long-gap esophageal atresia.[180] The technical aspects are demonstrated in Figure 69-19. A laparoscopic approach to gastric transposition has recently been reported and appears to be a viable, less invasive option.[181]

## ESOPHAGEAL ATRESIA WITHOUT TRACHEOESOPHAGEAL FISTULA

Infants born with isolated EA have almost no esophagus in their thorax. It is important to be aware of this fact in order to institute an appropriate treatment plan and avoid fruitless exploratory thoracotomy. The preoperative and operative treatment of this lesion was discussed extensively earlier in this chapter. In a review of 69 infants with isolated EA treated over a period of 50 years, Ein and Shandling[182] reported a 52% incidence of prematurity, an 11% incidence of Down syndrome, and a 10% incidence of duodenal atresia; all these rates are higher than typically reported in patients with EA-TEF. A recent 24-year review of the experience from Great Ormond Street Hospital for Children in London found that 71% of patients were male. Among the associated anomalies were 19% cardiac, 16% urogenital, 14% vertebral, and 7% anorectal malformation. A more recent review reports an 85% esophageal salvage rate but also describes the complicated preoperative and postoperative course for these infants including 60% anastomotic leak rate and severe gastroesophageal reflux disease.[183]

The clinical manifestations of an infant with isolated EA are similar to those of an infant with EA-TEF in terms of inability to swallow; in the former, however, the abdomen is typically scaphoid, and plain radiographs of the abdomen show no air in the gastrointestinal tract. A gastrostomy tube should be placed within the first 24 to 48 hours of life, and delayed primary repair using the various methods previously discussed should be attempted. Placement of the gastrostomy tube allows the early institution of enteral feedings, which leads to subsequent enlargement of the diminutive stomach and stretching of the distal esophageal pouch (Fig. 69-20). Enlargement permits the stomach to be used as an esophageal substitute if necessary. At the time of placement, a contrast imaging study can be performed to evaluate the unusual possibility of an occluded but present distal esophageal fistula to the trachea, which might suggest the potential for early esophageal repair.[112,113] A rigid bronchoscopy can also be done to eliminate the possibility of a proximal or occluded distal fistula. A period of observation and enteral nutritional support

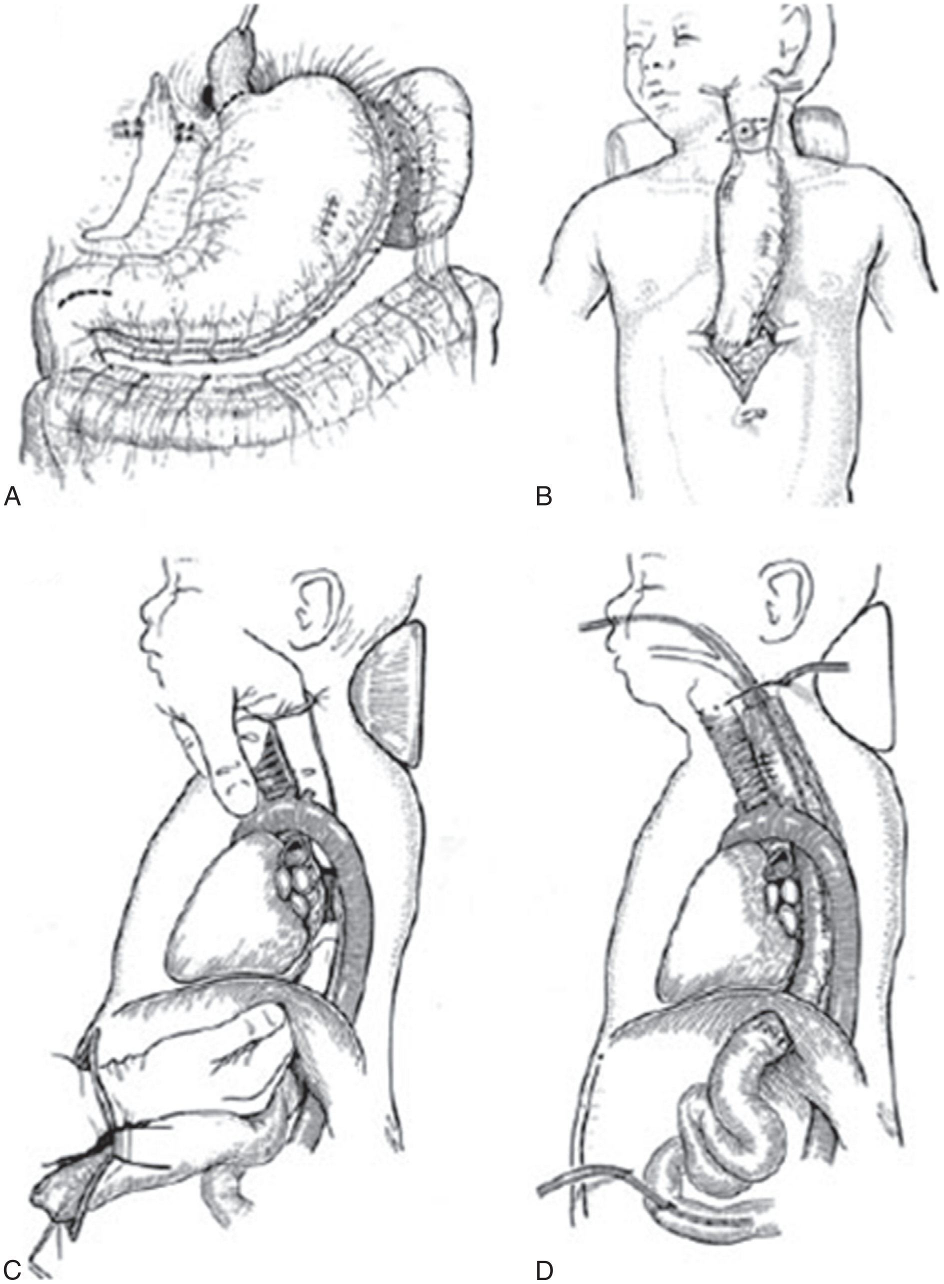


**FIGURE 69-19** **A** to **D,** Gastric transposition technique. (From Peditr Surg Int. 2010 Dec;26(12):1129-1134.)

is instituted with or without daily upper pouch bougienage. Over an 8- to 12-week period, the process of esophageal elongation can be monitored by imaging studies that use contrast material, metallic probes, bougies, or flexible endoscopy placed in the upper and lower esophageal segments (Fig. 69-21, *A* and *B*).

When no further elongation progress is evident or when the two ends of the esophagus can be brought to close proximity, an operation is performed. Thoracotomy or a thoracoscopic approach with dissection and mobilization of the proximal and distal esophageal segments is done and primary anastomosis is attempted. If these efforts do not allow primary anastomosis, circular myotomy, hiatal mobilization, Kimura procedure, proximal pouch flap esophagoplasty, or Foker's traction-elongation technique can be undertaken. When the two ends of the esophagus are clearly too distant for primary esophageal anastomosis despite preoperative attempts at elongation and consideration of these methods (i.e., lower esophagus does not reach above the diaphragm), we have proceeded with a primary gastric transposition to the cervical esophagus, typically without a thoracotomy. In these latter circumstances, many surgeons prefer to proceed to a cervical esophagostomy, preferably on the left side, with plans for a future esophageal replacement procedure. Postoperative complications are similar to those in infants with repaired EA-TEF (see the later section on outcomes); these adverse effects primarily include anastomotic leak and stricture, dysphagia, and gastroesophageal reflux disease (GERD).

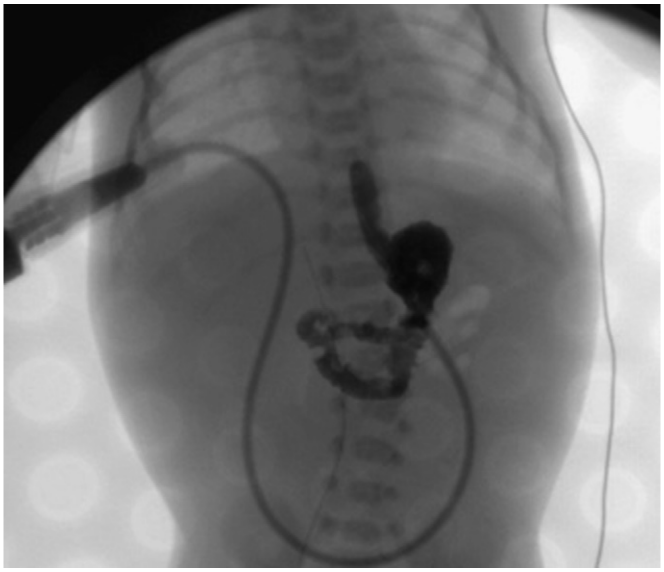

**FIGURE 69-20** Gastrostomy tube with contrast injection in an infant with isolated EA.

## ISOLATED (H-TYPE) TRACHEOESOPHAGEAL FISTULA

Congenital TEF without EA or the "H" type of TEF (perhaps more anatomically accurately called the "N" type) occurs in approximately 4% of esophageal anomalies reported. This anomaly is usually manifested in the first few days of life when the neonate repeatedly chokes on attempting to feed or has unexplained cyanotic spells.[184] When the infant is coughing or crying, intermittent abdominal distention can occur as air passes through the fistula into the stomach. Older infants and children are more likely to have recurrent bouts of pneumonia, typically involving the right upper lobe. A high index of suspicion is necessary in considering this diagnosis.

The diagnosis of isolated TEF can be suspected if plain radiographs of the chest show evidence of aspiration pneumonitis with gastric distention. A reliable way to establish the diagnosis is by tube video esophagography performed while the infant is prone; a small nasogastric tube is passed into the distal end of the esophagus, and contrast medium is gradually injected as the tube is slowly withdrawn. The radiologist performing the study must be familiar with this diagnostic approach because more than 50% of H-type fistulas may be missed on routine esophageal contrast swallow studies. Bronchoscopy with esophagoscopy can typically confirm the diagnosis and, if done immediately before surgery to divide the fistula, allows for the passage of a fine catheter or guidewire through the fistula to aid in subsequent identification at surgical exploration.[185]

Most isolated TEFs can be successfully divided through a cervical approach.[186] The site of a right-sided, low cervical incision is determined, and the infant is placed with the head extended and turned to the left. The sternocleidomastoid muscle is retracted posteriorly, with division of the sternal head if necessary; dissection then proceeds medially to the carotid sheath. Identification of the trachea and esophagus is facilitated by palpating the endotracheal and

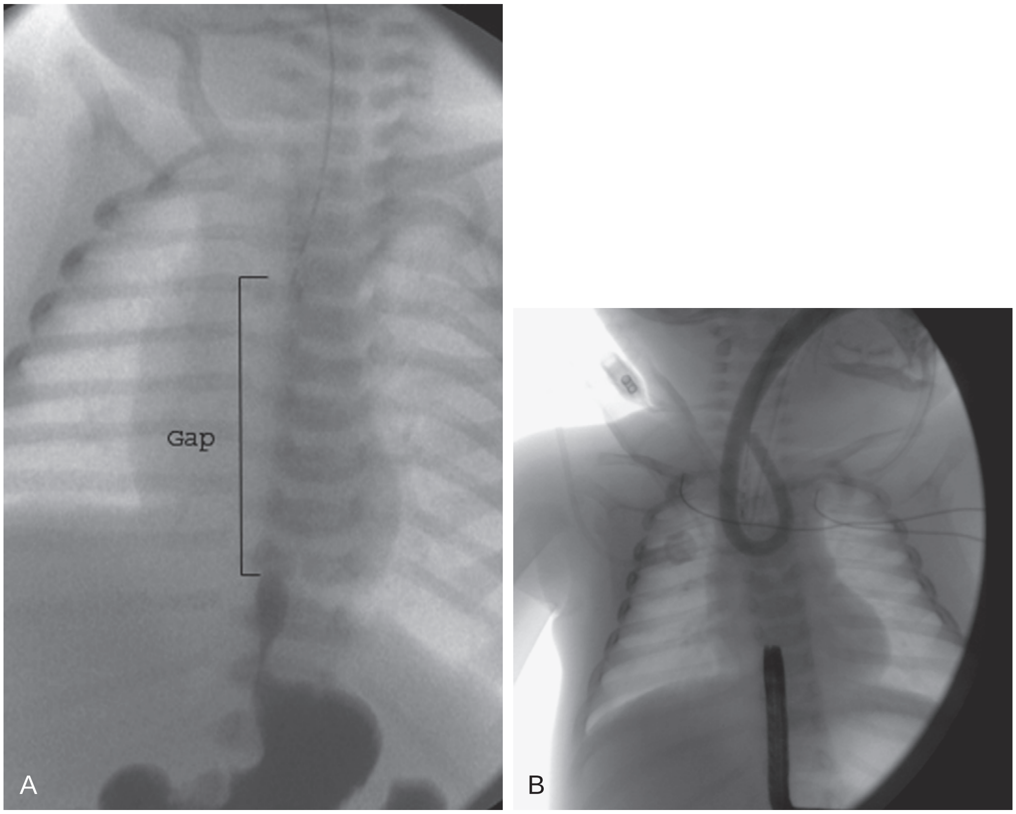

**FIGURE 69-21** A chest film taken with a Replogle tube pushing in on the upper esophageal pouch and a contrast injection through the gastrostomy tube demonstrates a long-gap isolated esophageal atresia **(A).** After 8 weeks, a repeat study with a bougie coiled in the upper esophageal pouch and a neonatal flexible endoscope passed through the gastrostomy site and up the distal esophageal pouch allows for assessment of interval narrowing of the gap **(B).**

nasogastric tubes. Division of the inferior thyroid artery and middle thyroid vein may be necessary to expose the plane between the trachea and esophagus. The recurrent laryngeal nerve must be identified and preserved. Identification of the fistula is facilitated by encircling the esophagus with Silastic slings, but it is important to be aware that the contralateral recurrent laryngeal nerve can be damaged during this maneuver. Once the fistula is identified (it is often higher than expected), traction stitches should be placed close to the esophagus through the superior and inferior extent of the fistula to avoid rotation of the esophagus after division of the fistula. On the tracheal side, 5-0 polypropylene sutures are placed at the superior and inferior limits of the fistula. The fistula is now divided close to the esophagus, and interrupted 5-0 Vicryl or PDS sutures are placed on the tracheal side to close the fistula. The esophageal side of the fistula is closed with absorbable polyglycolic acid sutures (Fig. 69-22). Some surgeons advocate interposing muscle tissue between the two opposing suture lines to reduce the likelihood of recurrence of the fistula. A right thoracotomy or thoracoscopic approach can be used on the rare occasion when the fistula is located well within the thorax or when a recurrent fistula from a previous EA repair is being approached.[187]

Postoperative complications include respiratory distress secondary to edema of the trachea or injury to the recurrent laryngeal nerves. The degree of preexisting lung disease and concerns about tracheal edema may warrant leaving the endotracheal tube in place for several days after the operation. Esophageal leak and recurrence of isolated TEF are rare.

## ESOPHAGEAL ATRESIA WITH AN UPPER POUCH FISTULA

There are two versions of this anomaly: (1) proximal pouch fistula in association with distal TEF (double fistula) and (2) proximal pouch fistula without distal TEF. Several reports have cited varying incidences of a fistula between the upper esophageal pouch and the trachea. The exact incidence of this type of fistula has probably been underestimated because some initially unrecognized proximal pouch fistulas have been reported as recurrent TEFs after repair of EA with distal TEF,[188] and some of these cases have been diagnosed as pure EA because the upper TEF was missed. A recent report by Bax and colleagues suggests that proximal pouch fistula without distal fistula is as high as 5.6% of all patients with EA.[189] The diagnosis can be made by a preoperative proximal pouch contrast study, preferably performed by a skilled pediatric radiologist under optimum conditions in the radiology suite using fluoroscopy and video recording or in the neonatal unit if necessary.[190] This study usually shows a small upper pouch in addition to identifying the fistula. However, a frequent point of confusion during this study and in the interpretation of results is the occurrence of spillover of contrast from the pouch up into the larynx and down into the trachea. Because of the potential for inaccurate interpretation, some surgeons rely on preoperative bronchoscopy to make or confirm the diagnosis of a proximal pouch fistula (Fig. 69-23).[190] Unfortunately, a small proximal fistula can also be missed when endoscopy is used. Another common approach to the diagnosis of this anomaly is complete mobilization of the upper pouch during repair of the EA in order to localize and repair

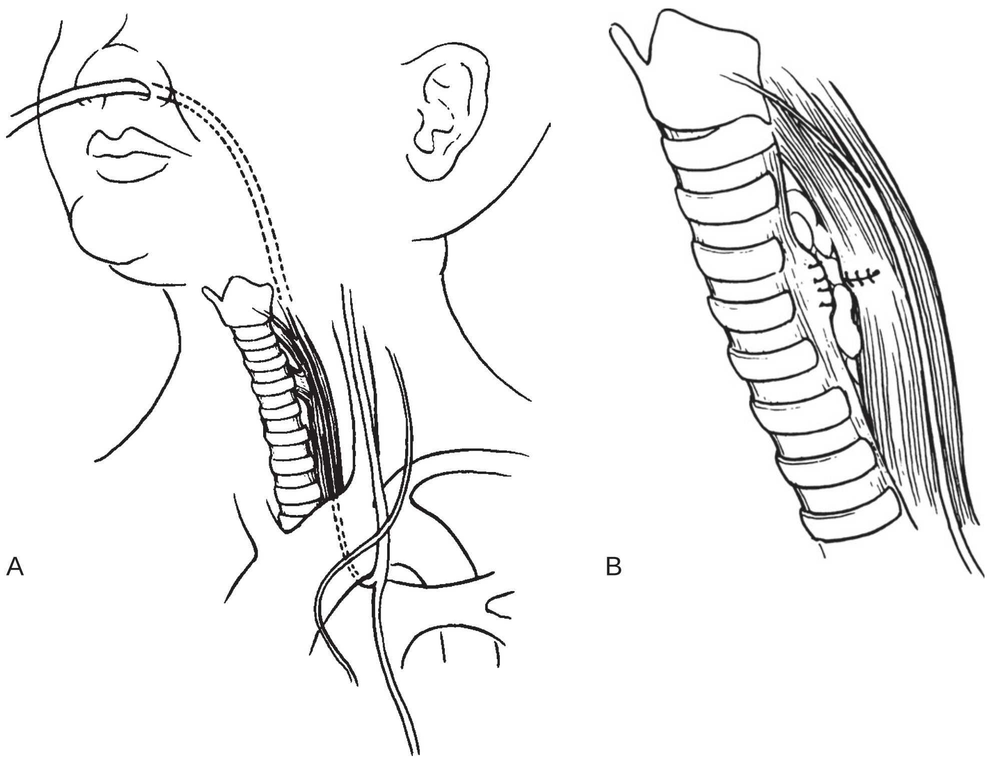

FIGURE 69-22 H-type tracheoesophageal fistula. **A,** Anatomic relationship between the fistula and the recurrent laryngeal nerve. **B,** After division, the fistula is closed by interrupted suture on both the trachea and esophagus.

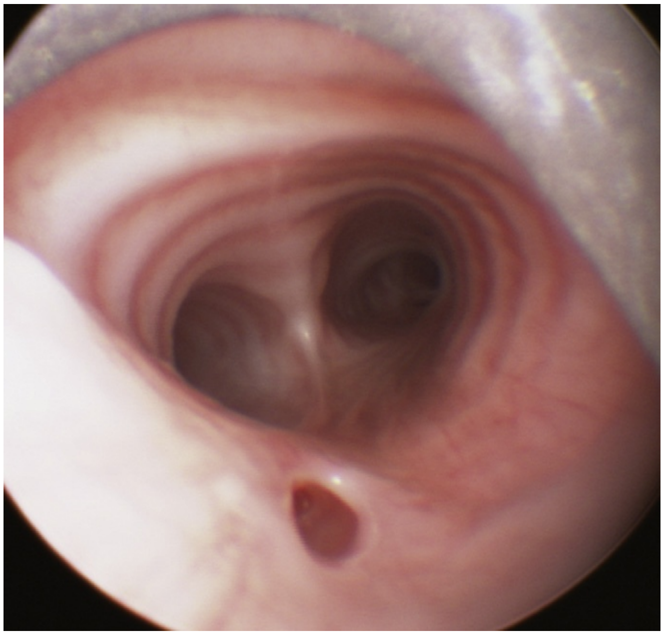

**FIGURE 69-23** Bronchoscopic view of an unexpected upper pouch tracheoesophageal fistula. *(See Expert Consult site for color version.)*

an unsuspected upper pouch fistula. As with the other diagnostic methods mentioned, proximal pouch fistulas may also be unrecognized during surgical exploration, in part because of the extreme proximal nature of some of these fistulas. A proximal pouch fistula should be suspected and specifically looked for if the upper pouch is unusually narrow or short at the time of preoperative imaging studies or at surgical exploration because such findings suggest decompression through a fistula.

Once identified, a proximal fistula should be surgically ligated and divided as with a distal TEF. If an upper pouch fistula is diagnosed after the initial repair of EA with or without distal TEF, a cervical approach can often be used as previously described for an H-type TEF.

# Outcomes

Survival rates for infants who have EA with or without TEF have improved dramatically in the past 50 years. Recent reviews reported 85% to 95% overall survival as compared with rates less than 40% before the 1950s.[64,65,105,191–194] However, subsets of infants with EA still have a worse prognosis. Waterston's risk classification scheme historically helped identify infants with EA who were at particular risk for a poor outcome and as such helped direct treatment options.[195] In recent years, other risk classification schemes have been proposed. A recent modified classification scheme suggests that revised class I (low-risk group) consisted of patients without major cardiac anomalies and birth weight greater than 2000 g; class II (moderate-risk group) consisted of patients without major cardiac abnormalities and birth weight less than 2000 g; class III (relatively high-risk group) consisted of patients with major cardiac anomalies and birth weight greater than 2000 g; and class IV (high-risk group) consisted of patients with major cardiac anomalies and birth weight less than 2000 g (Table 69-4).[196] Other recent evaluations suggest that infants with EA who appear to be at increased risk for death and long-term morbidity include those with (1) lower birth weight (<1500 g)/prematurity,[64,136] (2) major CHD,[66,191,193a] (3) severe associated anomalies and ventilator dependency,[92] and (4) a long gap length between the two ends of esophagus.[104]

# Complications

Despite excellent long-term survival for infants with EA, many significant complications can occur. In a recent evaluation of 134 EA patients older than 15 years, 49% had complications in the first year and 54% had complications after 1 year. Predictors of complications included twin birth, preoperative intubation, birth weight less than 2500 g, long-gap atresia, anastomotic leak, postoperative intubation longer than 4 days, and inability to feed at the end of 1 month.[197] Complications can generally be classified as early (including anastomotic leak, anastomotic stricture, and recurrent tracheoesophageal fistula) and late (including GERD, tracheomalacia, respiratory disease, and disordered esophageal peristalsis).

## EARLY COMPLICATIONS

### Anastomotic Leak

Whether open or thoracoscopic techniques are used, anastomotic leak at the esophagoesophagostomy occurs in approximately 13% to 16% of patients with EA.[123,198,199] Most leaks are clinically insignificant and can be managed with adequate drainage and nutritional support (Fig. 69-24). When a retropleural approach is undertaken and a patent mediastinal drain is in place, up to 95% of anastomotic leaks close spontaneously.[200] Even when transthoracic repair is followed by disruption and the pleural space is contaminated, adequate

**FIGURE 69-24** Anastomotic leak at the esophagoesophagostomy. The leak is contained and adequately drained. Right upper lobe atelectasis is common.

drainage can usually be achieved. This in turn allows spontaneous closure of the leak. Breakdown of the anastomosis is frequently followed by the formation of a stricture at the site of the leak and is sometimes associated with a recurrent TEF. Major disruptions of the esophageal anastomosis account for only 3% to 5% of postoperative leaks and are typically recognized early (24 to 48 hours) after the initial repair. The infant frequently deteriorates from tension pneumothorax or mediastinitis uncontrolled by drainage and antibiotics. Factors that probably contribute to anastomotic leak include poor surgical technique, ischemia of the esophageal ends, use of myotomy, and excessive tension at the anastomotic site.[201,202] In this critical setting, reoperation for control of sepsis with adequate drainage and attempted repair of the anastomotic leak are warranted. A pleural or pericardial patch, with or without an intercostal muscle flap buttress, may help secure anastomotic closure.[203,204] If the esophageal anastomosis is not repairable, cervical esophagostomy and delayed esophageal replacement may be required.

### Esophageal Stricture

Esophageal stricture is a common complication of anastomosis of the esophagus in EA, but the reported incidence varies widely depending on the criteria used to define a stricture. In a recent large series, stricture requiring dilatation is reported to occur in up to 80% of patients.[68,105,116,147a] Spitz and Hitchcock[91] proposed that stricture be defined as the presence of symptoms (dysphagia and recurrent respiratory problems from aspiration or foreign body obstruction) and narrowing noted on endoscopy or contrast esophagography (Fig. 69-25). Factors that have been implicated in the pathogenesis of esophageal stricture include poor anastomotic technique (excessive tension, two-layered anastomosis, and silk suture material), long gap, ischemia at the ends of the esophagus, GERD, and anastomotic leak. Reports of thoracoscopic repair of EA note stricture rates similar to many open operations (11% to 13%).[123,206] Up to 13% of infants and children will require removal of an esophageal foreign body after repair of EA with or without TEF, even in the absence of a stricture on contrast studies.[207] Parents have to be counseled about slow introduction of solids and keeping the food minced until the child has enough molar teeth to grind the food adequately because the scar in the area of anastomosis always remains.

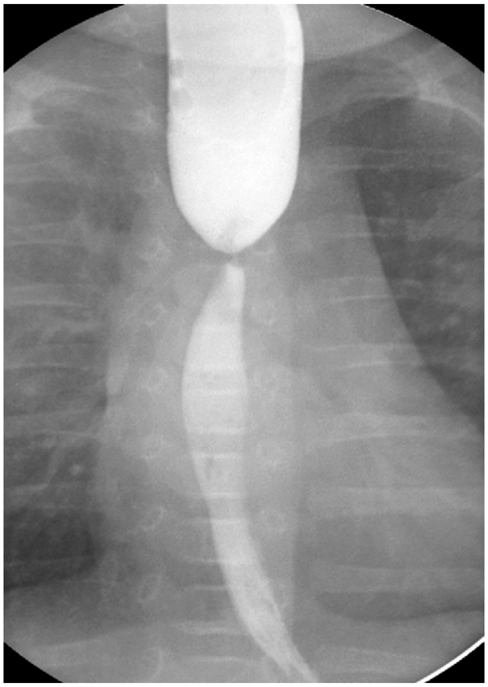

**FIGURE 69-25** Barium esophagogram showing an anastomotic stricture.

Clinically significant narrowing at the site of the esophageal anastomosis is traditionally treated by dilation performed via antegrade or retrograde bougienage. We have found that passing Savary-Gilliard type dilators prograde over a guidewire has many advantages: This method allows fluoroscopic assessment during sequential dilations, enables the use of contrast injection during the dilation session, and typically eliminates the need for rigid esophagoscopy. More recently endoscopic balloon dilators have been frequently used with good results.[208,209] This technique has the theoretic advantage of producing a uniform and radial force at the site of the stricture rather than the shearing axial force applied with traditional bougienage.[210–213] Many strictures respond to one to three dilations (53%) in the first months after esophageal repair. However, a recalcitrant stricture resistant to repeated dilations will require resection and reanastomosis or even esophageal replacement. Injection of triamcinolone at the stricture site during flexible esophagoscopy is used in many centers, mostly by pediatric gastroenterologists, but repeated injections may lead to adrenal suppression. Recently, the application of mitomycin C to the stricture under endoscopic control has been reported to reduce stricture formation after dilation. It is crucial to determine whether the esophageal stricture is associated with GERD by investigation with contrast esophagography, endoscopy, pH monitoring, or any combination of these studies. Because all EA patients demonstrate GER to some degree, children are routinely prescribed histamine-2 blockers at the time of discharge. In the presence of an anastomotic stricture or persistence of acid reflux, proton-pump inhibitors may be preferable. Many strictures do not respond to dilation attempts if severe GERD continues to bathe the stricture with acid.[212] When medical management of GER fails and the stricture does not respond to esophageal dilations, an antireflux procedure may be indicated. The stricture is often successfully treated with dilations after the antireflux operation; however, care must be given to not dilating the fundoplication because that significantly increases the possibility of recurrent GERD. The most recalcitrant strictures have been treated by resection and reanastomosis, or more recently by stenting. However, experience is still limited with the latter, and a fatal arterio-esophageal fistula from an unrecognized aberrant right subclavian artery has been reported.*

### Recurrent Tracheoesophageal Fistula

Recurrent TEF occurs in 3% to 14% of patients after initial operative division or ligation.[105,121,214–217,200] Recurrent TEF has been attributed to anastomotic leak with local inflammation and erosion through the previous site of TEF repair.

*From a poster presentation, “Arterio-esophageal Fistula from an Aberrant Right Subclavian Artery after Esophageal Stenting for Stenosis after Atresia Repair,” at the Annual Meeting of the Canadian Association of Paediatric Surgeons, Saskatoon, September 2010, by Lo and colleagues.

Techniques that have minimized the likelihood of recurrent TEF include the use of a pleural flap,[215] vascularized pericardial flap,[218–220] and azygos vein flap[221] interposed between the esophageal and tracheal suture lines. Although recurrent TEF typically occurs in the early postoperative period, it may not be recognized for months to years. Symptoms can be typical of those seen with a congenital H-type TEF including coughing and choking or cyanosis with feedings; however, less obvious symptoms such as recurrent pulmonary infections are more common. The diagnosis may be suggested by an air-filled esophagus on plain radiographs of the chest. Routine contrast swallow studies will miss up to 50% of recurrent fistulas. As with a congenital H-type fistula, contrast esophagography performed in the prone position under videofluoroscopy is a reliable method of establishing the diagnosis. Bronchoscopy with cannulation of the fistula with a 2- to 3-French catheter is also a reliable diagnostic approach and is invaluable in locating the fistula during the operative procedure. A recurrent TEF rarely closes spontaneously and typically requires surgical repair. Thoracotomy with fistula ligation and division is the operation of choice. To minimize the chance of recurrent fistulization, which has been reported in 10% to 20% of patients with a first-time TEF recurrence, pleura, intercostal muscle, or pericardium should be interposed between the esophagus and trachea.[222] A recent large series from the University of Michigan of 26 patients over 27 years reports postoperative complications to include leak (27%), esophageal stricture (15%), and recurrent TEF (11%).[223]

Endoscopic eradication of TEF by means of various chemicals or diathermy has been increasingly reported.[224–226] Diathermy or laser deepithelialization followed by fibrin glue has been reported in case reports and series with success rates as high as 85%[227,228]; however, others continue to report failure with chemical techniques.[229] A recent report of using argon plasma coagulation reports a 66% success rate.[230]

## LATE COMPLICATIONS

### Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) in infants and children with repaired EA is common, and the incidence seems to be increasing as suspicion and diagnostic investigation have become more common. In addition, the trend to preserve the native esophagus with many of the techniques described earlier in this chapter also promotes GERD. The magnitude of the problem is reflected in the finding that GERD occurs in 30% to 70% of patients after repair of EA.* The cause of GERD in this group of infants probably relates to shortening of the intra-abdominal portion of the esophagus because of anastomotic tension and/or esophageal motor dysfunction, either acquired as a result of operative manipulation or intrinsic to the congenital anomaly itself.[232–234] The consequences of GERD are then magnified by the poor or absent esophageal peristaltic pump, thus exposing the esophagus to prolonged acid contact. Esophagitis is frequently observed in older children and adolescents on long-term follow-up of patients with EA.[232,235–238] In several recent long-term follow-up studies, it appears that adults who had EA repaired as infants continue to be at risk for GERD and its complications,[239,240] including an apparent increased risk for the development of Barrett esophagus, perhaps as high as 9%.[239–241] In a recent case control study, 101 patients post EA repair with a mean age of 36 years (range 21 to 57) were compared with 287 controls. The authors found symptomatic GERD in 34% (vs. 8%), dysphagia in 85% (vs. 2%), and at endoscopy found an increased incidence of hiatal hernia (28%), Barrett esophagus (11%), esophagitis (8%), stricture (8%), and epithelia metaplasia (21%); manometry showed nonpropagating peristalsis in 80% and low distal wave amplitudes in all.[242] One case of esophageal adenocarcinoma was reported in a 20-year-old patient in whom an EA had been repaired during infancy.[243]

The diagnosis of pathologic GERD is suspected in patients with symptoms of vomiting, dysphagia, and recurrent anastomotic stenosis, which is occasionally associated with the impaction of a foreign body or food bolus. In addition, respiratory symptoms such as stridor, cyanotic spells, recurrent pneumonia, and reactive airways disease may indicate GERD rather than other conditions such as tracheomalacia.

The diagnosis of pathologic GERD in infants and children after repair of EA is suggested by upper gastrointestinal contrast study. Twenty-four-hour pH probe data, though not as standardized for children as they are for adults, typically document pathologic reflux.[232] Extensive esophageal manometric studies have consistently documented abnormal esophageal peristalsis and decreased lower esophageal sphincter pressures after EA repair; as a result, this test is probably not helpful in diagnosing GERD.[244] Multichannel esophageal impedance combined with pH monitoring may emerge as a superior test but is not widely available yet.[245]

In infants and children with pathologic GERD, aggressive medical management typically consists of thickening of feedings, positioning of the infant in a prone or upright posture, and administration of acid reduction agents such as histamine-2 blockers, proton pump inhibitors, and prokinetic agents. However, 45% to 75% of these infants ultimately undergo antireflux operations because of failed medical management, failure to thrive, chronic pulmonary infection, refractory anastomotic stricture, or the development of a distal esophageal stricture.[200,215,220] The choice of antireflux operation is controversial. The Nissen fundoplication has typically been considered the best option.[234,246–248] However, debilitating dysphagia and significant complications including wrap disruption and recurrent GERD in a third of patients have been frequent after the 360-degree wrap.[200,220,249,250] Because of the generally poor results with Nissen fundoplication in this setting, some surgeons have used the anterior Thal partial-wrap fundoplication in these patients. However, as other surgeons have modified the Nissen fundoplication to create a short, floppy wrap (1 to 1.5 cm over a large dilator), this operation continues to be commonly used.[246] In addition, because the esophagus is frequently shortened in the setting of repair of EA, some surgeons have used the Collis-Nissen fundoplication to gain intra-abdominal esophageal length.[171]

### Tracheomalacia

Substantial respiratory symptoms occurring after repair of EA-TEF can be due to tracheomalacia. Tracheomalacia has been noted to affect up to 75% of pathologic specimens from patients suffering from EA-TEF; however, the condition is problematic or significant in approximately 10% to 25% of

*References 105, 147a, 200, 215, 220, 231, 232.

infants after repair of EA-TEF, approximately half of whom require surgical correction.[215,251–253] It is often difficult to clinically distinguish these symptoms from those of recurrent TEF, anastomotic leak, or GERD.[254] Tracheomalacia is defined as generalized or localized weakness of the trachea that allows the anterior and posterior tracheal walls to come together during expiration or coughing. In infants with associated TEF, structural anomalies of the trachea were identified in 75% of 40 infants at autopsy, thus suggesting that embryologic events leading to TEF may contribute to the development of tracheomalacia.[254] The cartilage was shorter than normal and thereby failed to provide the support necessary to maintain a patent airway.[254] In infants, the trachea may also be easily compressed between the aorta anteriorly and the often dilated upper esophagus posteriorly after repair of EA-TEF; such compression has been considered a significant contributor to the pathophysiology of tracheomalacia. Kimura and colleagues[255] studied tracheomalacia with cine computed tomography and suggested that the primary cause of tracheomalacia is related to intrinsic tracheal weakness. This has been confirmed in the Adriamycin-induced EA-TEF rat model and may also provide more insight into the pathogenesis of the anomaly. The level of tracheal collapse is usually in the region of or just above the original site of the TEF in the distal third of the trachea, generally at the level of the aortic arch. Perhaps surprisingly, severe tracheomalacia appears less common in infants with pure EA,[256] but it has been reported.[182]

The clinical manifestations of tracheomalacia are broad and range from a "brassy" or "barking" cough in mild cases to recurrent pneumonia or acute, life-threatening apneic spells. Infants with tracheomalacia are often reluctant to feed because of difficulty breathing during feeding or cyanotic attacks. These symptoms usually appear after discharge from the hospital, when the infant is a few weeks to a few months of age.[256] Life-threatening apneic spells were noted in 27 of 32 children with tracheomalacia described by Filler and colleagues.[257] These spells occur during or within 5 to 10 minutes of a meal and are characterized by cyanosis progressing to apnea, bradycardia, and ultimately, cardiorespiratory arrest if not interrupted. The diagnosis is established by bronchoscopy with spontaneous ventilation, which reveals a slitlike lumen of the trachea at the involved area (Fig. 69-26). Because the symptoms overlap those of a stricture or GER, the initial investigation usually consists of a contrast esophagram; close attention to the tracheal air column on the lateral views during such a study will often reveal complete tracheal collapse during forced expiration (i.e., crying) or when contrast fills a distended upper esophagus just above the anastomosis.

Treatment of tracheomalacia remains controversial. Most infants with mild to moderate symptoms of tracheomalacia do not require operative intervention because the symptoms tend to improve with time. In infants with severe symptoms including acute life-threatening events, the operative treatment of choice is aortopexy.[258–261] This operation is usually performed through a left anterior mediastinotomy (Chamberlain approach) or anterolateral thoracotomy, and the ascending aorta and arch are sutured up to the posterior surface of the sternum after partial thymectomy. Lifting the aorta up in this fashion raises the anterior wall of the trachea and opens the tracheal lumen.[256,261] A proposed modification of this operation has been the use of a flap of pericardium based at the root of the aorta to be sutured to the sternum in cases in

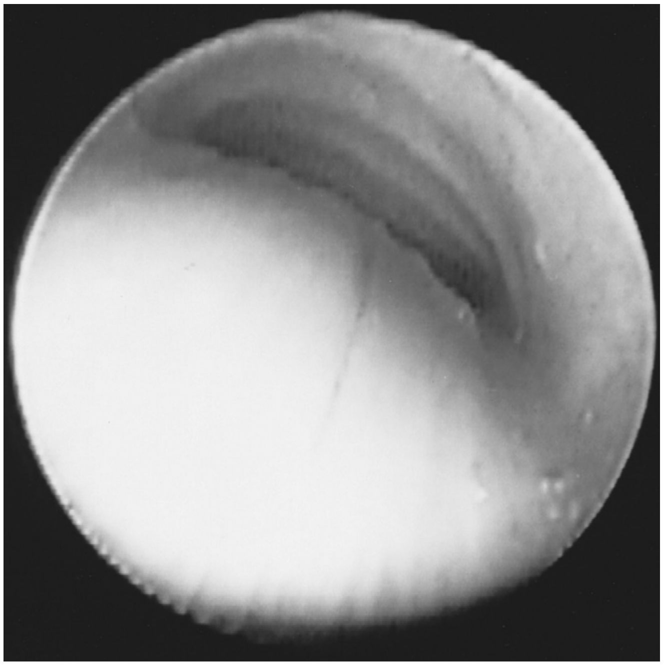

**FIGURE 69-26** Tracheomalacia after repair of esophageal atresia-tracheoesophageal fistula. A bronchoscopic view of the tracheal lumen during spontaneous respirations shows almost complete collapse of the trachea during expiration.

which the aortic arch would not reach the posterior aspect of the sternum without undue tension. An anterior mediastinal approach via a low transverse cervical incision for aortopexy and trachelopexy has recently been advocated.[263] Recently, a thoracoscopic approach for aortopexy has been reported to be a good alternative to thoracotomy.[264–266] Many surgeons use intraoperative bronchoscopy to document the adequacy of aortopexy with regard to opening the tracheal lumen as sutures are being tied or even before suture placement. Other surgical treatment options for tracheomalacia associated with EA have been suggested. The role of various stents in the treatment of tracheomalacia after repair of EA, though successful in case reports, has yet to be validated as a standard treatment method.[267–270] Filler and colleagues[257] recommend that an airway stent be considered for children in whom aortopexy fails to relieve tracheal collapse or for the rare cases of diffuse tracheobronchomalacia, for which aortopexy is not useful. Recently, glossopexy has been suggested as an early alternative to aortopexy to treat infants with suspected retrodisplacement of the tongue (glossoptosis).[271] Tracheostomy is a final treatment option if aortopexy fails, which is uncommon. It is fairly common to detect significant GER in patients with severe tracheomalacia; in such cases, we would advocate aortopexy before considering a fundoplication.

### Other Long-Term Quality-of-Life Issues

As previously discussed, the esophagus of an infant with EA has abnormal peristaltic activity that is secondary to the congenital defect itself, as well as secondary to operative repair of the lesion. The incidence of the problem approaches 75% to 100% in children and adults who have been studied with esophageal manometry. Dysphagia is worse after intestinal interposition for esophageal replacement. Occasional dysphagia has been reported to occur in up to 50% to 90% of adults,

with 30% having additional problems with choking.[253,272,273] This disorder is clinically significant in that it is responsible for many long-term symptoms after EA repair including dysphagia, esophageal foreign body obstruction, GERD, and recurrent respiratory problems. Although these symptoms may improve with time, early problems with feeding intolerance and food bolus obstruction can lead to failure to thrive. Many children must eat slowly and be selective with food choices. In a series of EA patients followed for 10 years, Lacher and colleagues[274] found 72% swallowed without problems; however, 41% had poor weight gain (<25$^{th}$ percentile).

In addition, recent reports have examined long-term respiratory outcomes after EA repair. One recent paper reports a greater than 60% incidence of recurrent respiratory infections, a 25% decrease in FEV1, and decreased maximal exercise performance at greater than 5 years beyond EA repair.[275] Another long-term follow-up study found respiratory symptoms in all patients including pneumonia 16%, bronchitis and asthma 52.3%, cyanosis episodes 9%, and cough 90%.[194] In our experience using small incisions and muscle sparing, thoracic deformities are extremely rare.

# Congenital Stenosis of the Esophagus

True congenital esophageal stenosis (CES) is a rare condition that has historically been confused with esophageal strictures secondary to inflammation, especially GERD. CES has been reported to occur once in every 25,000 to 50,000 births[276,277]; as of 2004, fewer than 600 cases have been described in the world literature. For unknown reasons, the incidence of CES seems to be higher in Japan than in other parts of the world.[278,279] The incidence of other anomalies associated with CES is reported to be 17% to 33%; these anomalies include EA with or without TEF; H-type TEF; cardiac anomalies; intestinal atresia; midgut malrotation; anorectal malformations; hypospadias; malformations of the head, face, and limbs; and chromosomal anomalies.[277] In addition, a report by Vasudevan and colleagues[280] noted that 5% of their patients with EA-TEF anomalies had CES with tracheobronchial remnants, whereas other reports suggest an incidence as high as 12% to 14% of patients with EA had associated CES.[278,281]

Classification schemes for CES have been numerous and confusing, in part because of the difficulty in differentiating congenital from acquired lesions. The definition and classification proposed by Nihoul-Fekete and colleagues[277] are perhaps the most clear. CES is defined as an intrinsic stenosis of the esophagus, present at birth, that is caused by congenital malformation of esophageal wall architecture.[277] This classification delineates three forms of CES: (1) a membranous web or diaphragm, (2) fibromuscular thickening, and (3) stricture secondary to tracheobronchial remnants in the wall of the esophagus.

A congenital membranous web or diaphragm is reported as the rarest of the three forms of CES.[282] It has been considered to represent a missed form of EA[25] and may be analogous to membranes in other parts of the gastrointestinal tract. It is usually a partially obstructing lesion located in the middle or lower portions of the esophagus. The membrane is covered on both sides with squamous epithelium and often has an eccentric opening. Symptoms typically occur at several months of age as the infant begins consuming solid food.

The second type of CES has been called *idiopathic muscular hypertrophy* or *fibromuscular stenosis* and in some reports has been the most common form of CES.[277] Its histologic characteristics are submucosal proliferation of smooth muscle fibers and fibrous connective tissue with normal overlying squamous epithelium.[277] A resemblance to hypertrophic pyloric stenosis has been suggested,[277,283] but no clear embryologic or pathogenic factors explain these lesions.

CES caused by tracheobronchial remnants is described as the most common type of CES in some reports and is certainly the most described and understood of the three types of CES. It is believed that CES caused by tracheobronchial remnants occurs as part of a spectrum of anomalies, including EA-TEF, related to separation of the foregut from the respiratory tract around the twenty-fifth embryonic day.[121] Tracheobronchial tissue is believed to become sequestered in the wall of the esophagus and comes to reside in the typical distal location because of the faster growth rate of the esophagus.

CES secondary to tracheobronchial remnants was first reported in 1936 by Frey and Dusche[284] in a 19-year-old woman who died with the diagnosis of achalasia.[121] In 1964 Holder and colleagues[62] reported three cases of distal esophageal stenosis in their review of 1058 infants with EA, TEF, or both. After several additional reports,[285,286] Spitz, in 1973, first demonstrated a clear congenital basis for this disorder.[287] In addition, 71 cases of CES have been reported in the Japanese literature as of 1981[279]; 6 cases were reported in the Chinese literature (out of 76 total cases of CES in 1987).[288] An additional three cases of CES have been reported, one of each type described earlier.[289]

## DIAGNOSIS

Symptoms of CES usually begin in infancy with progressive dysphagia and vomiting, generally after the introduction of semisolid or solid foods around the age of 6 months. Some case reports, however, describe severe symptoms of regurgitation and respiratory distress in the newborn.[277] In some patients, a foreign body in the esophagus may be the first symptom noted.[290] The correct diagnosis is frequently difficult to establish. Contrast esophagography typically reveals an abrupt distal esophageal narrowing, most often interpreted as a stricture related to GERD. Stenosis secondary to fibromuscular hypertrophy can result in a more tapered narrowing (Fig. 69-27). CES caused by webs or fibromuscular hypertrophy can be manifested as midesophageal or even upper esophageal stenosis.[291] Over time, the esophagus proximal to the stenosis can dilate, and contrast study results can be interpreted as achalasia.[292] Additional studies helpful in differentiating CES from achalasia and strictures caused by GERD include esophageal manometry and pH monitoring. Esophagoscopy typically shows esophageal narrowing with normal-appearing mucosa at the level of the stenosis in cases of CES. Recently, high-frequency endoscopic ultrasonography has been reported to be helpful in the diagnosis of CES.[293]

## TREATMENT

Treatment of CES should relieve the symptoms of stenosis and maintain the antireflux mechanism of the gastroesophageal junction. Bougienage has been successful in treating CES secondary to esophageal webs and fibromuscular

FIGURE 69-27 Barium esophagogram showing narrowing of the midesophagus as a result of congenital esophageal stenosis.

hyperplasia. Antegrade and retrograde tapered dilators have been the traditional form of bougienage, but more recent use of hydrostatic balloon dilation has been successful.[277,292,294,295] A series of dilations may be required for resolution of the stenosis. Membranous webs are typically adequately treated with dilation, and one report described successful endoscopic excision of a congenital web.[280,289,296,297]

Traditionally, most cases of CES secondary to fibromuscular hypertrophy and tracheobronchial remnants have been treated by surgical excision, either as the primary approach or after failed attempts at dilation.[294]

More recent recommendations suggest dilations should be aggressively attempted before committing to resection.[295] When resection is required, it is important to clearly identify the location of the stenosis before surgery by contrast esophagography in order to plan the operative approach. A right thoracotomy is typically used for stenosis in the midesophagus and a left thoracotomy for stenosis in the lower part of the esophagus. An abdominal approach should be used for CES in the abdominal portion of the esophagus. At exploration, the extent of the stenosis can be difficult to determine; the use of a balloon catheter passed beyond the stenosis, inflated, and pulled back against the stenosis has been suggested as a helpful technique.[298] Alternatively, a bougie passed from above or preoperative flexible upper endoscopy may demonstrate the stenotic area. In most cases, the stenosis is less than 3 cm in length and segmental resection and end-to-end esophageal anastomosis can be accomplished. Care should be taken to preserve the vagus nerves. Case reports have documented innovative surgical approaches including stenosis resection using limited myectomy, leaving the mucosa intact,[299] as well as thoracoscopic[300] and laparoscopic[301] approaches. In cases of long fibromuscular hypertrophy unresponsive to dilation, resection and esophageal replacement with the colon, stomach, or jejunum may be necessary. If the stenosis is near the gastroesophageal junction, most surgeons advocate segmental resection with esophageal anastomosis and an antireflux procedure to prevent postoperative reflux. Modified Hill gastropexy and Nissen fundoplication, with or without pyloroplasty, have been most commonly used[277,298]; however, Collis gastroplasty in combination with Nissen fundoplication has been reported to be effective for managing esophageal shortening and postoperative GERD.[278,294,302]

### RESULTS

Good long-term results have been reported for dilation and operative resection.[269] In patients who have undergone distal esophageal CES resection without an antireflux procedure, significant GERD has developed and required a subsequent antireflux operation. Reported complications from treatment by dilation include esophageal perforation and failure of therapy. Complications of resection and anastomosis include esophageal leak with mediastinitis, which can be successfully treated by mediastinal drainage.[270,272]

## Laryngotracheoesophageal Cleft

A laryngotracheoesophageal cleft (LTEC) is a rare congenital anomaly consisting of a midline communication between the larynx, trachea, and esophagus. The malformation was possibly first described in 1792 by Richter in his doctoral thesis, in which he described an infant who choked and vomited on feeding.[303] The infant died, but because no autopsy was performed, the diagnosis was unconfirmed. An infant with LTEC was next described in 1949 by Finlay.[304] In 1955 Pettersson[305] performed the first successful correction of a laryngotracheal cleft.

As with EA-TEF, the embryogenesis of LTEC is not completely understood. The long-held theory is that there is an arrest of the cranial extension of the tracheoesophageal septum that permits the persistence of an esophagotrachea.[306–308] More recent studies have suggested that as with EA-TEF, initial normal development is followed by a far-reaching fusion of the trachea and esophagus.[32] Although no consistent pattern of inheritance has been seen, sporadic familial associations have occurred; LTEC is reported with the “G” syndrome and the Pallister-Hall syndrome.[309] The incidence of LTEC favors males by a ratio of 5:3.[310]

Various associated congenital anomalies occur in the setting of LTEC including gastrointestinal, genitourinary, and cardiac malformations.[310] EA with TEF occurs in 20% to 37% of patients with LTEC.[310,311,312] Other associated gastrointestinal malformations include anal defects (21%), anomalies of rotation and fixation (13%), and meconium ileus (8%).[310,313] Genitourinary anomalies occur with an incidence of 14% to 44% and include hypospadias, inguinal hernias, undescended testes, and renal agenesis.[310,313] Cardiovascular anomalies, identified in 16% to 33% of patients, include ventricular septal defects, coarctation of the aorta, and transposition of the great vessels.[310]

To more adequately delineate therapy, several classification schemes have been described. In reporting the first surgical repair in 1955, Pettersson described three types of clefts: type I, limited to the larynx and involving part or all of the cricoid plate; type II, extending beyond the cricoid lamina to the cervical trachea; and type III, involving the entire trachea down to the carina. In 1991 Ryan and colleagues[314] suggested a type IV in which the cleft extends beyond the carina to involve one or both mainstem bronchi.

Symptoms of LTEC vary depending on the extent of the cleft, but most patients immediately after birth exhibit respiratory distress aggravated by feeding. Additional symptoms can include a characteristic toneless or hoarse cry, cyanosis, choking, increased secretions, and recurrent aspiration pneumonia. It is not unusual for the severity of associated anomalies to obscure the presence of LTEC, especially if it is a minimal type I or II lesion. On the basis of the common symptoms of LTEC, the diagnostic evaluation typically proceeds along the line of the more commonly suspected diagnosis of EA-TEF or tracheomalacia. Contrast esophagography demonstrates rapid confluence of contrast material in the upper part of the esophagus and trachea; however, it is often difficult to know whether this is secondary to spillover at the level of the larynx or passage of contrast through a cleft. Rigid endoscopy under general anesthesia is the definitive method for diagnosis of LTEC, but it can still be difficult to identify a cleft unless the index of suspicion is high and unless the frequent mucosal infolding at the level of the subglottic region is pushed open to reveal the cleft (Fig. 69-28).

Management of infants with LTEC begins by maneuvers to minimize aspiration and stabilize the airway. Ryan and colleagues[314,315] recommended avoiding endotracheal intubation before surgery if possible, but it is often necessary to intubate the trachea and perform tube gastrostomy before definitive surgical repair of extensive LTECs. Operative procedures vary depending on the severity of the cleft. Asymptomatic type I clefts may require no operative intervention, and symptomatic clefts have been successfully repaired endoscopically.[310] Type II LTEC can be approached through a lateral pharyngotomy, posterior pharyngotomy, or anterior laryngofissure. The lateral exposure has been most often reported; this method permits easy access to the cleft and allows asymmetric incisions in the mucosa, thereby avoiding contiguous suture lines. The major disadvantage to this approach is its risk to the recurrent laryngeal nerves. The anterior laryngeal approach exposes the larynx and upper part of the trachea and has no risk for recurrent laryngeal nerve injury. Concern about postoperative laryngeal stability has been raised, and some surgeons recommend the use of stents during the healing process.[310,316]

Operative management for types III and IV LTEC requires a combined cervical and thoracic approach. Donahoe and colleagues[311,314,315] have described the use of a specifically designed bifurcated endotracheal tube with flanged ends that can be positioned during bronchoscopy to suspend the trachea anteriorly with a ureteral catheter sling (Fig. 69-29). The endotracheal tube allows for confident airway control during the multiple position changes frequently required during the operation. A right thoracotomy is performed, and the tracheoesophageal cleft is exposed retropleurally. The tracheoesophageal groove is incised on the right and opened from the carina to the thoracic inlet. Separation of the two tubes is completed by incising along the left side of the common esophagotracheal wall, and an approximately 1-cm flap of esophagus running the length of the trachea should be left to help create the neomembranous portion of the trachea. It is important to size the esophageal flap correctly in order to avoid stenosis or a floppy posterior wall, which can result in tracheal obstruction. As the dissection proceeds, it is also important to push away and thus protect the left vagus and recurrent laryngeal nerves. Closure of the trachea and esophagus is accomplished in a caudal-to-cranial fashion with running polypropylene suture for the esophagus and interrupted polypropylene for the trachea. A right cervical incision is then made to expose the upper portion of the esophagus, trachea, pharynx, and larynx; the repair is continued with inclusion of a three-layer repair of the larynx and placement of a tracheostomy tube, which can be custom-designed to avoid undue pressure against the posterior tracheal repair. Some surgeons prefer an anterior approach and divide the larynx and trachea in the midline, as described for type II defects.[317] Cardiopulmonary bypass has been used both as a supporting technology

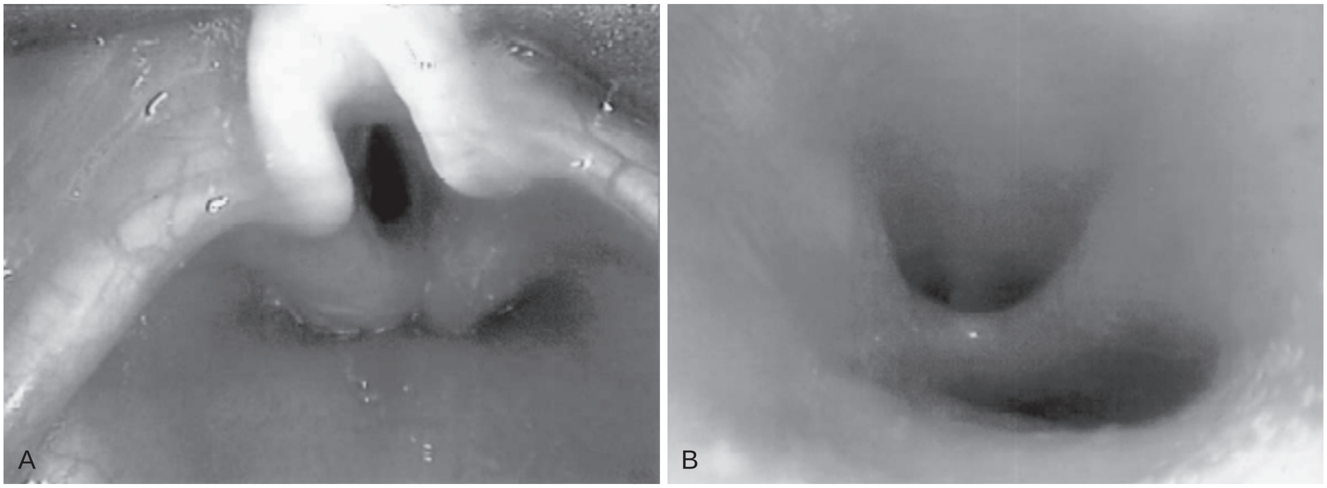

**FIGURE 69-28** Endoscopic view of a type III laryngotracheoesophageal cleft. **A,** Proximal end of cleft may be difficult to appreciate at first glance. **B,** Distal end of cleft ends just proximal to the tracheal bifurcation.

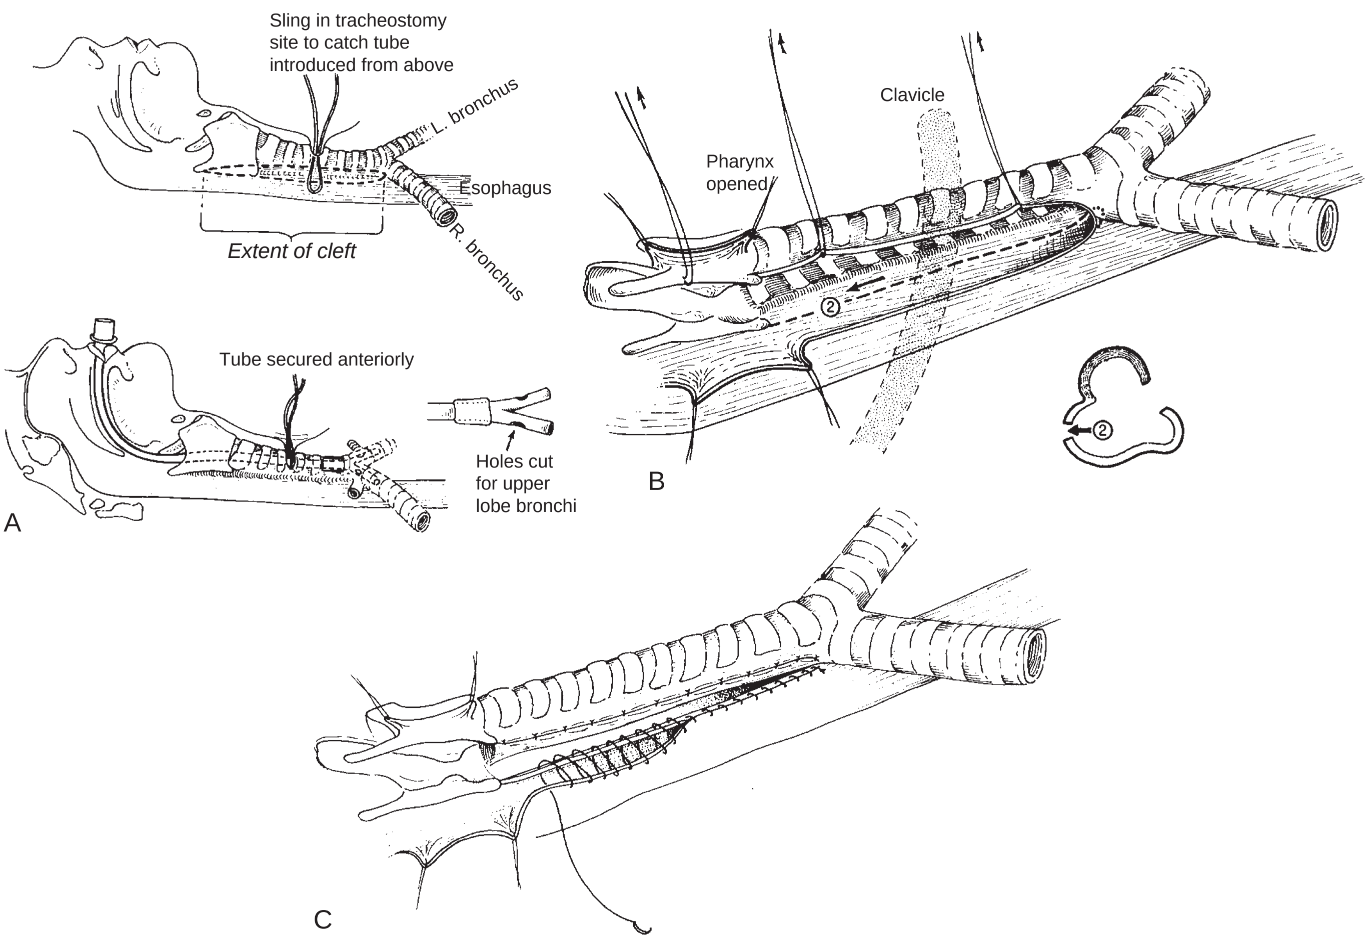

**FIGURE 69-29** Repair of a type III laryngotracheoesophageal cleft. **A,** Stabilization of a bifurcated endotracheal tube is done at bronchoscopy with a loop passed through a tracheotomy, which draws the endotracheal tube forward. **B,** A cervical and thoracic approach allows retropleural exposure of the cleft. A longitudinal incision is made in the right tracheoesophageal groove below the tracheal rings. The incision is extended inferiorly and across the esophagus and up the left side, with approximately 1 cm of esophageal wall left attached to the trachea to allow adequate tissue to close the trachea. **C,** The trachea has been closed with interrupted sutures, and the esophagus is closed in running fashion up to the thoracic inlet. Closure of the laryngeal portion of the cleft and the lateral pharyngeal wall is not yet accomplished. (From Donahoe PK, Gee PE: Complete laryngotracheal cleft: Management and repair. J Pediatr Surg 1984;19:143.)

during the anterior approach[318] to repair a type IV cleft and as support in the form of extracorporeal membrane oxygenation for one patient treated via a lateral thoracic and cervical approach.

Few patients with these complex anomalies are treated at any single institution.[310,315,319] Postoperative survival rates continue to be rather poor and range from 50% to 75%, depending on the severity of the malformation, associated anomalies, and prematurity. Anastomotic leakage is reported to occur in approximately 50% of repairs and typically requires reoperation via a different approach.[310] In addition, an inability to wean patients from the ventilator, pharyngoesophageal dysfunction, and GER are common postoperative complications. A reduction in morbidity and mortality depends, in part, on earlier recognition so that secondary complications can be prevented. At present there is no clear consensus about the best surgical approach; however, treatment is clearly complex and should be undertaken at centers with multidisciplinary expertise.

CHAPTER 70

# Caustic Strictures of the Esophagus

Alastair J. W. Millar and Alp Numanoglu

## Historical Note

Corrosive ingestion is a disease of the industrial age.[1] The tragic consequences of ingesting caustic substances and the evolution of treatment methods have been well summarized by Tucker and colleagues.[2] Esophageal dilatation of the resulting stricture, initially using blind bougie dilatation through the mouth, has changed little in principle but greatly in practice as a result of technologic advances.[3,4] Development of the distally lighted esophagoscope, introduction of string-guided retrograde dilatation via gastrostomy, and improvements in general medical and nutritional support have nearly eliminated early mortality.[2,5–7] On the basis of experimental evidence, the use of steroids and antibiotics became widespread in the 1950s and 1960s in an attempt to reduce the incidence of stricture by inhibiting inflammation, scar formation, and infection.[8–19] There has been some recent progress in managing the fibrotic healing process (e.g., mitomycin C and increasing use of stents). However, mortality still occurs from pharyngeal and laryngeal burns resulting in edema and airway obstruction, massive ingestion with perforation, and complications after stricture dilatation or surgical bypass of an irreversibly damaged esophagus.[20–26]

## Epidemiology

The ingestion of corrosive substances remains a major health hazard in children, despite aggressive educational programs aimed at both children and adults, preventive labeling and packaging, and even legislation limiting the strength and availability of caustic substances.[1,2,6,27–30] In rural areas and in developing countries, caustic soda in both crystal and liquid form is used in home industry for soap making, fruit drying, and container cleaning on farms.[31] In addition, the availability of innumerable over-the-counter caustic cleaning agents virtually ensures that children will continue to be at risk. The most distressing aspect is that most ingestions occur in children younger than 3 years and are entirely preventable. Boys are more frequently involved.[1,23,27] Toxic ingestion in children older than 5 years is suspect, and ingestion in adolescents (where girls predominate) is usually intentional[1,32]; in these cases, larger volumes and more potent corrosive and caustic materials tend to be used. Although mortality is rare, morbidity is often devastating and can be associated with lifelong consequences. Comprehensive statistics dating back to the 1970s indicate a decrease in the incidence of ingestion; however, in developing countries, the many reports of esophageal replacement procedures bear witness to this serious worldwide public health problem.[1,24,31,33–35] This is particularly true in areas where corrosive substances are available in containers that are not childproof or where such substances have been decanted from larger containers for use in homes.[1] There is still a great need for adult education and for legislation to ensure correct labeling and safe packaging and to restrict the strength and availability of caustic agents.[27,29,30]

Approximately 20% of ingestions of caustic substances result in some degree of esophageal injury.[15,32,36] Early management strategies for ingestion are now well defined, particularly the use of fiberoptic endoscopy to assess the extent and severity of injury.[37–39] However, controversy still surrounds the use of steroids, antibiotics, and esophageal stents, as well as the timing, frequency, and method of esophageal dilatation in the prevention and management of caustic strictures. Indications for definitive esophageal surgery or bypass and the type of procedure to use are also subjects of ongoing debate.[22]

## Cause

Strong alkalis that are sold in both liquid and granular form are the principal cause of severe injury (Table 70-1).[27] Household bleach, dishwasher detergents, and other cleaning agents, all of which are moderately alkaline, are the most frequent corrosive materials ingested. However, these burns are usually limited to the esophageal mucosa, without extensive necrosis or subsequent stricture formation.[27,40] A wide variety of caustic substances can cause direct injury to living tissues, particularly to moist mucous membranes, including corrosives such as potassium and sodium hydroxide (lye) and phenols; reducing agents such as hydrochloric and nitric acids; desiccants such as sulfuric acid; oxidizing agents such as chromic acid, sodium hypochlorite, and potassium permanganate; and protoplasmic poisons such as acetic and formic acids.[6,41,42] The physical form of the substance ingested and its pH play a substantial role in the site and type of

**TABLE 70-1**

postingestion esophageal injury, with a pH greater than 12 or less than 1.5 being associated with severe corrosive injuries.[1,12,41,43,44] Crystalline drain cleaners in the form of concentrated sodium hydroxide tend to adhere to the oropharynx or become lodged in the upper esophagus, where injury is most severe.[12,45–47] Highly concentrated caustic liquids usually pass rapidly through the oropharynx and cause injury to the entrance of the esophagus, the midesophagus, and immediately proximal to the esophagogastric junction.

Unlike alkaline solutions, which do not have much taste, strong acids are bitter, burn on contact, and are usually expectorated. However, when swallowed, they pass rapidly through the esophagus and cause the most substantial damage in the antrum of the stomach. The injury tends to be worse when the stomach is empty.[48] The duodenum and proximal small intestine are relatively protected by pylorospasm.[6,49–51] Ferrous sulfate as tablets (Clinitest) or capsules may also induce caustic injury to the esophagus or stomach.[52] Disk batteries contain concentrated potassium or sodium hydroxide, but they rarely lodge in the esophagus because of their small size.[53] If charged, these batteries may also cause injury to adjacent mucosa because of hydrolysis at the negative electrode.

# Pathophysiology

Much of what is known about the pathology of caustic injury in children has been derived from adult experience with self-inflicted injury and experimental studies in animals.[44–46,54–59] Injury to mucosal surfaces occurs within seconds after contact with a strong acid or alkali.[44,46] The nature of the injury caused by acidic and alkaline substances differs considerably. With acid ingestion, coagulation necrosis of the mucosa, hard eschar formation, and usually limitation of acid penetration through the mucosa occur. With alkali ingestion, tissue penetration with liquefactive necrosis is followed by destruction of the epithelium and submucosa, which may extend through the muscle layer.[8,41,44] Ischemia and thrombosis are dominant early processes.[60] A friable discolored eschar develops, under which tissue destruction continues until the alkali is neutralized. The esophagus is damaged principally at the areas of holdup: the cricopharyngeal area, the midesophagus where it is crossed by the aortic arch and left mainstem bronchus, and immediately above the esophagogastric junction. Immediate spasm and disorganized motility occur; these events may result in delayed emptying and even gastric regurgitation.[61] Hemorrhage, thrombosis, and marked inflammation with edema may be seen in the first 24 hours after injury. Depending on the degree of burn, inflammation may extend through the muscle layer until perforation occurs. After 48 hours, there is evidence of thrombosis of submucosal vessels, which gives rise to local necrosis and gangrene. Bacterial contamination leads to the development of small intramural abscesses, which may extend to the mediastinum with full-thickness injury.[9] After several days, necrotic tissue is sloughed, edema decreases, and neovascularization begins. This early reparative or subacute phase is evident from the end of the first week through the second week after injury. Scar formation begins in the third week, when fibroblast proliferation replaces the submucosa and muscularis and stricture formation commences. Mucosal re-epithelialization begins during the third week and is usually complete by the sixth week. It is during this period that adhesions may form, narrowing or obliterating the esophageal lumen. The end result may be a fibrotic stricture and a shortened esophagus.[8,62] If the injury is transmural, necrosis may extend to the surrounding mediastinum, leading to mediastinitis, or in an anterior direction into the trachea, giving rise to tracheoesophageal or even aortoesophageal fistulas.[21,26,63,64]

Steroids have been used to modify the inflammatory response both at the site of the burn and in the deeper tissues, with the ultimate goal of less extensive scarring.[9,12,44,47,65,66] However, the extent of the initial injury largely determines the outcome of the healed injury; this can range from mucosal re-epithelialization, with loss of esophageal glands and some submucosal fibrosis but preservation of the muscularis, to complete replacement of the esophageal wall by fibrous tissue.[46,67] Once the muscle of the esophagus has been destroyed, it cannot regenerate; at that point, maturation of the fibrous replacement with epithelialization of the luminal surface is the only "positive" outcome.[11] Reduction of scar tissue formation by induced inhibition of intermolecular covalent bonding of collagen with lathyrogens and other antifibrotic agents has been demonstrated experimentally, and recently mitomycin C has been reported to be efficient at a dose of 1 mg/mL concentration applied locally with a soaked swab for 4 minutes immediately after dilatation.[10,19,22,38,65,68–73]

# Clinical Presentation

Most infants and children who ingest caustic substances present with few symptoms or signs.[36–38,74] Only approximately one quarter have substantial objective evidence of corrosive ingestion.[36,75] The extent and severity of injury depend on

the concentration and form of the ingested substance. Crystalline alkalis tend to adhere to moist surfaces and cause immediate pain; in this case, oropharyngeal burns and primarily upper esophageal and laryngeal injury result. Esophageal burns in the absence of objective oropharyngeal evidence may occur in a small percentage (≤10%) of patients and should not deter the clinician from taking the appropriate diagnostic steps.[76] However, most patients with extensive oropharyngeal injury present with substantial esophageal damage; esophageal injury is unlikely if only the tongue and soft palate are involved.[36–38,75]

The viscosity and specific gravity of corrosive acids are lower than those of liquid alkalis. As a result, acid ingestion is associated with rapid transit through the esophagus; thus this organ may be largely spared. Damage occurs primarily in the antrum of the stomach because of the pooling of swallowed acid proximal to the pylorus, which goes into spasm on contact with the ingested acid.[25,50,58,77]

Obvious signs and symptoms of injury may be evident, with inflammatory mucosal edema in the oropharyngeal area and severe pain in the mouth and in a retrosternal direction.[74,75] This is often associated with agitation and tachycardia. Drooling and inability to swallow indicate severe posterior pharyngeal or upper esophageal injury.[47,65] Acute obstruction of the upper airway may result from posterior pharyngeal and laryngeal edema caused by spillage of the caustic agent into the upper airway.[32,78]

Concentrated ammonia fumes may be inhaled, causing nasopharyngeal edema and leading to respiratory injury.[32] Although rare, esophageal perforation with mediastinitis, peritonitis, and shock may occur.[21,47]

## Initial Management and Diagnosis

Initial management is directed at maintaining an adequate airway and oxygenation and ensuring cardiovascular stability. A few patients may require immediate intervention to maintain the airway. Once respiratory and hemodynamic stability has been achieved, the noxious agent, its composition and concentration, and the circumstances of ingestion should be investigated. Although the caregiver should be able to identify the ingested substance, this information is often lacking. Many health regions have poison centers where detailed product information is available.[79] In cases of caustic ingestion, inducing vomiting or encouraging the ingestion of any liquid is contraindicated because the alkali is mostly neutralized by gastric acids, and the consequences of acid regurgitation may cause further injury. Also, inhaled or aspirated vomitus may introduce corrosive matter into the upper airway, leading to acute inflammation and edema with airway obstruction.

Because the history and physical examination are unreliable in assessing the degree of esophageal involvement, endoscopic examination of the oropharynx and upper gastrointestinal tract is crucial.[37] Fiberoptic endoscopy is both accurate and safe, especially when done within 24 to 48 hours after ingestion.[3,7,38,39,54] Unnecessary treatment is avoided when esophageal injury can be excluded; however, there is still debate about which patients with a history of ingestion require endoscopy. Some advocate endoscopy only in symptomatic patients.[80,81]

Technetium-labeled sucralfate radioisotope scanning of the esophagus has been used successfully as a screening device, with lack of sucralfate adherence indicating the absence of significant injury (Fig. 70-1).[82] Using endoscopy findings to grade the severity of the injury, one can predict the long-term outcome, particularly with regard to subsequent stricture formation; however, it is sometimes difficult in practice to obtain an accurate assessment (Table 70-2).[32,54,83] An attempt is made to visualize the entire upper gastrointestinal tract, but identifying circumferential or grade III injuries provides sufficient information to initiate treatment protocols; attempts at further visualization are unnecessary and potentially dangerous.[32,67] Perforation in this situation is a severe complication that may be accompanied by mediastinitis and even mortality. In the presence of visual evidence of a pharyngeal burn with stridor, early esophagoscopy is contraindicated because of the risk of aggravating the airway obstruction.[30] Indirect fiberoptic laryngoscopy is useful to assess the upper airway.[47] Esophagoscopy may be done at the same time if esophageal intubation is required, or it may be done later, when edema of the upper airway has resolved. Initial radiographic studies should be restricted to the neck, chest, and abdomen if aspiration or respiratory burn is suspected. If fever, systemic sepsis, and upper abdominal signs are present, perforation may have occurred and a water-soluble contrast esophagogram may be useful to provide evidence of perforation.[38] A contrast esophagogram is usually done after 10 to 14 days, when an assessment of the entire esophagus and upper

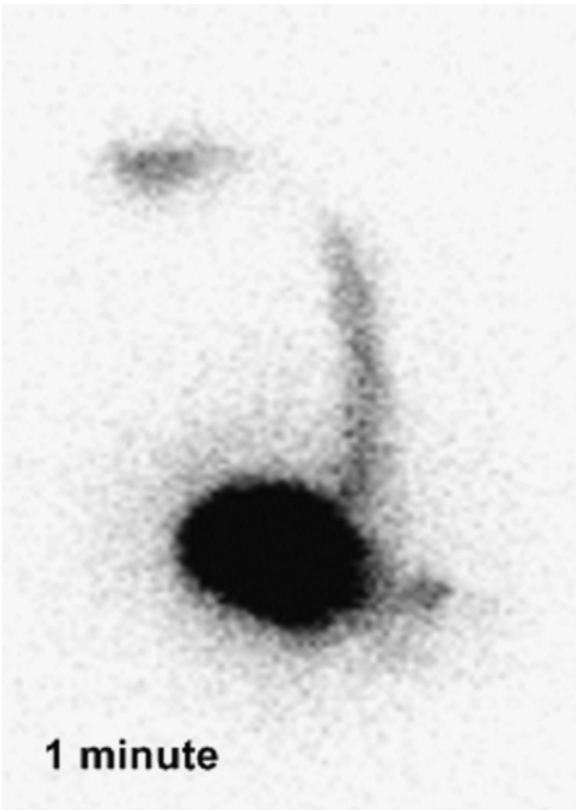

FIGURE 70-1 Technetium-99m–labeled sucralfate isotope scan after caustic ingestion. There is abnormal adhesion of sucralfate to the entire esophagus. Residual buccal activity is noted. The findings are in keeping with a caustic injury to the entire oesophagus. Endoscopy confirmed grade 2 injury to the distal two thirds of the esophagus.

**TABLE 70-2**
**Endoscopic Grading of Injury Severity**

| *Grade* | *Description* |
|---|---|
| 0 | Normal |
| I | Edema and hyperemia of mucosa |
| IIa | Friability: hemorrhage; erosion blisters, exudates, or whitish membranes; superficial ulcers |
| IIb | Grade IIa plus deep, discrete, or circumferential ulceration |
| IIIa | Small scattered areas of necrosis; areas of brownish black or gray discoloration |
| IIIb | Extensive necrosis |

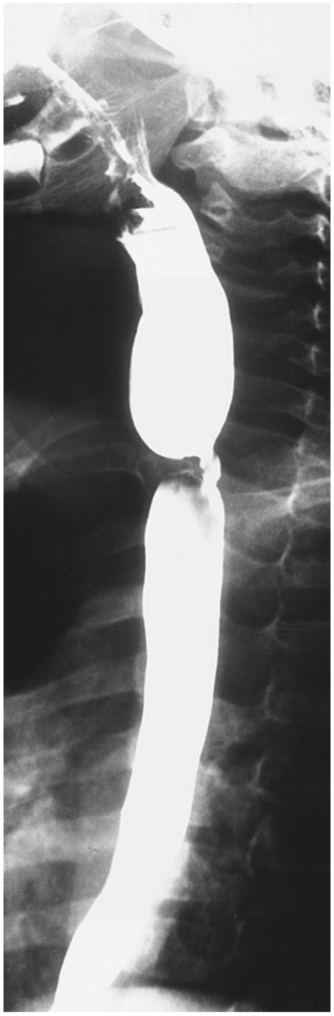

FIGURE 70-2 Localized stricture from ingestion of caustic crystals in a 4-year-old. The patient was managed successfully by local resection and primary esophageal anastomosis.

gastrointestinal tract can identify the extent of injury and may help in choosing the appropriate therapy (Fig. 70-2).[84]

# Treatment

If a known mild irritant such as hypochlorite bleach has been ingested without evidence of injury, treatment can be expectant.[4,39,75] If the substance ingested is not known and symptoms are apparent, endoscopy is indicated.[4,83,85,86]

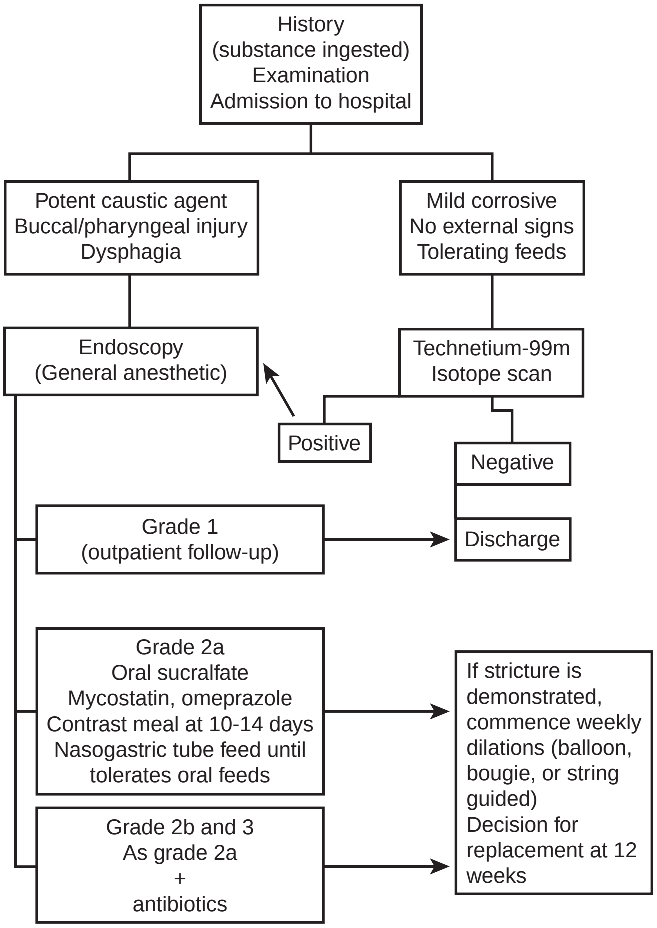

FIGURE 70-3 Management protocol for caustic strictures of the esophagus.

For patients with first-degree burns (grade I injury), no specific treatment is necessary. Liquid oral intake is initiated and extended to solids. If solid foods are tolerated, the child can be discharged. Clinical follow-up at 2 to 3 weeks is indicated, and contrast examination is done if residual clinical symptoms of dysphagia are noted. Our management protocol is summarized in Figure 70-3.

Patients with moderate (grade IIa) or severe (grade IIb and III) injuries require further treatment aimed at the prevention of stricture formation because up to 50% will develop strictures.[76,87] Although most patients with grade IIa injuries recover completely, close follow-up is required and endoscopy and dilatation must be done as prophylactic measures.[3,4] Major controversy surrounds the treatment options for severe injuries—namely, the use of steroids and antibiotics, esophageal stents, and esophageal dilatation.[88] Grade IIIb injuries are rare in the pediatric age group and usually occur in adolescents attempting suicide. These injuries may require immediate and aggressive surgery if extensive necrosis and perforation are present, especially if the stomach is also involved.[54,57,89]

The use of systemic steroids is based on the knowledge that they inhibit the inflammatory response, which is backed up by animal experiments.[8,9,12,28,44] However, in clinical trials using a variety of dosing regimens, no statistical difference in the prevention of stricture formation was evident.[90,91] Extensive retrospective reviews have also failed to show any significant

benefit of steroid therapy for patients with severe injuries.[47,54,92] More recently, the use of high-dose steroids (dexamethasone 1 mg/kg/day) has been advocated.[11,65,93] However, the number of patients in these studies was small, and morbid conditions such as mycotic infection of the esophagus, osteitis, peptic ulceration, and osteoporosis were significant.

For patients with severe injuries, a nasogastric tube may be passed for early feeding purposes. In patients who are unable to swallow, the tube can be used for enteral feeding, to serve as a guide for prograde dilatation and to maintain patency of the esophageal lumen.

In most cases, oral feeding commences as soon as the patient can swallow saliva. If dysphagia occurs, an esophagogram can identify the extent of involvement. Concomitant use of antifungal agents, antacids, and acid-secreting inhibitors ($H_2$ receptor blockers or proton pump inhibitors) is widespread, but their efficacy has not been proved.[3,4,6,30]

## Complications of Injury and Treatment

If a stricture is demonstrated on contrast radiography done 10 to 14 days after injury, a program of dilatation is commenced (Fig. 70-4).[4] Various methods can be used, ranging from mercury-filled bougies, flexible-graded bougie dilatation, guidewire-directed metal olives (Eder-Puestow system), or various balloon dilators.* Dilatation should always be attempted with great care. Initial passing of bougies for prograde dilatation should never be done blindly. If there are several strictures and visualization is difficult, it is much safer to place a transesophageal string, which is then used to guide the dilators either retrograde through the gastrostomy or antegrade through the mouth.[2] This is best done by initially passing a soft-tipped, flexible guidewire into the distal esophagus through a gastrotomy.[16,101] Easy access to the gastroesophageal orifice is gained by advancing a polyvinyl chloride endotracheal tube up the lesser curve through the gastrotomy or passing a guidewire under vision using a transgastric fiberoptic endoscope.[103] For satisfactory dilatation of a stricture, a general anesthetic is required in the early stages to protect the airway.

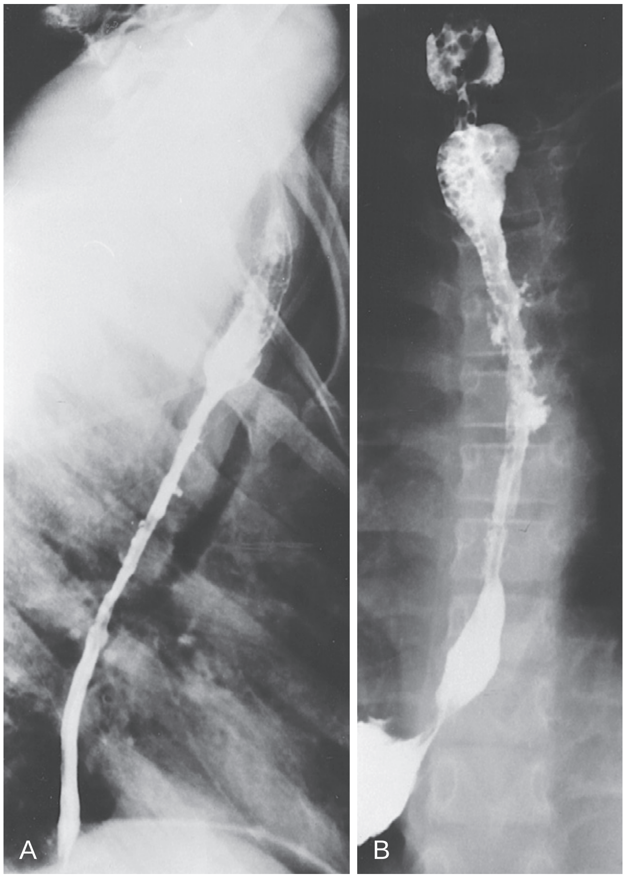

**FIGURE 70-4** **A,** Early esophagogram after caustic ingestion. **B,** Several areas of full-thickness ulceration progressed to extensive strictures, which required esophageal bypass.

To be effective, dilatations should be done at least once a week, commencing with catheters that are one or two French sizes smaller than the estimated diameter of the stricture. It is generally prudent not to dilate more than two to three sizes larger than the size of the first dilator meeting resistance. Initially, dilatation should be continued as long as esophageal healing and a progressive increase in esophageal caliber are noted, along with reestablishment of normal feeding. Factors indicating a poor prognosis are delay in presentation, extensive grade III injury, ongoing esophageal ulceration, a densely fibrotic stricture that cracks on dilatation, a stricture longer than 5 cm, and inadequate lumen patency despite repeated dilatations over a 9- to 12-month period.[23,104] No data support the routine use of prophylactic antibiotics; however, if systemic infection or transmural necrosis occurs, appropriate antibiotic therapy should be commenced.[44,75,96] During recovery, it is essential to provide adequate nutrition; in most cases the gastrointestinal tract can be used, with access through the nasogastric tube or by placement of a feeding gastrostomy or jejunostomy tube.

If dilatation fails and a dense stricture develops, it requires treatment.[94] As with other benign esophageal strictures, the incidence and severity of gastroesophageal reflux must be investigated and excluded as a contributing cause of the persisting stricture.[23,63,95,105–107] Gastroesophageal reflux should be managed surgically, if necessary, before definitive procedures to resect a stricture or replace the esophagus are attempted (Fig. 70-5).[47,108] Localized strictures may be resected with an end-to-end anastomosis. However, the whole esophagus must first be carefully assessed endoscopically to confirm that the stricture is indeed localized, because histologic evidence of fibrotic injury may be much more extensive than is evident on radiography.[23,35] A healthy color of the esophageal mucosa and distensibility with air insufflation at esophagoscopy are useful signs when assessing the esophagus. Local injection of steroids (1% triamcinolone acetate) into short strictures has had some success when combined with dilatation but has not been assessed prospectively. Likewise, application of mitomycin C has also been used with reported success (vide supra).[13,16,19,63,109–111]

*References 3, 4, 23, 29, 85, 94–102.

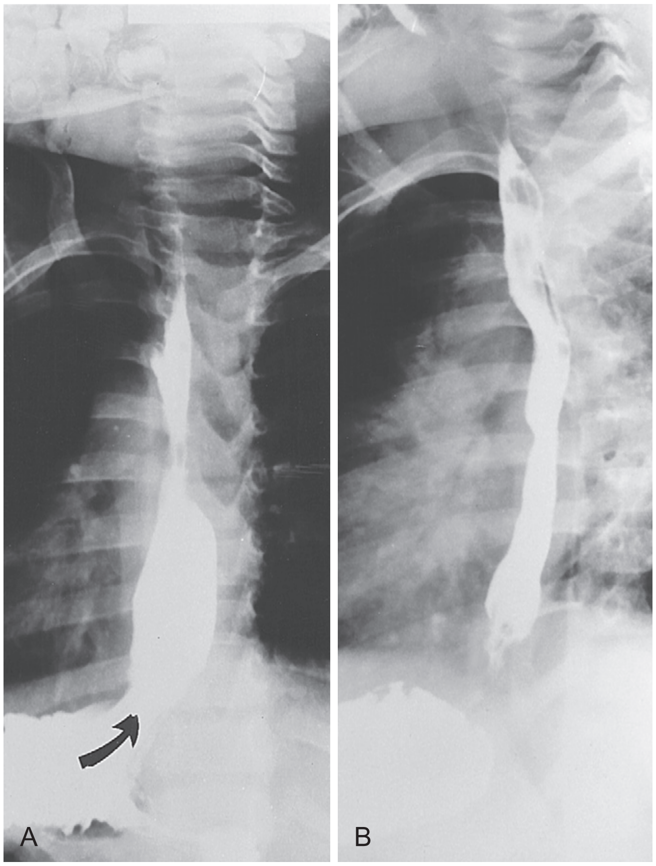

FIGURE 70-5 **A,** Contrast esophagram of a persistent caustic stricture of the midesophagus, with esophageal shortening and marked gastroesophageal reflux (*arrow*). **B,** This resolved after antireflux surgery and dilatation.

Some investigators advocate the use of esophageal stenting by means of an indwelling nasogastric tube.[112–114] The lumen is maintained, and adhesion of de-epithelialized areas of the esophagus is prevented; simultaneously, tube feedings can be given. Over the years, various types of stents have been used (e.g., silicone, polytetrafluoroethylene).* If used, stents should remain in place for at least 6 weeks, at which time epithelial healing should be complete and fibrosis will have begun to mature. However, in many cases these tubes are not well tolerated; they may promote gastroesophageal reflux, and if an extensive inflammatory response through the muscle occurs, the stent must be in place for much longer to be effective. Stents have also been used in the management of esophageal fistulas resulting from caustic injury or dilatation therapy, mainly as a temporizing measure before surgical repair or esophageal bypass.[64,120]

## Long-Term Outcome

Extensive caustic injury may heal without stricture or may respond to the various prophylactic and therapeutic measures outlined. However, residual motility dysfunction can be expected, and an achalasia-like picture has been described.[121–123]

Carcinoma of the previously injured esophagus is a real risk, but the disease usually has a latency period of 15 to 40 years.[4,56,124–130] However, a lethal squamous cell carcinoma of the esophagus has been reported just 1 year after injury.[131] Also, Barrett esophagus has been observed following lye-induced injury.[87,132] Thus long-term surveillance with esophagoscopy is advocated. In this regard, two prudent questions arise: To what extent should the clinician try to preserve the damaged esophagus? When should attempts at dilatation be abandoned?[133,134]

Currently, there is a trend toward earlier esophageal bypass in a severely injured esophagus, with the addition of resection of the damaged esophagus.[3,28,66,104] Complications such as abscess or cyst formation in the bypassed but retained esophagus are rare, and carcinoma has not been reported.[23,104]

Esophageal perforation, as evidenced by pain, fever, and tachycardia, is a life-threatening iatrogenic complication of esophageal dilatation (Fig. 70-6).[46,103] With immediate recognition by endoscopy or contrast swallow, many patients with a perforated esophagus can be treated conservatively with systemic antibiotics and parenteral nutrition.[135–137] Established methods of management with either thoracostomy drainage or primary repair with proximal and distal esophageal and gastric diversion are reserved for patients with delayed recognition or extensive disruption. Transesophageal water irrigation with chest drainage as a supplement to conservative measures has also been advocated.[135] If dilatation has failed or if the esophagus cannot be salvaged, esophageal bypass or substitution is indicated. Operations currently used are colonic interposition, gastric tube esophagoplasty, jejunal interposition, and gastric advancement (see Chapter 71).* Colonic patch procedures have also been used for less extensive but persistent strictures.[86,103,141–143] Deciding which procedure to use and whether to bypass or resect the injured esophagus is influenced by local practice and the morbidity and mortality from esophageal resection. Clearly, the risks associated with resection must be less than the risk of cancer in the retained but bypassed esophagus.[86,124,144–146]

## Results

Between 1957 and 2010, 522 children with caustic injuries of the esophagus were treated at the University of Cape Town teaching hospitals (Red Cross War Memorial Children's Hospital and Groote Schuur Hospital). The average age was 35 months, with a range of 7 to 206 months. Forty-five percent were younger than 2 years. In recent years (1990 to 2010) there has been a trend toward an increasing number of patients presenting to hospitals with caustic ingestions (1432), but only 500 patients (35%) required hospitalization. Of these, only 39 (8%) developed strictures. The mean age was 4.5 years, with equal gender distribution. Most children ingested household cleaners or disinfectants.

*References 23, 28, 35, 68, 86, 104, 138–140.

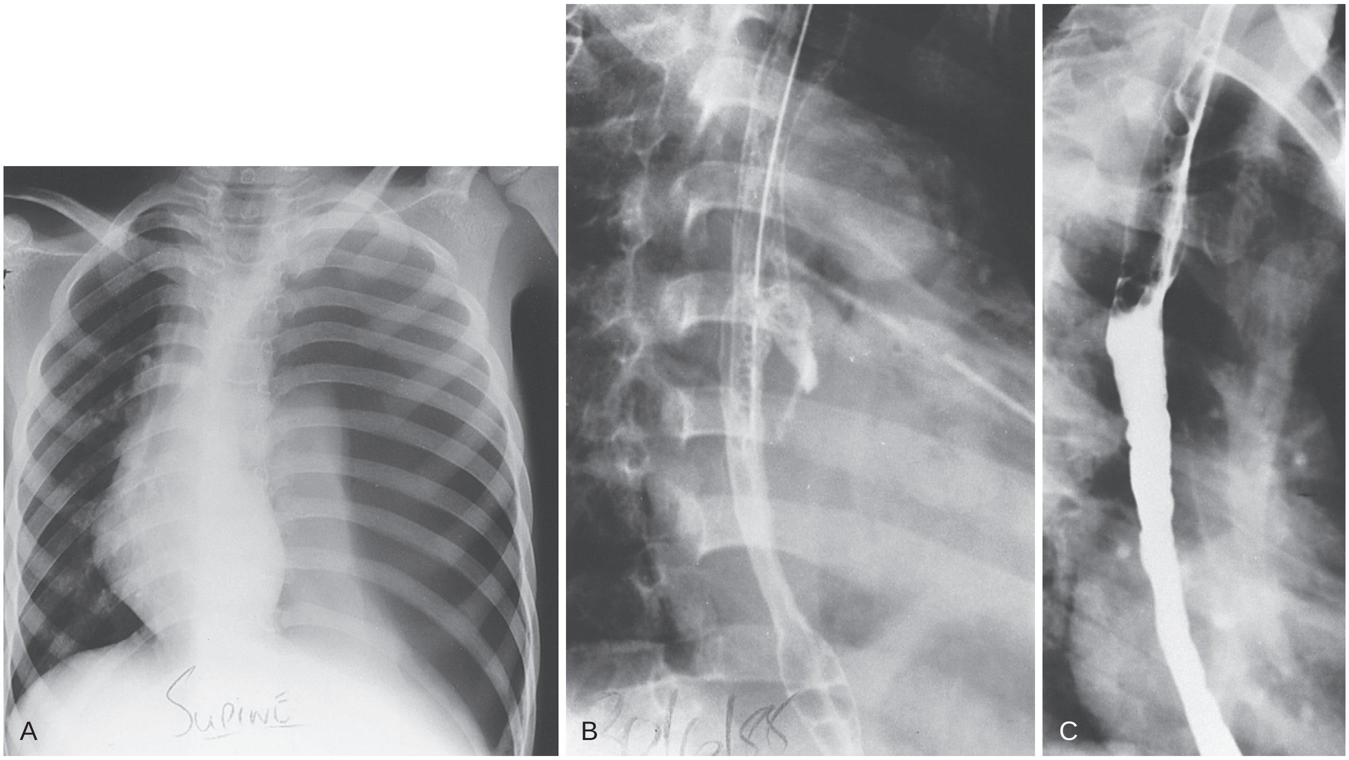

**FIGURE 70-6** Left-sided tension pneumothorax secondary to perforation after dilatation of an upper esophageal caustic stricture. **A,** Treatment by tube thoracostomy drainage. **B,** Contrast study 10 days later shows that the leak has been contained. **C,** Healed esophagus 12 weeks after perforation. Esophageal replacement was not required in this case.

Overall, 97 of the 522 (18.5%) patients developed fibrous strictures of the esophagus. Caustic soda was the most common corrosive agent (92 of 97 patients) and was taken in the crystal form by 31 children. Acid burns were responsible for only four strictures. One patient with an acid burn who had extensive esophageal injury developed a severe stricture of the stomach antrum and upper jejunum; another patient presented 8 months after ingesting soldering acid with a near-complete antral stricture. Of the 97 patients with strictures, 49 (50%) responded to repeated dilatations, whereas the other 48 required operative management. Ten of the 48 had severe oropharyngeal burns in addition to the scarred esophagus, and 6 of these patients required tracheostomy. The 97 patients had an average of 18 dilatations (range, 1 to 38). The 49 who responded to dilatation had an average of 17 dilatations over a period of 13.6 months (range, 0.5 to 20 months); the 48 children with strictures who required esophageal replacement were dilated an average of 12.7 times (range, 1 to 31) over a 13.7-month period (range, 0.5 to 87 months). The outcome was poor when presentation was delayed for more than 1 month, with 8 of 10 such patients requiring esophageal bypass. Length of stricture greater than 5 cm was another adverse factor; 17 of 18 patients with this finding did not respond to dilatation.

Complications in the 97 patients with stricture are summarized in Table 70-3. The most significant complication was esophageal perforation, which occurred in 13 patients. Perforation occurred after an average of six dilatations.

**TABLE 70-3**

**Complications of Caustic Strictures of the Esophagus ($N = 97$)**

| *Complication* | *No. of Patients* |
|---|---|
| Perforation | 13 |
| Tracheoesophageal fistula | 1 |
| Gastroesophageal reflux | 7 |
| Pneumonia | 8 |
| Cerebral abscess | 1 |
| Hemorrhage | 1 |
| Tracheostomy | 6 |

Two perforations occurred during the first dilatation, and others occurred after as many as 14 dilatations, indicating that perforation can occur at any stage. With early recognition, perforation was associated with minimal morbidity and some patients could be treated conservatively with intravenous antibiotics alone. If extension of the inflammatory process or perforation into the mediastinum or pleura occurred, these areas were drained. One patient developed a tracheoesophageal fistula and had esophagectomy of an extensively scarred esophagus, followed by posterior mediastinal left colonic interposition. No complications such as cyst or abscess formation have occurred in the retained esophagus in patients receiving a retrosternal interposition. Seven patients developed gastroesophageal reflux, six of whom underwent antireflux surgery. Four subsequently responded to dilatations, whereas the other three required esophageal replacement (Table 70-3).

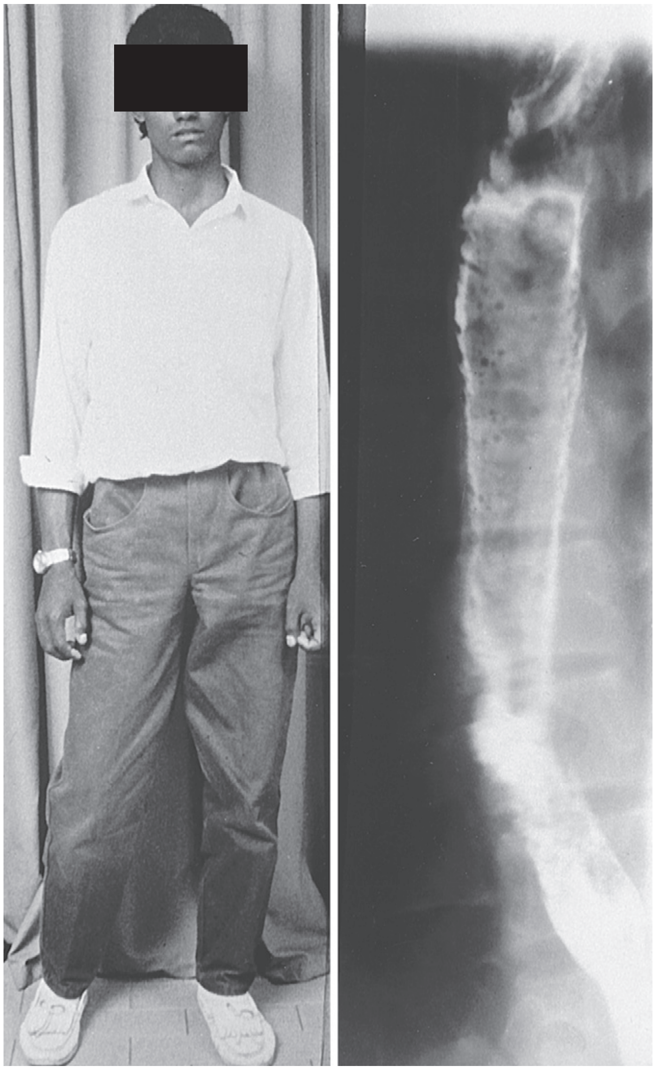

**FIGURE 70-7** Young man 21 years after substernal left colonic esophageal replacement for caustic injury, with accompanying esophagogram. He recently developed fatal squamous carcinoma of the cricopharynx nearly 30 years after caustic ingestion.

Since 1969, we have performed an isoperistaltic retrosternal left transverse and left descending colon interposition based on the ascending branches of the left colonic vessels in 39 cases and local resection with end-to-end anastomosis in 1 case. Details of the operative procedure have been reported.[23] Colonic interposition has proved to be a successful conduit for all nutritional needs, with satisfactory long-term results (Fig. 70-7). Recently following an international trend, we have moved to resection of the damaged esophagus and the transmediastinal placement of the graft (see Chapter 71).[68,140]

CHAPTER 71

# Esophageal Replacement

Lewis Spitz and Arnold G. Coran

The need to replace the esophagus is becoming increasingly rare. This mainly results from improved methods of retaining the native esophagus in infants born with long-gap esophageal atresia. In addition, general awareness of the damage that can occur as a consequence of intractable gastroesophageal reflux has resulted in more aggressive approaches in antireflux surgery, and with the introduction of childproof containers, fewer lye and caustic injuries to the esophagus occur. Nevertheless, there continue to be instances where substitution of the esophagus is required and it is important for the pediatric surgeon to be aware of the various options available for replacement.

## Indications for Esophageal Replacement

### ESOPHAGEAL ATRESIA

Infants with long-gap esophageal atresia (EA) constitute the main group that requires esophageal replacement because of failure to achieve end-to-end anastomosis. Numerous maneuvers have been adopted to overcome the long-gap EA and obtain a primary anastomosis, thereby allowing retention of the infant's native esophagus. A list of these techniques is shown in Table 71-1. For infants with an isolated esophageal atresia, it is important to exclude an upper pouch tracheoesophageal fistula. Where there is only a small nubbin of distal esophagus above the hiatus, or no intrathoracic esophagus at all, a replacement is clearly going to be required and it is best at an early stage to perform a cervical esophagostomy and allow the infant to go home pending a later replacement procedure. The infant is now free from the danger of aspiration, and appropriate bonding with the family can take place at home. Where the gap between the proximal and distal esophagus is between four and eight thoracic vertebral bodies or if at thoracotomy an anastomosis cannot be achieved even under extreme tension, delayed primary repair should be attempted. The infant is fed by gastrostomy while suction is applied to the upper esophageal pouch for a period of 6 to 12 weeks. During this time, the gap between the two ends of the esophagus gradually diminishes. If primary anastomosis is still impossible at this stage, further delay is unproductive and esophageal substitution is required. It would now be possible to perform a primary interposition procedure, or if circumstances do not permit, then a cervical esophagostomy is performed with later replacement procedure. Although it is obvious that the patient's own esophagus is the best esophagus, persisting with futile attempts to retain the native esophagus in the presence of major complications (e.g., empyema, intractable stricture, repeated recurrent fistulas) is occasionally detrimental to the well-being of the infant. In such situations, it is clearly in the patient's best interest and safety to abandon the esophagus and perform a replacement procedure at a later stage.

### PEPTIC STRICTURES

Antireflux surgery is usually performed for pathologic gastroesophageal reflux before intractable strictures develop. The majority of severely scarred and inflamed strictures of the esophagus will resolve with effective antireflux surgery followed by regular postoperative esophageal dilations. A small percentage requires limited "sleeve" resection of the strictured area, but some will fail to respond and will require esophageal replacement.

### CAUSTIC STRICTURES

Although uncommon in developed countries as a result of legislation mandating childproof containers for caustic substances, many children in developing countries continue to sustain caustic esophageal injuries. Most cases are mild and respond to repeated dilations. Full-thickness injury to more than a short segment of the esophagus invariably results in an intractable stricture, which fails to respond to dilations and usually requires substitution. Continuing with dilatations at regular intervals for longer than 6 to 12 months is unproductive. The need to resect the damaged esophagus continues to be disputed. The risk for malignant conditions and the ease with which esophagectomy can be performed in children favors resection and substitution rather than bypass procedures. Caustic strictures are discussed extensively in Chapter 70.

| Gastric transposition[77,79,80,86,113] |

## MISCELLANEOUS INDICATIONS

The need for replacement because of bleeding esophageal varices is virtually obsolete as a result of the success of alternative techniques, particularly sclerotherapy, banding, and portosystemic shunts. Tumors of the esophagus may require resection of extensive lengths of the esophagus. Examples of such tumors in children are diffuse leiomyoma and inflammatory pseudotumor. The esophagus may be extensively damaged by prolonged impaction of foreign bodies such as aluminum can ring pulltops, which are radiolucent and may escape detection on conventional radiography. Other unusual indications for esophageal replacement include intractable achalasia, diffuse candidiasis in children with immune deficiency, scleroderma,[1] epidermolysis bullosa,[2] and human immunodeficiency virus (HIV) strictures.[3]

# Characteristics of an Ideal Esophageal Substitution[4]

- The substitute must function as an efficient conduit from mouth to stomach to satisfy the nutritional needs of the child.
- Gastric acid reflux into the conduit must be minimal; if reflux does occur, the substitute should be resistant to gastric acid.
- The substitute should not impair respiratory or cardiac function.
- The operative technique should be technically unchallenging and adaptable to small children.
- The conduit should not produce any external deformity.
- The conduit must grow with the child and continue to function into adult life.

# Types of Esophageal Replacement

Although the colon has been the most frequently used organ for esophageal substitution in children, dissatisfaction by some surgeons has led to use of other alternatives. The methods most commonly used are shown in Figure 71-1.

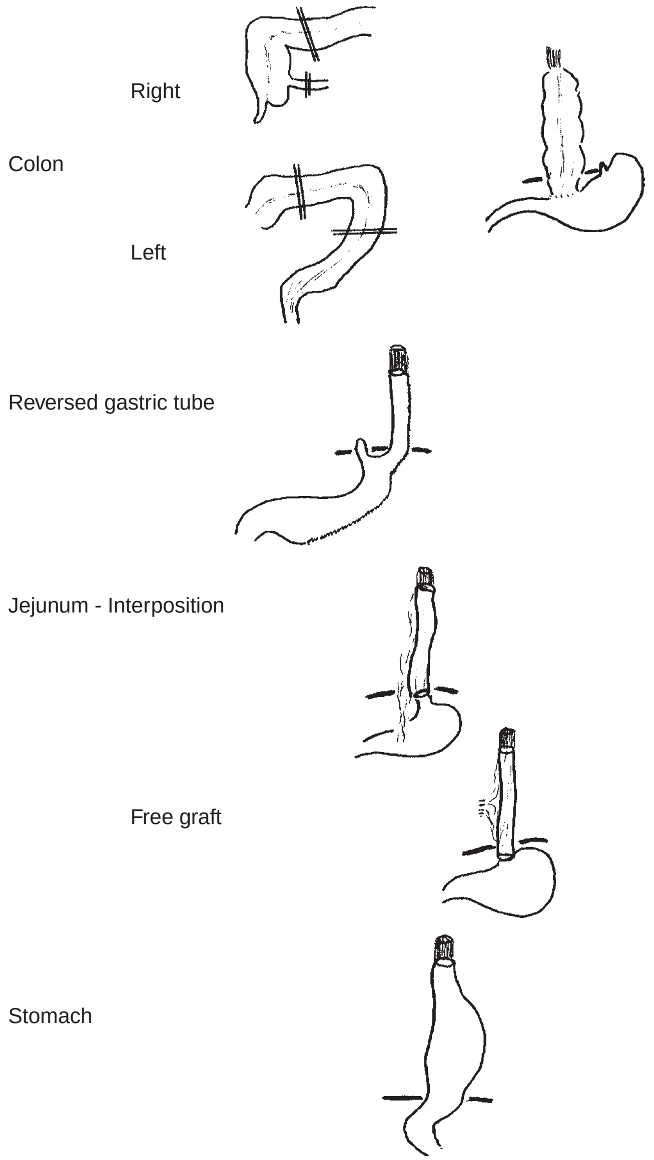

**FIGURE 71-1** Methods for esophageal replacement.

The advantages and disadvantages of the various substitution procedures are outlined in Table 71-2.

Several artificial prostheses have been used as substitutes for the esophagus. All of these have only functioned for short periods.[5,6]

# Route for Positioning the Esophageal Substitute

The posterior mediastinum is the shortest distance between the cervical region and the abdomen for esophageal replacement.[7] Colonic interpositions were originally placed subcutaneously on the anterior chest wall, but the cosmetic appearance with this method is unacceptable and it has been abandoned. The advantages and disadvantages of the other routes are outlined in Table 71-3.

# Timing

Although esophageal replacement is possible in newborns, the procedure should generally be delayed until the infant is thriving and weighs at least 5 kg. In the interim, it is important to stimulate the swallowing reflex by offering sham oral feedings during regular gastrostomy feedings. Infants who achieve good sham-feeding will undoubtedly rapidly accept oral nutrition when the esophageal substitute has been successfully connected. In all cases, adequate mechanical preparation of the intestine is essential because the organ that had been selected for esophageal replacement may be unsuitable and an alternative technique may be required.

Excellent comprehensive reviews of the history of esophageal replacement have been documented by May and Samson in 1969[8] and Postlethwait in 1983.[9]

# Colonic Interposition

Colonic interposition continues to be a widely used procedure for esophageal replacement in children. In adults with carcinoma of the esophagus, the currently preferred technique is gastric transposition, with colonic interposition being reserved as a secondary procedure.

## HISTORY

In 1911 Kelling[10] used a segment of transverse colon based on the left colic artery to bypass the esophagus. Unfortunately, the patient died before an attempt could be made to join the cervical esophagostomy to the upper end of the colon. In 1911 Vulliet[11] preserved the mesenteric pedicle to the right end of the colon transplant in a cadaver. In 1914 Von Hacker carried out the first successful colonic interposition in an adult.[12] The first successful colonic bypass in a child was reported by Lunblad in 1921.[13] The patient underwent the procedure for an esophageal stricture at 3 years of age and lived until he was 37 years old, at which time he died accidentally. Ochsner and Owens[14] reviewed the literature in 1934 and could find only 20 reported cases of colonic esophagoplasty. In 1951 Rudler and Monod-Broca[15] described the retrosternal ileocolonic graft. In 1955 Dale and Sherman[16] described two infants with EA who had reconstruction of the esophagus at 2 years of age using a right colonic retrogastric anterior mediastinal interposition. Four years later, Battersby and Moore[17] reported five cases of right colon replacement for congenital atresia of the esophagus. The three children who had substernal placement of the colon survived. They recommended delaying the procedure until the infant was at least 9 months of age. Major advances in the use of the colon for esophageal replacement were documented by Sherman and Waterston in 1957,[18] by Waterston in 1964,[19] Azar and colleagues in 1971,[20] and Belsey in 1965.[21] Waterston and Belsey[22] were strong proponents of the transpleural route using the left colon supplied by the left colic vessels. In 1967 Otherson and Clatworthy[23] stated that the colon was the best organ for esophageal replacement in children and recommended delaying the operation until the child was 18 to 24 months old so that gravity in the erect position would assist in food passage through the colonic interposition. Freeman

**TABLE 71-2**
**Substitution Procedures**

| *Method* | *Advantages* | *Disadvantages* |
|---|---|---|
| Colon | Adequate length | Precarious blood supply |
| | Reflux seldom occurs | Graft necrosis |
| | | High incidence of leaks and strictures |
| | | Involves three anastomoses |
| | | Redundancy over long-term |
| | | Slow transit of food |
| Gastric tube | Adequate length | Long suture line |
| | Good blood supply | High incidence of leaks and strictures |
| | Size of conduit appropriate | |
| | Rapid transit | Reflux—Barrett syndrome |
| Stomach | Adequate length easily attained | Bulk of stomach in thorax |
| | | Reflux common early on |
| | Excellent blood supply | Poor gastric emptying |
| | Single anastomosis | Affects pulmonary function |
| | Ease of procedure | Affects growth |
| Jejunum | Appropriate size | Precarious blood supply |
| | Retention of peristaltic activity | |
| | Length can be a problem | Three anastomoses |
| Free jejunal graft | Appropriate size | Specialized technique for |
| | Good peristaltic activity | microvascular anastomosis |
| | | Prolonged operating time |
| | | Precarious blood supply |
| | | High failure rate |

**TABLE 71-3**
**Routes for Positioning the Esophageal Substitute**

| *Route* | *Advantages* | *Disadvantages* |
|---|---|---|
| Retrosternal | Ease of procedure | Longest route from neck to abdomen |
| | Useful when transpleural and mediastinal routes are unavailable because of inflammation or previous surgery | Angulation of graft |
| | | Problems with access if cardiac surgery required |
| Transpleural | Convenience and ease of procedure | Displacement of lung |
| | | Requires thoracotomy |
| **Posterior Mediastinal** | | |
| Most direct route | Organ contained in mediastinum | Mediastinum may be unavailable because of previous surgery, fibrosis, or inflammation |
| | Little or no compression of lung | |
| | Thoracotomy not always required | |

and Cass, in 1982,[24] advocated placing the transposed colon in the route of the native esophagus in the posterior mediastinum and reported an impressively low rate of complications.

## SURGICAL TECHNIQUE

Colonic interposition entails use of either the right colon based on the ileocolic vessels placed in the retrosternal position or the left/transverse colon based on the left colic vessels positioned in a retrohilar position in the left pleural cavity or in the posterior mediastinum (Fig. 71-2).

## RIGHT COLON RETROSTERNAL TECHNIQUE

The abdomen is opened either through a midline upper abdominal incision or a transverse upper abdominal muscle-cutting incision that transects both rectus abdominis muscles. The entire colon must be mobilized and exposed to provide detailed and accurate assessment of its blood supply. In a study of 600 specimens, Sonneland, Anson, and Beaton[25] reported that only 24% of specimens showed the typical textbook picture of three vessels to the right side of the colon arising from the superior mesenteric artery.[25] The middle colic artery was absent in 3.6% of cases. The marginal artery was occasionally absent. In individual children, the anatomy of the vascular supply determines the section of colon most appropriate for the interposition procedure. The blood supply to the right colonic interposition is based on the middle colic artery. However, if a segment of terminal ileum is to be used in the interposition,[26] the ileocolic vascular supply to the graft must be preserved if possible. The length of intestine to be used is carefully estimated, and bulldog clamps are placed across all vessels that require division. The clamps are left in position for at least 10 minutes to ensure that the blood supply is adequate, that the marginal vessels continue to pulsate, and that the color of the section of colon selected for the interposition remains normal. The blood supply can be further evaluated by removing the appendix and observing the flow of blood in the appendicular artery. If the blood supply seems to be satisfactory, the vessels that require division are carefully and securely ligated and divided. It is important to preclude hematoma formation in the mesentery. The ileum is divided between the clamps, and the distal stump is closed in preparation for its relocation into the neck. The transverse colon is then divided to the left of the middle colic artery, and intestinal continuity is restored by an end-to-end ileotransverse colostomy.

A transverse cervical incision that encircles the previously constructed cervical esophagostomy is made. The incision should extend to the midline of the neck approximately 1 cm above the manubrium sterni. The upper border and posterior surface of the manubrium is exposed by dividing the cervical fascia and the origin of the sternomastoid muscle. It may be necessary to enlarge the opening into the retrosternal space by removing the upper part of the manubrium, sternoclavicular joint, or both.

The retrosternal tunnel is developed from above through the cervical incision in a plane directly posterior to the sternum and anterior to the thymus and pericardium and from below following division of the anterior attachments of the diaphragm. The tunnel must be wide enough to accommodate at least two to three fingers.

The stomach is then mobilized to allow the colon and its vascular pedicle to pass behind the stomach, over the anterior

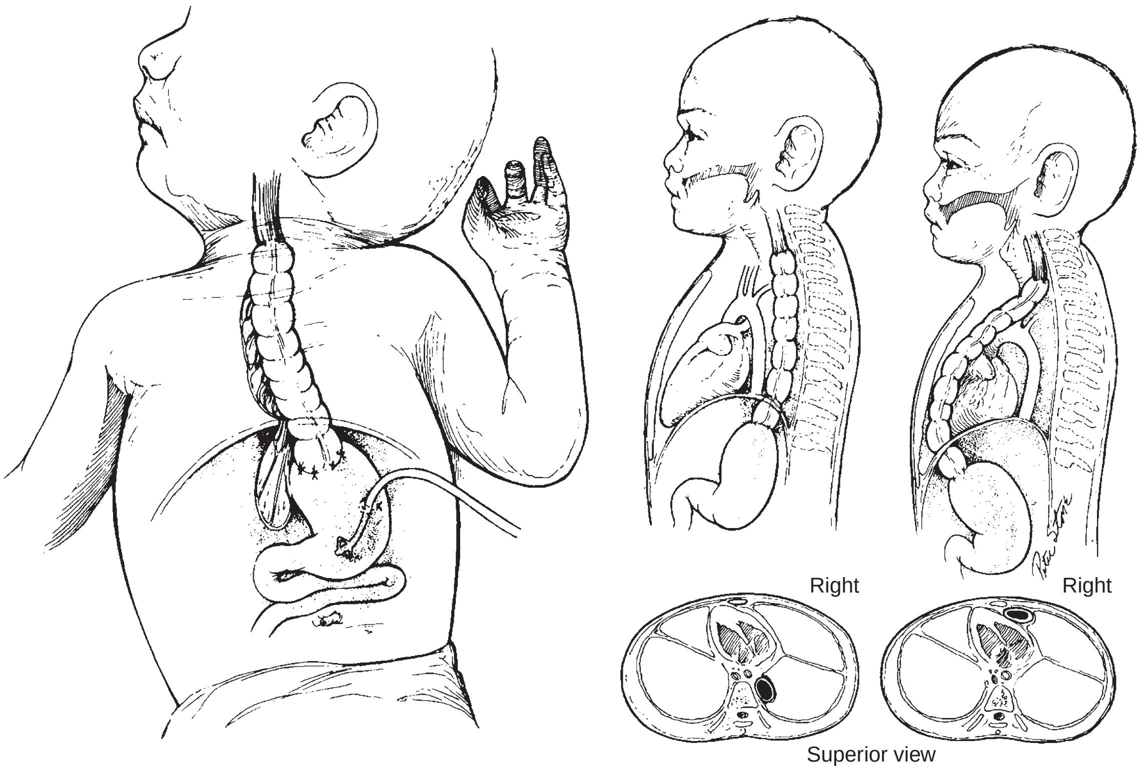

FIGURE 71-2 Colon esophagoplasty. The colon may be placed in retrosternal or retrohilar position with equal success. (From Randolph JG: Surgical problems of the esophagus. In Sabiston D, Spencer F [eds]: Gibbon's Surgery of the Chest, 3rd ed, Philadelphia, WB Saunders, 1976. Used with permission.)

surface of the liver, and through the retrosternal tunnel into the neck. It is vital to ensure that there are no kinks or twists in the graft that may impair the blood supply. The distal end of the colonic interposition is anastomosed to the anterior wall of the stomach close to the lesser curvature. An antireflux submucosal gastric tunnel has been devised as a method of preventing reflux of gastric acid into the colon graft.[27] The proximal end of the graft, which will comprise the ascending colon or the terminal ileum, is anastomosed end to end to the distal end of the cervical esophagus. During preparation of the esophagus for anastomosis, it is imperative to preserve its blood supply and to meticulously mobilize the full thickness of the esophagus. The length of the colonic interposition must be just sufficient to bridge the gap between the esophagus and the stomach. Excess colon should be resected before anastomosis while the blood supply to the remaining graft is preserved. Redundancy is a problem that increases with time and can lead to stasis. Pyloroplasty or pyloromyotomy is generally recommended to prevent this complication.

## LEFT/TRANSVERSE COLON TRANSPLEURAL TECHNIQUE

The left colon transpleural technique was originally described by Waterston.[19] For this method, the left transverse colon based on the ascending branch of the left colic artery is placed isoperistaltically in the retrohilar position. In the original description, the entire procedure was performed through a left thoracic incision with access to the abdomen provided by detaching the diaphragm peripherally from the chest wall. An alternative approach is to use separate abdominal and thoracic incisions or a thoracoabdominal incision.[21] Intestinal continuity is restored by end-to-end colo-colic anastomosis. The colon graft is passed in a retrogastric and retropancreatic direction and then through a separate lateral incision in the posterior diaphragm into the left pleural cavity. The colon is passed behind the hilum of the left lung and into the neck by tunneling through the Sibson fascia in a posterior direction to the subclavian vessels and lateral to the carotid sheath. The proximal end of the colonic interposition is anastomosed end to end to the cervical esophagus, and the distal end is anastomosed either to the distal stump of esophagus (in cases of esophageal atresia) or preferably to the posterior wall of the stomach. Pyloroplasty is again recommended. Freeman and Cass[24] modified the procedure by placing the colon in the posterior mediastinum in the site of the normal esophagus.

## RESULTS

With modern anesthetic techniques and postoperative management, mortality from colonic interposition alone should be negligible.[28] Graft necrosis should also be rare, particularly if meticulous attention is paid to ensuring that the graft has an adequate blood supply and that the vessels do not kink as the graft is passed behind the stomach. Venous obstruction may result in gradual infarction of the colonic interposition weeks or months after surgery. The most common complications are anastomotic leakage, particularly that which involves the esophagocolonic anastomosis in the neck and stricture formation. Leaks are attributed to a poor blood supply to the proximal end of the colon or to damage to or impairment of the blood supply to the esophageal wall. Most leaks resolve spontaneously within a few weeks, but some progress to stricture formation. Strictures at the cervical anastomosis generally resolve with dilations, but resection of the strictured area and revision of the anastomosis are occasionally necessary.

The incidence of complications subsequent to colonic interposition in the various large series in the literature is shown in Table 71-4.

Gastric reflux into the colonic interposition may occur and occasionally results in peptic ulceration of the colon. This may progress to hemorrhage or, on rare occasions, perforation with resultant empyema. Late deaths from perforation and empyema have been reported.

Complications after bypass procedures have also been described in the retained esophagus.[29,30] Shamberger[31] described eight patients who developed chronic inflammation in the esophageal remnant, including three cases of Barrett syndrome. Others have documented mucocele and empyema developing in the retained esophagus.[32]

Peristalsis in the colonic segment is usually absent, and food is conducted through the colon by gravity.[13,33–36] The intrathoracic colon may become increasingly redundant with time, and this may result in delayed emptying and stasis, which increases the risk for regurgitation and aspiration. It may be necessary to resect the redundant portion of colon, but in so doing, care must be taken to avoid damage to the blood supply of the remaining colon. This can be done by resecting the mucosal/submucosal tube of the redundant distal colon, opening the remaining muscular tube of the redundant colon on its antimesenteric side, and creating a new cologastric anastomosis on the top of the open muscular cuff where the blood supply to the proximal colon runs. One of us (author AGC) has done this in 12 cases, and the results have been excellent with removal of all the redundancy and elimination of all symptoms.

The nutritional state of children after colonic interposition seems to be satisfactory.[37] Children who originally had EA tend to be in the lower percentiles for height and weight, whereas those who had esophageal replacement for caustic stricture fall into a normal growth curve.[4,34,38–41] Nearly half of patients with colonic interposition have depleted stores of iron.[42] Coopman and colleagues[43] reviewed the long-term outcome following colonic interposition in 32 children. Complications were identified in 58% in the first year postoperatively, and in the long term 85% experienced problems including abnormal lung function (58%), feeding difficulties (50%), scoliosis (35%), and nutritional deficiencies in 25%.

# Gastric Tube Esophagoplasty

## HISTORY

In 1905 Beck and Carrell[44] constructed tubes of the greater curvature of the stomach in dogs and cadavers; the tubes were brought antethoracically into the neck. In 1912 Jianu[45] successfully used this tube intrathoracically in two patients with strictures. In 1948 Mes[46] showed that a tube of the greater curvature of the stomach could reach the neck. Later, Gavriliu in Hungary[47–49] and Heimlich[50,51] in the United States popularized this method of esophageal replacement. More recent advocates for gastric tube esophagoplasty include Burrington and Stephens,[52] Cohen,[53] Ein,[54] and Anderson.[55,56]

## SURGICAL TECHNIQUE

The abdomen is opened through a transverse supraumbilical incision, and the gastrocolic omentum is divided at a safe distance from the gastroepiploic arcade (Figs. 71-3 and 71-4).[55] The right gastroepiploic artery is divided at the point of origin of the gastric tube; the site of division must be chosen carefully to avoid narrowing the pyloric outlet. The optimum location is usually approximately 2 cm proximal to the pylorus, where a vertical incision is made through the anterior and posterior walls of the stomach. With an 18-French to 24-French chest tube placed in the stomach along the greater curvature to act as a guide to ensure the construction of an appropriately sized gastric tube, a gastrointestinal anastomosis (GIA) stapler[57] is applied 1½ to 2 cm from the greater curvature, encompassing both anterior and posterior gastric walls. The staple line is placed, and the stomach is cut parallel to the greater curvature. Three to four applications of the stapler are usually required. The short gastric vessels are divided, and the spleen is protected during the construction of the tube. Splenectomy is *never* necessary. The staple lines on the gastric tube and on the native stomach are reinforced simultaneously with interrupted Lembert sutures of 4-0 nonabsorbable material. If the left gastroepiploic artery has been previously ligated and is unavailable to supply the antiperistaltic tube, an isoperistaltic tube based on the right gastroepiploic artery can be constructed.

The route to the neck is selected at this point, and either a retrosternal tunnel is created or a left thoracotomy is performed in the sixth intercostal space. The neck incision is placed in the suprasternal notch for a substernal tube and in the left anterior triangle for the transthoracic route. Finger dissection from cervical and thoracic approaches assists selection of the safest place to incise the Sibson fascia. This position may be anterior or posterior to the subclavian vessels, depending on which space is larger. An incision is made in the diaphragm in a medial and anterior direction to the aortic hiatus, and the gastric tube is drawn into the chest and passed in a proximal direction into the neck. The orientation of the pedicle is maintained to prevent twisting or kinking of vessels. Anastomosis with the cervical esophagus is done with a single layer of nonabsorbable sutures. A few sutures placed between tube and diaphragm anchor the tube in the chest. The gastrostomy is reestablished in the remnant of the stomach. The chest and neck are drained, and the abdomen is closed without drainage. If the left gastroepiploic artery was damaged during a previous operation, the right gastroepiploic artery can be used to support the vascular pedicle and the tube would be constructed in the reverse (isoperistaltic) direction. In this instance, after creation of the gastric tube, the stomach is rotated in a posterior direction so that the tube can be brought to the neck.

## RESULTS

The gastric tube tends to retain its shape without the redundancy and dilation that tends to occur in colon grafts. Reflux is almost always present and may cause Barrett changes in the proximal esophageal stump.[58] Peptic ulceration has been reported as a long-term complication associated with gastric tubes.[59,59a,60] Nocturnal coughing is a common problem that can be alleviated by elevating the head of the bed and avoiding fluids shortly before bedtime. The gastric tube supports nutrition well. Children with lye strictures fall into normal growth curves, whereas those with EA tend to fall in lower percentiles for weight and height but grow satisfactorily and maintain good nutrition.[38]

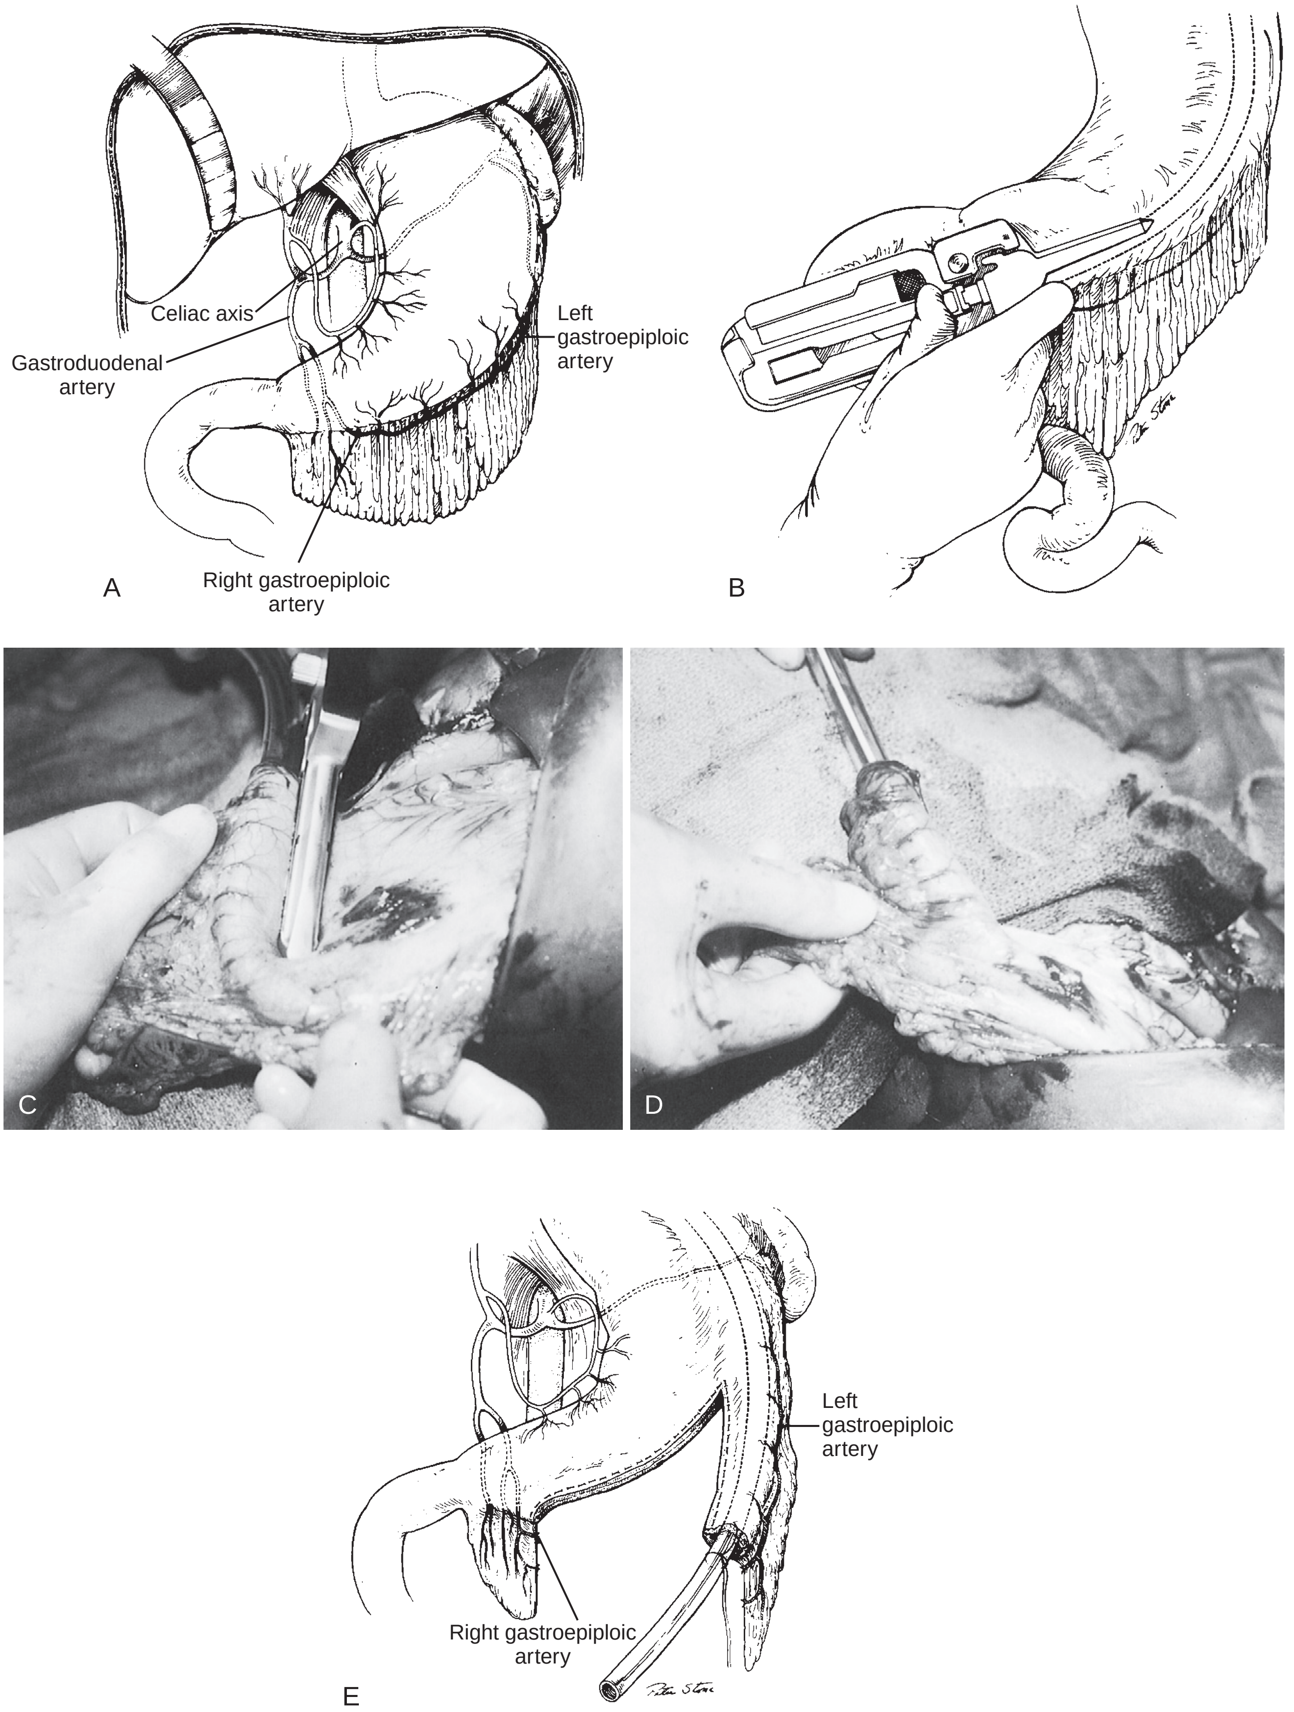

**FIGURE 71-3** Reverse gastric tube construction. **A,** Tube is vascularized by the left gastroepiploic artery. The right gastroepiploic artery is divided where shown, and the arcade is carefully preserved. **B** through **E,** Step-by-step division of the stomach by the gastrointestinal anastomosis stapler, using a chest tube along the greater curvature as a guide to ensure uniform size of the gastric tube. Oversewing of the staple line on the tube and stomach is also shown.

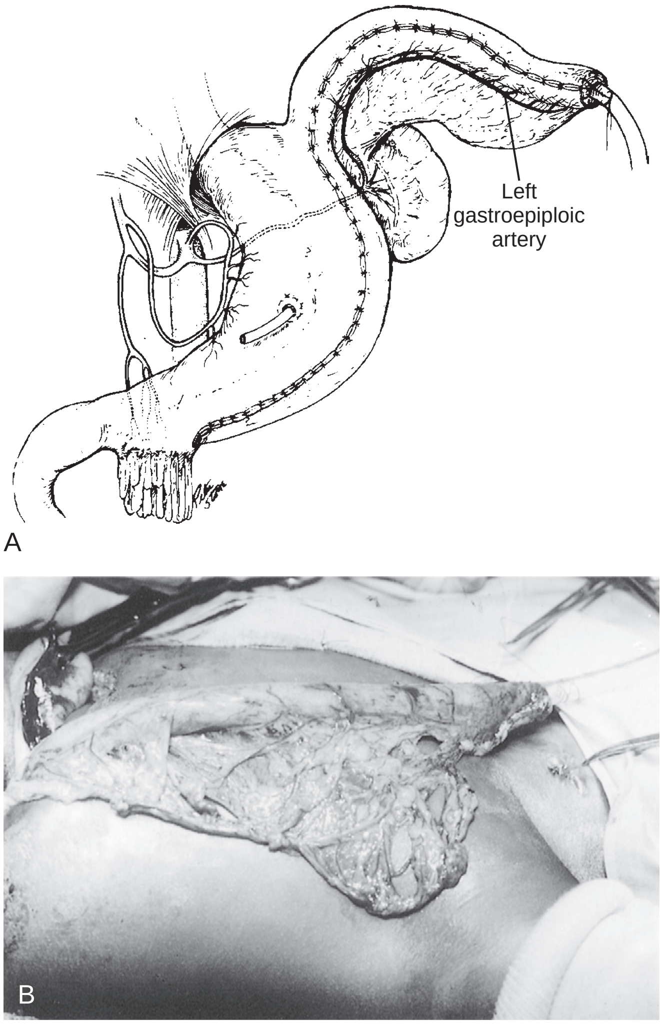

FIGURE 71-4 Reverse gastric tube. **A,** The spleen has been preserved; staple closures of the tube and stomach have been reinforced by interrupted sutures. **B,** The tube is placed over the chest and reaches the cervical esophagostomy, to which the clamp is pointing. The intrathoracic course is even shorter.

Mortality associated with gastric tube esophagoplasty is low, but leaks and strictures are common. Perforation of the gastric tube occasionally occurs.[60] Peristalsis is generally absent, and the tube empties by gravity (Table 71-5).

# Jejunal Interposition

## HISTORY

In 1906 Roux[61] used the jejunum in an antethoracic direction to bypass a caustic stricture in a 12-year-old child. Follow-up of this patient was published by Picot-Roux and Hase in 1950.[62] The patient did well until 1940, when a large fistula developed subsequent to trauma, and in 1941, an epithelioma was found in the cutaneous portion of the esophagus; this disorder was successfully treated with radiation therapy. The patient died of unrelated causes at 53 years of age. In 1913 Lexer[63] combined the Roux isolated jejunal loop with a cutaneous skin tube when the jejunum was not long enough to reach the neck. Approximately 20 years later, Ochsner and Owens[14] reviewed the literature of antethoracic esophageal replacement and found that of 240 patients, 56% had tubes constructed of jejunum. In 1946 Reinhoff[64] performed the first intrathoracic jejunal replacement of the esophagus. He recommended the shorter intrathoracic route and stated that the jejunum was long enough to reach the neck. Longmire[65] reported a jejunal interposition for caustic stricture in which the inadequate blood supply to the upper end of the jejunum was supplemented by an anastomosis between the internal mammary artery and the mesenteric artery of the jejunum in 1951. The advantages of the jejunum as an esophageal substitute are that peristaltic activity is preserved, and its caliber is similar to that of the normal esophagus. The results of jejunal interposition are shown in Table 71-6. The most recent series is reported by Bax[66,67] where there was no mortality and a 20% leak rate in 24 cases.

*One stricture required resection, and 10 patients required dilatations (>4 times in 6 patients).

## SURGICAL TECHNIQUE

Two methods of jejunal replacement of the esophagus are used[64,68]: (1) transection of the jejunum distal to the ligament of Treitz, in which the proximal end of the loop is brought up through the thorax into the neck to join the esophagus, the distal end is anastomosed to the stomach, and intestinal continuity is restored by a jejuno-jejunal anastomosis; and (2) interposition of an isolated jejunal segment, either pedicled[66] or with microvascular anastomosis of the jejunal pedicle is done.

# Gastric Transposition

## HISTORY

In 1922 Kummell mobilized the esophagus in two patients by bluntly freeing it with the fingers introduced from the cervical and abdominal wounds.[69] Next, the stomach was

transplanted into the esophageal bed and the esophagus was anastomosed to the stomach. Although both patients died, this was the first attempt at gastric transposition by means of the mediastinal route. In 1938 Adams and Phemister[70] successfully resected a carcinoma in the lower thoracic esophagus of a 53-year-old patient and restored continuity by esophagogastrostomy. In 1944 Garlock's successful reestablishment of esophagogastric continuity after resection of the esophagus for carcinoma of the middle third in a 58-year-old male was reported.[71] At follow-up, the only complication was regurgitation in the recumbent position. This problem was controlled by sleeping on two pillows. In 1945 Sweet[72] recorded 12 esophageal resections with esophagogastric anastomosis above the arch of the aorta, and in 1948[73] he described the successful application of his technique following resection of a carcinoma of the upper thoracic esophagus with anastomosis of the stomach to the cervical esophagus. Soon thereafter, successful pharyngogastrostomy was described. Replacement of the esophagus by gastric transposition is currently the procedure of choice in adults with carcinoma, but its use in children has been limited.[74] Atwell[75] reported six children who had gastric transposition; two died, but good long-term results were achieved in the other four patients.

## SURGICAL TECHNIQUE

Transhiatal gastric transposition without thoracotomy is the procedure of choice (Fig. 71-5).[74,76–79] This procedure is sometimes contraindicated in the presence of extensive scarring from previous surgery or mediastinal inflammation.[80]

To preserve the vascular arcades of the gastroepiploic vessels, the initial feeding gastrostomy should ideally be sited on the anterior surface of the body of the stomach, well away from the greater curvature.

The stomach is exposed through an upper midline or left subcostal abdominal incision. Alternatively, a left oblique muscle-cutting incision that may extend into a left thoracotomy may be used, particularly if resection of a fibrotic esophagus or previous colonic interposition is required.

The gastrostomy is carefully mobilized, and the defect in the stomach is closed in two layers with interrupted 4-0 polyglycolic acid sutures.

Adhesions between the stomach and the left lobe of the liver are lysed while care is taken to preclude damage to the major blood vessels. The greater curvature of the stomach is mobilized by ligating and dividing the vessels in the gastrocolic omentum and the short gastric vessels. These vessels should be ligated well away from the stomach wall to preserve the vascular arcades of the right gastroepiploic vessels. Meticulous care must be taken to avoid damaging the spleen. The lesser curvature of the stomach is freed by dividing lesser omentum from the pylorus to the diaphragmatic hiatus. The right gastric artery is carefully identified and preserved while the left gastric vessels are ligated and divided close to the stomach (see Fig. 71-5, *A*).

The lower esophagus is exposed by dividing the phrenoesophageal membrane, and the margins on the esophageal hiatus in the diaphragm are defined. The inevitably short blind-ending lower esophageal stump in patients with isolated EA is dissected out of the posterior mediastinum by a combination of blunt and sharp dissection through the diaphragmatic hiatus. The vagal nerves are usually divided during this part of the procedure. The body and fundus of the stomach are now free from all attachments and can be delivered into the wound. The esophagus is transected at the gastroesophageal junction, and the defect is closed in two layers with 4-0 polyglycolic acid sutures. A Heineke-Mickulicz pyloroplasty or pyloromyotomy is usually performed, although whether it is necessary continues to be controversial.[81] The second part of the duodenum may need to be Kocherized to obtain maximum mobility of the pylorus. The abdominal part of the procedure and dissection into the posterior mediastinum through the esophageal hiatus may be carried out laparoscopically.[82]

The highest part of the fundus of the stomach is identified, and stay-sutures of different material are inserted to the left and the right of the area selected for the anastomosis. These sutures help to avoid torsion of the stomach as it is drawn through the posterior mediastinum into the neck (see Fig. 71-5, *B*).

Attention is now turned to the neck, where a previously constructed cervical esophagostomy is mobilized through a 3- to 4-cm transverse incision. Care must be taken not to damage the muscular coat of the esophagus. The recurrent laryngeal nerve that courses upward on the posterolateral surface of the trachea is identified and preserved. A plane of dissection between the membranous posterior surface of the trachea and the prevertebral fascia is established, and a tunnel is created into the superior mediastinum by blunt dissection immediately in the midline. A similar tunnel is fashioned from below in the line of the normal esophageal hiatus in the tissues posterior to the heart and anterior to the prevertebral fascia.[40] When continuity of the superior and inferior posterior mediastinal tunnels has been established, the space to be occupied by the stomach is developed into a tunnel the width of two to three fingers (see Fig. 71-5, *C*).

If thoracotomy was required for resection of a fibrotic esophagus (e.g., in cases of caustic or reflux esophagitis) or a nonfunctioning prior interposition, or when blunt dissection would be hazardous because of fibrosis from previous surgery or infection, the transthoracic part of the procedure is carried out under direct vision. The remainder of the operation is done in the same manner as that for the mediastinal procedure.

A long, blunt hemostat is passed into the posterior mediastinal tunnel from the cervical incision, and the two stay-sutures on the fundus of the stomach are grasped. The hemostat is gently withdrawn, which pulls the stomach up through the esophageal hiatus and the posterior mediastinal tunnel into the cervical incision. Alternatively, a large, stiff chest tube may be passed from the cervical incision into the mediastinum and abdomen and then sewn to the fundus of the stomach and drawn back into the neck, maintaining the sutures in the right orientation. Orientation of the fundus is checked by realigning the stay-sutures in their correction position. The end of the esophagus is anastomosed to the highest part of the stomach using a single layer of interrupted 4-0 polyglycolic acid sutures.

A large-caliber (12-gauge) nasogastric tube is inserted into the stomach through the esophagogastric anastomosis. The tube remains in place to allow free drainage and is aspirated at regular intervals to prevent acute gastric dilatation in the early postoperative period. A soft rubber drain is placed at the site of the anastomosis, and the wound is closed in layers.

The surgeon then returns to the abdomen, where the margins of the diaphragmatic hiatus are sutured to the antrum of

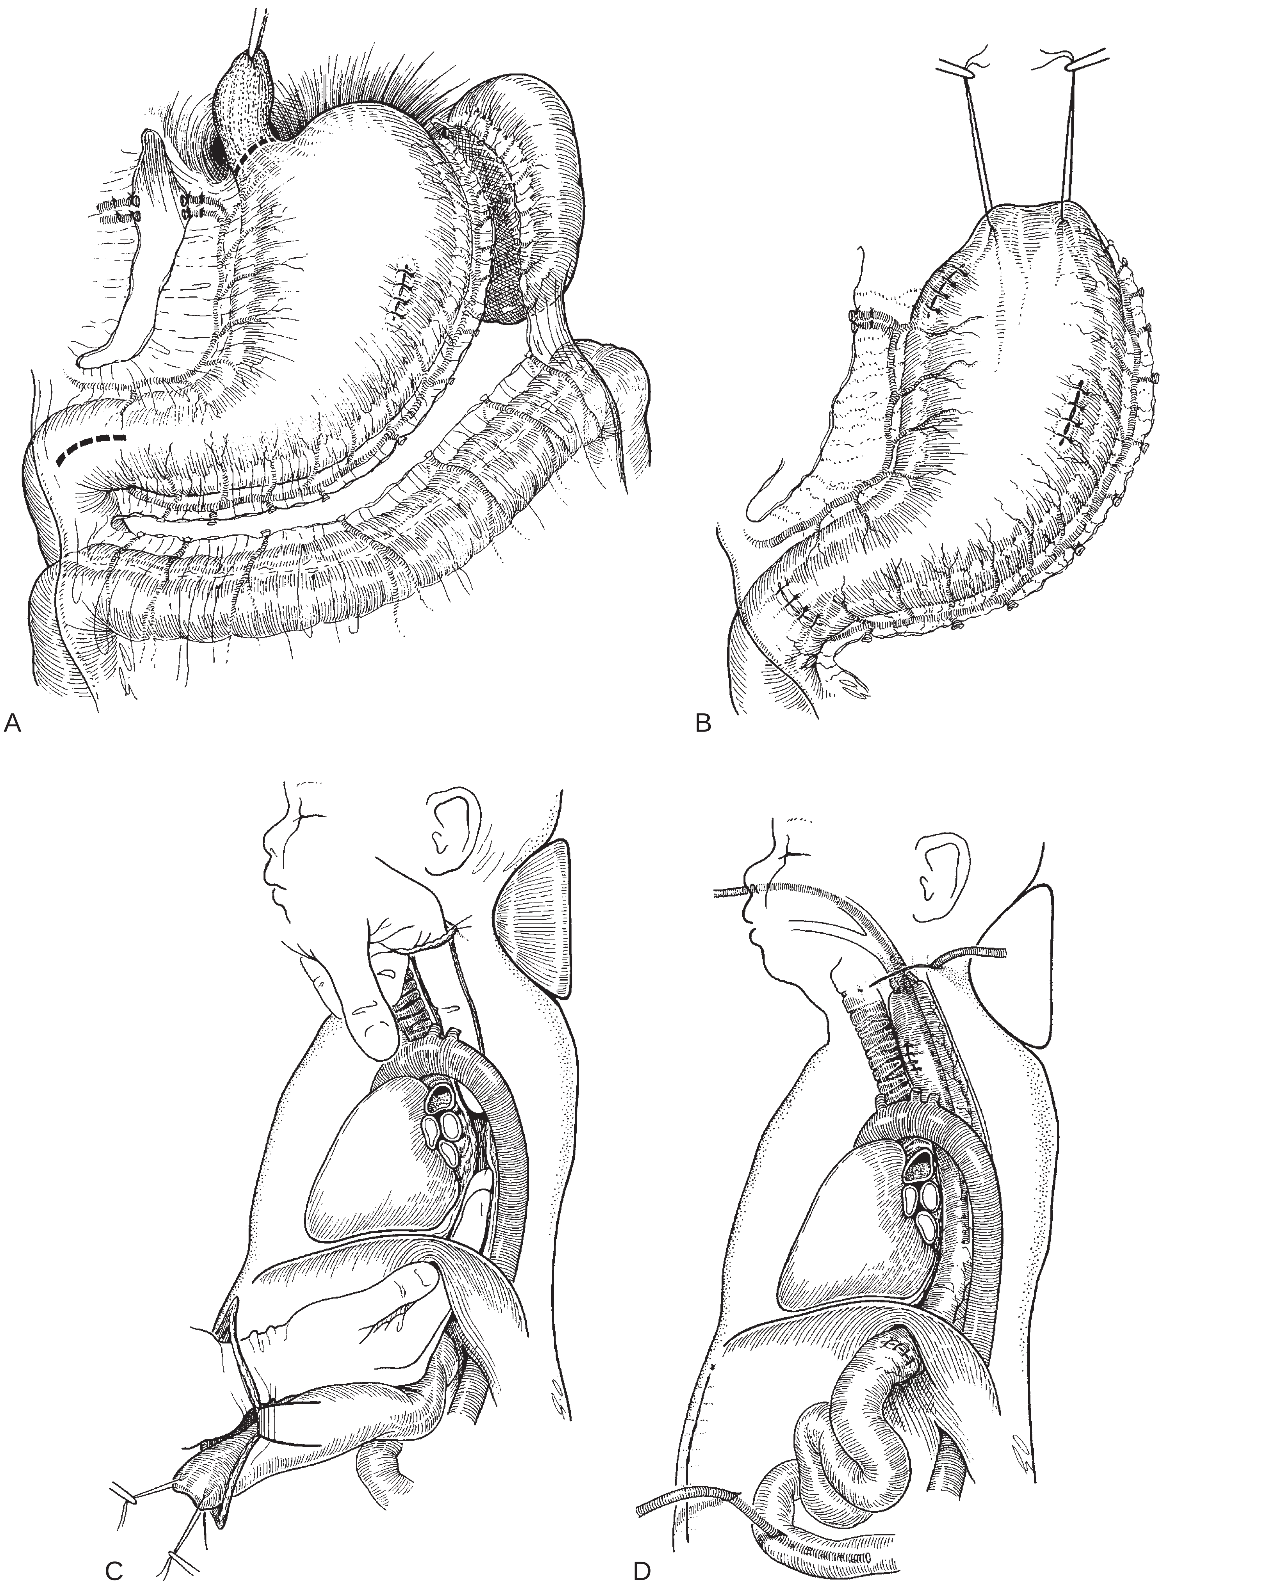

**FIGURE 71-5** **A,** Technique of gastric transposition. Mobilization of the stomach along the greater and lesser curvatures, preserving the right gastroepiploic and right gastric vessels. The short gastric vessels are carefully divided, with care being taken to avoid trauma to the spleen. The left gastric vessels have been ligated and divided. The duodenum (to which the Kocher technique has been applied) and the site of pyloroplasty are indicated. The short stump of esophagus in a case of isolated atresia is shown being mobilized from within the esophageal hiatus of the diaphragm. The gastrostomy site has been sutured. **B,** Pyloroplasty has been completed, the distal esophageal stump has been resected, and the two sutures on the fundus of the stomach indicate the highest point of the stomach at the proposed site for the esophagogastric anastomosis. **C,** Fashioning of the posterior mediastinal tunnel by blunt dissection from above by means of a cervical incision to mobilize the esophagostomy or expose the esophagus in the case of caustic injury and from below by means of the esophageal hiatus in the diaphragm. The dissection is done strictly in the midline in the prevertebral plane. **D,** The final position of the stomach in the posterior mediastinum with the esophagogastric anastomosis in the lower neck and pyloroplasty situated immediately within the peritoneal cavity below the esophageal hiatus. A jejunostomy tube has been placed for postoperative enteral feeding.

the stomach with a few interrupted sutures so that the pylorus lies immediately below the diaphragm in the midline. A fine-bore or button loop feeding jejunostomy has been found to be of considerable value in providing enteral nutrition in the first few weeks after gastric transposition before full oral nutrition is established (see Fig. 71-5, *D*).

## POSTOPERATIVE MANAGEMENT

Careful monitoring of vital functions is essential in the early postoperative period. Extensive dissection of the soft tissues in a posterior direction to the trachea has been done, and the resulting edema may cause respiratory compromise. Elective endotracheal or nasotracheal intubation with or without assisted ventilation for a few days may simplify the postoperative course and reduce the incidence of respiratory problems.

Jejunal feedings are instituted on the second or third day after surgery. The safest method of delivery of nutrition by this method is a slow, continuous infusion rather than by a bolus technique, which can provoke a "dumping" effect. Contrast swallow is done 7 days after surgery, and if no leak is identified at the anastomosis, careful oral feeding may begin. The cervical drain is removed when the integrity of the anastomosis has been demonstrated.

The results of gastric transposition in the larger series in the literature are shown in Table 71-7. In the period 1981-2005, 192 gastric transpositions were performed at Great Ormond Street Hospital, London.[83] The most common indication for esophageal replacement was EA in 138 cases, 76 of whom had failed primary repair, while 48 had isolated atresia without fistula. Twenty-nine children had intractable caustic strictures. More than 80% of patients were referred from abroad or from other centers within the United Kingdom. The method of replacement was via the posterior mediastinum without thoracotomy in 98 patients (51%). In the remainder a thoracotomy was necessary because of dense mediastinal scarring secondary to the original injury (caustic, perforation) or as a result of previous failed attempts at esophageal reconstruction. All patients are currently routinely paralyzed and mechanically ventilated for at least 48 to 72 hours postoperatively.

There have been nine deaths (4.6%), eight of whom had had complex courses before the transposition. Anastomotic leakage at the esophagogastric connection occurred in 12% of cases, all except one of which closed spontaneously. Strictures developed in 20% of cases, all but three of whom responded to endoscopic dilatation.[84] In these three cases, stricture resection and reanastomosis was successfully carried out through a cervical approach. Strictures were more common after caustic injury (38%). Swallowing problems postoperatively were encountered in 30% of cases.

Establishing oral feeding can be extremely difficult, particularly in infants with EA who have not been properly sham-fed. The jejunal feeding tube greatly simplifies postoperative nutrition and avoids the need for parenteral nutrition. Vomiting, which may be bilious in nature as a consequence of pyloroplasty, is common in the early postoperative period, especially when the child is recumbent.

A follow-up of 17 patients who had gastric transposition more than 5 years previously has shown that the intrathoracic stomach functions as a conduit as opposed to a reservoir for both liquids and solids.[85] Rapid emptying (>50%) of both liquids and solids occurred within 5 minutes of ingestion in 82% of patients. Dumping symptoms are occasionally an early feature, but these symptoms resolve within a few weeks in most cases. Of 17 children, 13 were within normal percentiles for height and 11 were within normal percentiles for weight. Low stores of iron are a feature in all types of esophageal replacements and were documented in all patients who had had gastric transposition. All but one child had restricted pulmonary function, with a mean total lung capacity of 68% and a mean forced vital capacity of 64% of expected values. It is uncertain at present whether these reduced values are a consequence of the primary condition or a direct result of gastric transposition.[85]

In 90% of our patients, the long-term outcome was judged to be good to excellent in terms of absence of swallowing difficulties and other gastrointestinal symptoms such as dumping or diarrhea. There has been no deterioration in function of the transposed stomach over time.[83]

One of us (author AGC) has had personal experience since 1985 with 169 gastric transpositions in infants and children. Follow-up has been obtained in 144 of these patients. These 144 patients consisted of 111 with EA, the vast majority of which were long-gap EA, 17 with lye strictures, 5 cases of diffuse leiomyomatosis, 2 patients with recurrent gastroesophageal reflux who had undergone multiple operations, 6 cases of failed colonic transpositions, and 3 recurrent tracheoesophageal fistulas who had undergone multiple previous operations with continued recurrence. More than 90% of patients had undergone previous esophageal surgery including previous esophageal replacements in 20%. After the initial early experience with this procedure in which a thoracotomy or thoracoabdominal approach was used, in the last 100 patients the posterior mediastinal dissection was done via the abdomen and the neck without any complications including serious bleeding. Ten patients with long-gap pure EA did not undergo a previous cervical esophagostomy before the gastric transposition. A feeding jejunostomy was done selectively but usually in infants with pure long-gap EA because of their difficulty in learning to feed postoperatively.

There has been no mortality in this series. There has been no loss of gastric conduit. In one patient, the gastric transposition was taken down due to a severe stricture, a result of failure to return for follow-up for more than 1 year. There have been two major complications: In one child with a lye stricture, the anastomotic leak tracked into the mediastinum and required drainage. She recovered but suffered a cardiac arrest 3 months later during dilation with residual brain

damage. The leak rate was 16%; all leaks closed spontaneously and required no further surgery. The stricture rate was 18%. All strictures have responded to dilations. Strictures were more common in caustic injuries. There was only one case of documented dumping syndrome, which responded to a carbohydrate-free diet. More than 90% of the patients are feeding orally. One of the most difficult problems was food aversion in babies with pure EA. In some cases, it took longer than 1 year for these infants to learn how to feed orally.[86]

In summary, there are several alternatives to esophageal replacement, with advantages and disadvantages for each, and the method chosen depends largely on the surgeon's experience and somewhat on patient-related factors, but good results can be obtained in a reproducible fashion with colon or gastric transposition or with gastric tubes.

CHAPTER 72

# Disorders of Esophageal Function

Juan A. Tovar

The esophagus acts as a conduit interposed between the pharynx and the stomach and has no significant secretory or absorptive functions. Its main function is propulsive, and its disorders induce several pathologic conditions that mirror their adult counterparts, although with specific pediatric features. Some of these disorders are related to malformations and manifest themselves during infancy and childhood. Most are incompletely understood due to our limited knowledge of the mechanisms of regulation of gastrointestinal motility and also because of the insufficiencies of the diagnostic tools that are difficult to apply in children due to size and collaboration problems. In the present chapter these motor disorders are addressed.

## History

In contrast with gastroesophageal reflux, the existence of disorders of esophageal function in children has been acknowledged only recently. With the exception of achalasia[1,2] and "esophageal diverticulum" likely corresponding to cricopharyngeal achalasia,[2] they were not even mentioned in the first modern textbooks of the specialty.[1–4] The nature of the functional disturbances involved in their pathogenesis and their sometimes elusive symptoms have been understood only recently, when the necessary miniaturized diagnostic tools were developed. Since these conditions were investigated, new clinical situations in which dysmotility plays a role were identified and examined.

## Embryology

The esophagus derives from the foregut or cranial part of the endodermal tube that runs longitudinally along the embryonal body. Cranially it starts at the lower end of the pharynx and caudally it is in continuity with the stomach, which is an expansion of the foregut.[5] The endodermal lining of this foregut is surrounded by muscle fibers that originate from the mesoderm and arrange themselves in two layers: the external, in which they are disposed longitudinally, and the internal, in which they adopt a circular pattern.

On the fourth week of gestation the respiratory anlage appears on the ventral side of the foregut and progressively undergoes branching until configurating the definitive tracheobronchial tree.[5] Endodermal-mesenchymal interactions and the influence of various genes, transcription factors, and growth factors contribute to shaping the lung and its multiple types of cells.[6,7] The endodermal lining undergoes changes leading to differentiation into either esophageal or tracheobronchial epithelia.[8] Tracheo-esophageal separation is crucial for normal organogenesis, and several malformations or dysfunctions of the esophagus have their origin at this point. On completion of these phases, the esophagus acquires its final configuration with two muscular layers, a submucosa and a polystratified, nonkeratinized mucosa. The reason why the muscle of the upper third of the organ is striated while that of the distal two thirds is smooth is unclear,[9] as is the mechanism by which this mucosa, which was originally endodermal, acquires its final ectodermal pattern. Esophageal glands derived from the endoderm form in the submucosal layer and secrete alkaline fluid that contributes to buffering acid.[10]

From weeks 4 to 11, neuroblasts issued from the cranial neural crest colonize the foregut in a cranio-caudal direction[11] and settle in the intermuscular and submucosal layers establishing fibrillar connections that will account for neural control of esophageal function by the parasympathetic and sympathetic systems.[12] Nonadrenergic noncholinergic (NANC) or nitrergic innervation is present in the myenteric plexus on week 12 and in the submucosal plexus on week 14. It is fully developed by week 22[13] or 23.[14] Both the vagus nerves and the sympathetic paravertebral chains are of neural crest origin, and their development parallels that of the intramural innervation.

The diaphragm is functionally related to the distal esophagus: The stomach and a part of the esophagus are located below the diaphragm, whereas most of the organ remains intrathoracic. Parts of the muscle fibers of the diaphragm have truncal mesodermal origin, and some are originally cervical.[15,16] The central tendon and other connective structures derive from the posthepatic mesenchymal plate that contributes to the closure of the pleuroperitoneal canals.[17]

## Anatomy

The upper end of the esophagus is in continuity with the pharynx. Its muscle fibers fuse with those of the cricopharyngeal muscle, the lower portion of the inferior pharyngeal constrictor that acts as an upper esophageal sphincter (UES). The esophageal body is located into the posterior mediastinum in close contact with the spine posteriorly, with the trachea and heart anteriorly, and with both pleural spaces on the sides. The vagal trunks run and branch on the surface of the esophagus. Esophageal length ranges from 10 cm in the newborn to 35 to 40 cm in adults. The lower end of the esophagus traverses the hiatus to become intra-abdominal before joining the stomach. On this end there is no distinct sphincter, but the circular fibers adopt at the gastroesophageal junction a horizontal U shape on the right side (clasp fibers), whereas on the left side they arrange themselves in another U-shaped structure that overrides the gastric incisura extending downward on the anterior and posterior faces of the stomach (sling fibers).[18] The diaphragmatic sling that forms the hiatus departing from the right crus overlaps the distal esophagus and the sphincter. Its striated fibers are closely attached to the esophagus separating the thoracic space lined by pleura from the abdominal one lined by peritoneum. These structures constitute altogether a zone of high pressure in which the lower esophageal sphincter (LES) and the crural sling are the main functional structures. In contrast with other segments of the gastrointestinal tract, the esophagus is devoid of serosal layer, although it is in part in close contact laterally with the right and left mediastinal pleurae in the thorax and anteriorly with the peritoneum in its short intra-abdominal portion. The muscle layers are quite similar to those of the intestine except for the nature of the muscle fibers, which are striated in the upper third and smooth for the remaining extent of the organ.

The intermuscular and submucosal plexuses contain ganglion cells connected among themselves and with the parasympathetic vagi and recurrent nerves, thoracic sympathetic trunks, and celiac plexus by a dense fibrillar network. The respective cholinergic and adrenergic mediators exert respectively positive and negative motor influences on the organ. Relaxation is mediated by nitrergic nerve endings that have their neurons in the intramural plexuses.[19] The c kit-positive interstitial cells of Cajal are distributed among the muscle fibers, where they may play a pacemaker role.[20–23] The extent to which these cells are related to neural control is not fully clear yet.[24]

## Physiology

The function of the esophagus is the transport of the alimentary bolus from the pharynx to the stomach. Secondarily, this organ takes in charge the clearance of the fluid that eventually refluxes from the stomach.

As a mechanism to avoid the invasion of the larynx by digestive juices and the insufflation of the esophagus by air during inspiration, the UES keeps a permanent tone that only relaxes during deglutition, when the glottis is closed and respiration ceases.[25] On the other hand, the unfavorable pressure conditions imposed on the esophagus by its intrathoracic location require permanent closure of the distal end to prevent reflux. This function is ensured by the LES, which also maintains its permanent tone except during deglutition.[26] The balance between the cholinergic and the nitrergic mediators regulates the permanent closure of the sphincter and its relaxations.[27]

The intrathoracic location of most of the esophagus and the intra-abdominal location of the stomach maintain an abdomino-thoracic pressure gradient. The intermittent negative inspiratory thoracic pressures coupled with the permanently positive abdominal pressures thus tend to push the gastric contents back into the esophagus.[28] The resting tone of the LES opposes this gradient assisted by the rhythmic contractions of the diaphragmatic crural sling, which further close the lumen during inspiration. At this moment the unfavorable gradient is more powerful and the sling displaces the cardia downward, accentuating the angle of His and lengthening the intra-abdominal segment of the esophagus.[29] The synergic play of these smooth and striated muscular structures has been extensively studied in animals[30–32] and bears some resemblance with the mechanism of anorectal continence in which the permanent resting tone is provided by the internal sphincter, and the intermittently required additional closure is achieved by voluntary contraction of the striated muscle complex and the external sphincter.

Deglutition is only possible if the upper and lower esophageal sphincters relax. This happens whenever the pharyngeal muscles mount a propulsive wave, and relaxation lasts until the peristalsis of the esophageal body triggered by pharyngeal contractions reaches the lower end of the organ. In order to effect these propulsive waves, the muscles of the esophagus contract in a coordinated craniocaudal manner progressing along the entire length of the organ to push the esophageal contents into the stomach. These are *"primary"* waves. Normal muscle layers and neural control are necessary for achieving this complex function, and motor disorders of the esophagus are likely the result of their anomalies.

Reflux is the retrograde passage of gastric contents into the esophagus and it is to a certain extent normal because the permanent tone of the LES fails several times every day, particularly during meals, allowing the permanent gastroesophageal pressure gradient to push gastric juice backwards. This sphincter may be permanently insufficient in some patients, particularly in neurologically impaired ones,[33] but it is presently acknowledged that most episodes of reflux in adults and children are due to nondeglutitory extemporaneous relaxations of the sphincter.[26,34,35] During these relaxations, the esophageal lumen is invaded by acid gastric juice. The mucosa is not prepared for this insult, and it has to clear this fluid promptly in order to avoid permanent damage. For this purpose the esophagus mounts peristaltic contractions that may be independent of deglutition, that arise at different levels of the organ and that are progressive and therefore able to force the refluxed material back into the stomach. These are *"secondary"* waves[36] aimed at clearing the esophagus of the bulk of the refluxed fluid. Complete clearance is only achieved after several swallows of alkaline saliva with some help from the alkaline secretion of esophageal glands.[37,38] The normal esophagus may also produce a limited number of simultaneous nonpropulsive motor waves that close the lumen along its entire length. These are known as *"tertiary"* waves, and when they are too frequent they contribute to some of the motor disturbances of the esophagus.[39–43]

## Methods Used for Evaluating Esophageal Function

For many years the barium swallow has been the main tool for investigating the esophagus. It shows not only anatomic anomalies of the organ but also abnormal contractility and relaxation of the upper or lower esophageal sphincters. However, irradiation is unavoidable if prolonged assessment is required and this has progressively limited its use. This method remains necessary for some of the conditions alluded to in this chapter, as we show later.

Scintigraphy with liquid or solid radionuclide-tagged meals has helped to clarify the normal mechanisms of esophageal clearance and is useful for assessing esophageal transit and esophageal and gastric emptying. However, it is of relatively limited use in children.[44–47]

Endoscopy with suitable fiberscopes allows direct inspection of the esophageal lumen and mucosa. Some contractility disorders may be detected by this procedure, but its main usefulness resides in the information obtained by inspection and biopsy of the mucosa. Some of the functional disorders are related to esophagitis and this can be adequately detected by endoscopy and biopsy.

Extended pH-metry is primarily intended to quantitate the extent of acid exposure of the esophagus. Because there is a clear correlation between the motor function and the clearance capacity of the organ, the information gained by pH probes may be crucial for understanding some of the motor disturbances.[34,44,48–50]

Manometry is the main tool for examining the motor function of the esophagus. This procedure is based on the principle of Pascal that states that the pressures exerted on any point of a liquid are transmitted in all directions with similar strength. Using tip-occluded probes with lateral holes perfused at constant rates, the pressure at any point of the esophageal lumen can be recorded through pressure transducers connected in a "T" to the perfusion system. Assemblies of several probes with spaced holes can explore the progression of pressure waves along the organ (Fig. 72-1).[34,35,40,50–60] Solid-state sensors can replace the perfused probes, but their fragility and high cost limit their use.

Manometry is also helpful for assessing the sphincteric function. Using one single perfused probe or assemblies of several of them with radially arranged orifices and withdrawing the recording orifices at a constant speed through the gastroesophageal junction allows recording of the pressure profile of both the UES and LES.[35,40,52,61,62] For the LES the profile shows the gastric pressure followed by a "plateau" corresponding to the overlapping LES pressure and the crural sling contractions.[63] Furthermore, it allows detection of the point at which the esophagus becomes intrathoracic because there is an "inversion point" at which the positive pressure inspiratory deflections become negative (Fig. 72-2). Stationary sphincter manometry with one of the orifices at the sphincteric level allows detection and assessment of the extent of relaxation.

However, because it was understood that reflux is possible with normal sphincteric pressures, more attention was paid to relaxations; therefore continuous sphincteric recording probes with constantly perfused sleeves located at the appropriate level were developed.[26,34,35,64,65] This, coupled with the availability of fine extruded Silastic probes, has permitted the study of gastroesophageal physiology in small and premature babies during relatively long periods of time.[66,67]

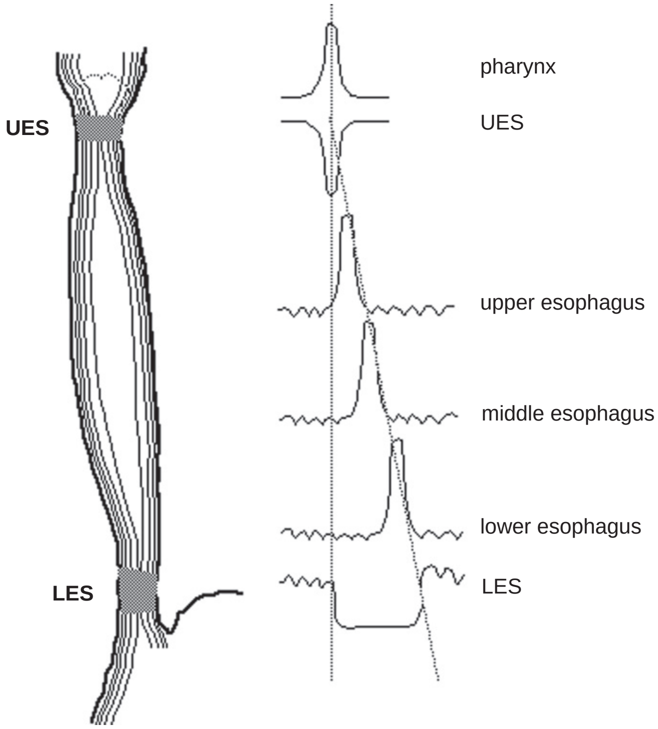

**FIGURE 72-1** Schematic drawing of the pressures recorded manometrically within the lumen of the esophagus during deglutition. Contraction of the pharyngeal constrictors is accompanied by relaxation of the cricopharyngeal muscle or upper esophageal sphincter (UES). Progressive peristaltic waves are generated in the body of the esophagus. The lower esophageal sphincter (LES) remains relaxed during the entire process and closes subsequently with a postrelaxation peak.

Manometry requires bulky, expensive, and delicate equipment and some collaboration on the side of the patient that may be difficult to obtain in children in whom sedation might change the registered pressures.[68,69] High-resolution manometry could provide more detailed data on esophageal motor function in children.[70]

The recently introduced 24-hour ambulatory manometry coupled with pH-metry generated important information on several esophageal disorders in adults and also in children.[71–80] However, the size of the solid-state sensor probes and the bulk of the equipment have limited these tests to older children for the moment.[43,50,59,81] These techniques benefit from the development of extended recording of pressures or pH, reduced to electrical signals that can be analyzed and measured with the assistance of purposefully designed software. It is likely that these diagnostic tools will be further miniaturized and adapted to children in the near future, thus enlarging the scope of manometric studies.

The more recent tool available for the assessment of esophageal function is multichannel intraluminal impedance (MII) coupled with manometry and/or pH-metry.[82,83] Changes in esophageal width cause proportional changes in luminal impedance and, with the assistance of several electrodes and adequate storing systems, a long-duration recording is possible. MII allows sequential analysis of the impedance variations caused by the passage of gas or liquid in either

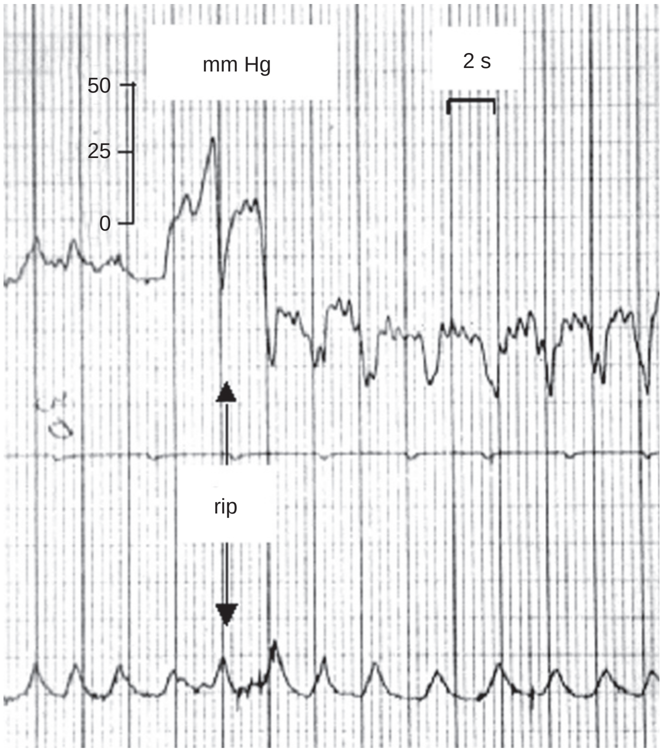

FIGURE 72-2 Pull-through manometric recording of the lower esophageal sphincter (LES) in a normal child (*upper tracing*) with simultaneous recording of the abdominal pressures (*lower tracing*). Intragastric pressures are first recorded with positive inspiratory deflections. A "plateau" corresponds to the high pressure zone of the LES. When the probe enters the thoracic esophagus, intraluminal inspiratory deflections become negative (respiratory inversion point, rip). From then on the pressure baseline is lower and the inspirations are recorded by negative waves. Withdrawal speed is 1 mm/sec, and time between vertical marks is 2 seconds.

direction. Reflux detection is possible and, when the measurements are coupled with pH recordings, its acid or nonacid nature can be ascertained. Furthermore, MII allows assessment of deglutition and esophageal motor activity (Fig. 72-3).

However, there are several limitations for the use of MII: Although this procedure sheds light on the little known field of nonacid or alkaline reflux, analysis of 24-hour tracings requires ample expertise and specialist time that considerably limit its use. Computer-assisted analysis has been used for reflux studies, but little has been done in terms of esophageal function investigation.[84–91] Furthermore, these limitations are even greater in children because of size, the need for patient cooperation, and the ethical restraints for establishing baseline control values, which also apply to other invasive functional tests in children.

# Disorders of the Upper Esophagus

The cricopharyngeus occasionally fails to maintain its permanent tonus or to relax during deglutition. This leads to difficult swallowing and consequent choking that may threaten life during early infancy.

Permanent *cricopharyngeal relaxation* is sometimes seen in neurologically impaired patients who undergo repeated episodes of aspiration.[92] *Delayed* or *incomplete relaxation* may be observed in children with Chiari syndrome,[93,94] 22q11.2 deletion,[95] or after diazepam medication.[96] Absence of relaxation *(cricopharyngeal achalasia)* occurs rarely as a primary phenomenon or secondary to neuromuscular disorders.[92,97] In all these conditions the leading symptoms are choking during feeding and respiratory distress during early infancy, which may prompt urgent diagnostic workup. Barium meal or cineradiography depicts simultaneous opacification of the respiratory and digestive tracts in cases of permanent relaxation and dilated pharynx with permanent upper esophageal closure and occasional passage of contrast into the trachea in cases of delayed or absent relaxation.[97,98]

Manometry is useful for the diagnosis of cricopharyngeal disorders because it shows the incompleteness or absence of relaxation of the muscle during deglutition.[92,93,99,100] However, it is particularly difficult to perform in infants because the use of perfused catheters in the upper esophagus is unpleasant for the baby who chokes, coughs, and does not collaborate. Recordings with sphincteric sleeves depict better the lack of relaxation with less risk of fluid aspiration.[101]

Gastrostomy may be necessary for feeding babies with permanent cricopharyngeal relaxation and also in those with UES achalasia.[94,102] Achalasia of the muscle can be treated by balloon dilatation,[103–105] but extramucosal myotomy is more effective.[99,106] If reflux is present, a concurrent fundoplication should be considered because insufficiency of both the upper and lower esophageal closure mechanisms may be devastating.[107] Some nonspecific histologic changes of the muscle obtained during myotomy have been reported in cricopharyngeal achalasia.[108]

# Disorders of Esophageal Body

## PRIMARY MOTOR DISORDERS

Abnormal motility of the body of the esophagus is a frequent cause of symptoms in adults in whom *diffuse esophageal spasm*,[72,109–112] *nutcracker esophagus*,[113,114] or other abnormal motor patterns impairing the propulsion of the bolus are occasionally diagnosed after investigation for dysphagia, noncardiac chest pain, or suspected reflux. Simultaneous, nonpropulsive contractions or an excessive proportion of long-duration waves alternating with normal ones are found in the first of these conditions, whereas extremely powerful, high-amplitude waves that can be peristaltic or retrograde are demonstrated in the second one.[72,76,115] Nutcracker esophagus has been seen to evolve into achalasia.[116]

Manometry is the main diagnostic tool, and its accuracy has improved considerably since 24-hour ambulatory recordings became available because the disturbances may not be permanent and appear only occasionally at some point of the circadian cycle. Because of the difficulties of performing this procedure in children, primary motor disorders of the esophageal body were practically unheard of in them until recently, although apnea, bradycardia,[117] and bizarre posturing[118] had been considered as expressions of motor disturbances. However, introduction of better manometric techniques produced growing evidence of their existence at this age. Food impaction in the absence of stenosis has been found in association with manometric patterns similar to those of adult nutcracker esophagus (Fig. 72-4), but this

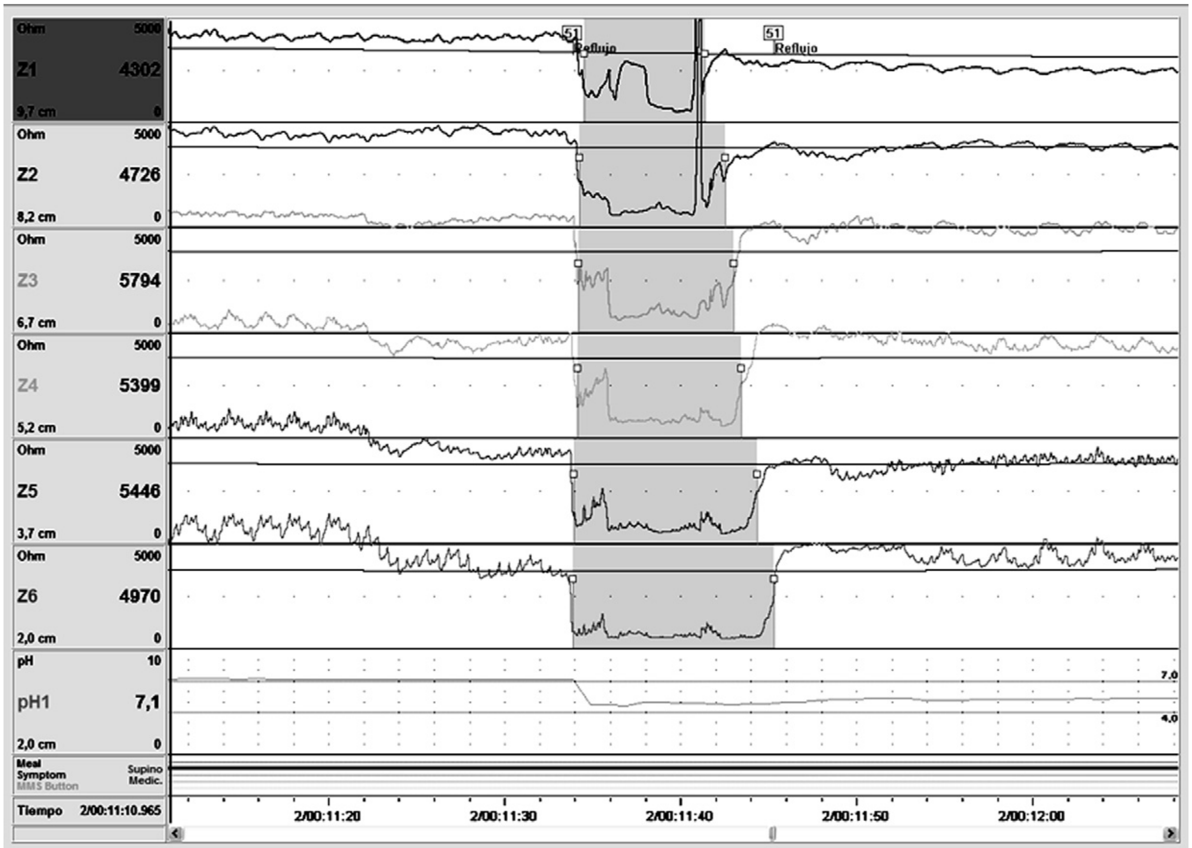

**FIGURE 72-3** Multichannel intraluminal impedance (MII) tracing in a 6-year-old child with gastroesophageal reflux. The lower pH tracing reveals a pH fall that unchains a retrograde fall of impedance revealing increased esophageal lumen width (reflux episode). Shortly after, the baseline width is nearly recovered in an antegrade sequence revealing swallowing. However, this event does not clear completely the refluxed acid because the pH tracing does not come back to normal. Using a pH of 4 as a threshold for defining reflux, this episode would have been disregarded. With this technique, it is considered as a weakly acidic reflux episode.

disorder might not be primary because most patients have either reflux[58,59,119,120] or eosinophilic esophagitis.[121,122]

Pharmacologic treatment of primary motor disorders with prokinetics or calcium channel blockers[123,124] is rarely indicated in children with these conditions.[125] Sildenafil, a drug that helps to induce NO-related relaxation of the esophageal body and LES, has been introduced for the treatment of motor disorders in adults,[126–128] but it has not been used in children until now. Balloon dilatation or extended myotomy, procedures occasionally used in adults, have not been used in children.

## SECONDARY MOTOR DISORDERS

Abnormal esophageal motility has been demonstrated in several syndromes and chromosomal disorders: Damaged peristalsis sometimes associated with reflux was found in children with both *Down syndrome*[129–131] and *Cornelia de Lange syndrome*.[132–136] *Scleroderma*,[137–139] *polymyositis-dermatomyositis*,[140] and *lupus*,[141] which are well-known causes of esophageal dysmotility in adults, may rarely start during childhood. *Babies breast-fed by mothers with silicone implants*[142] may also undergo esophageal motor disturbances similar to those of scleroderma.

**FIGURE 72-4** Nocturnal ambulatory manometric recording of intraluminal lower esophageal pH (1) and upper (4), middle (5), and lower (6) esophageal pressures in a 10-year-old boy with recurrent episodes of nonobstructive food impaction. The tracing demonstrates a pattern of nutcracker esophagus with long-duration, apparently peristaltic waves that are extremely powerful, particularly at the lower end of esophageal body (>200 mm Hg or 3 to 4 times above normal). This happens during sleep and without reflux, as seen in the pH tracing.

More relevant for pediatric surgeons are the motor disturbances of the esophagus suffered by survivors of neonatal operations for *esophageal atresia with or without tracheoesophageal fistula*.[47,143–147] In this malformation the structure of the muscle layers[148] and the abnormal extrinsic[149,150] and intrinsic[151,152] innervations impair the peristaltic pump for life. This is particularly harmful in this condition in which the function of the LES is also abnormal because both failures make gastroesophageal reflux (GER) a nearly constant part of the disease independently of the type of repair.[61,153] In addition, esophageal shortening due to the neonatal anastomosis,[154] abnormal hiatus,[155] and perhaps operative denervation may influence dysmotility. Many studies demonstrated that the LES function is abnormal in survivors of neonatal operations for esophageal atresia,[61,146] and some others showed that peristalsis is permanently damaged even many years after the anastomosis.[60,89,144,147,156,157] The clinical relevance of these disorders is probably greater than it was previously thought. Patients operated on for esophageal atresia have swallowing problems that are perceived by them as minor but that are almost constant when specifically searched for.[144,158] Their esophagus cannot fight reflux and, because of the structural basis of these dysfunctions, not much benefit can be expected from prokinetic medication. Furthermore, the spontaneous improvement of reflux with age that is part of the natural history of the disease in children cannot be expected in patients operated on for esophageal atresia, whether by thoracotomy or through a minimally invasive approach.[159]

GER should be treated in patients with esophageal atresia when it is symptomatic and/or when it causes esophagitis. Dysmotility, a constant problem with this malformation, does not preclude a complete fundoplication, which should be loose. Gravity is probably the main esophageal emptying force before or after the plication and there should be no problem if the wrap is loose enough. However, the proportion of long-term failures of the plication is high in this group of patients because all the causes of GER and dysmotility remain active in spite of the new valve.[160,161]

Other conditions relevant to pediatric surgeons involve esophageal motor disorders: *chronic intestinal pseudoobstruction,* a heterogeneous group of gastrointestinal dysfunctions with myogenic or neural basis, is characterized by distal esophageal dysmotility with simultaneous, short-lasting, low-amplitude waves[162–164] that may help in the diagnosis. However, dysmotility is widespread and the esophageal part is not the most significant.[165] Patients with *Hirschsprung disease* have simultaneous and double-peaked esophageal waves,[166] and children with *congenital central hypoventilation syndrome*[167] or *Goldenhar syndrome*[168] also have dysmotility. Survivors of neonatal operations for *congenital diaphragmatic hernia* have radiologic and clinical evidence of abnormal esophageal motor function[157,169–172] that might be related to innervation anomalies.[173] Esophageal dysfunction involving lowered sphincteric pressures or abnormal distal esophageal contractility has been described in children with *chronic renal failure*,[174] *Noonan syndrome*,[175] and *Pierre-Robin sequence*.[176] The same anomalies were found in adults with *celiac disease*.[177] A number of children with this disease also have eosinophilic esophagitis, and this could explain the esophageal disturbances.[178]

Children with *corrosive injuries* of the esophagus have impaired peristaltic activity both in the acute postinjury period[179] and when scars are established.[180] These manometric findings were confirmed by radionuclide[181] and combined studies.[182] The contribution of dysmotility to the clinical course and prognosis in this condition is still unclear, although it is believed that secondary esophagitis aggravates them.

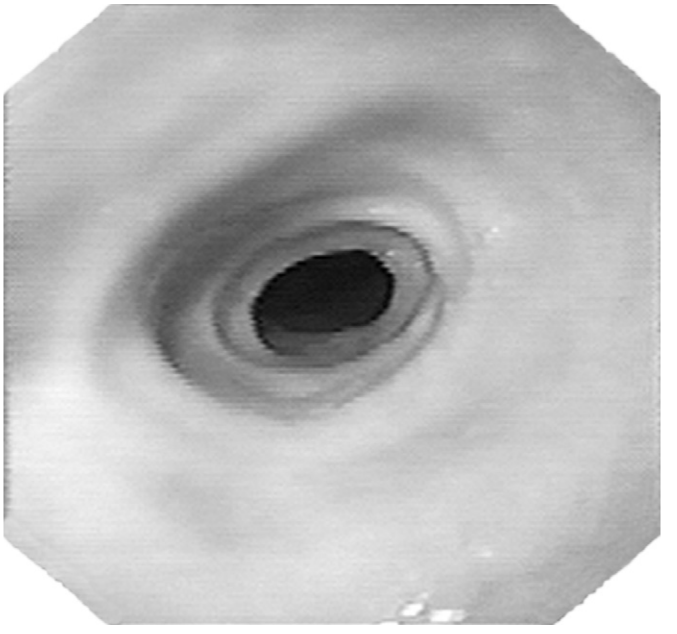

**FIGURE 72-5** Typical "multiple-ring" pattern of the esophagus on fiberoptic endoscopy in an 11-year-old girl with dysphagia due to eosinophilic esophagitis. On biopsy the mucosa was heavily infiltrated with eosinophils. pH-metry was normal, and the patient did well after a course of treatment with steroids.

In the past few years we have treated a growing number of patients with *eosinophilic esophagitis,* a condition of probably allergic origin in which there are symptoms of reflux or food impaction.[121,183–186] Reflux and stenosis are usually ruled out, and a typical aspect of Schatzki ring[187] or multiple rings[188] is seen on endoscopy (Fig. 72-5); heavy infiltration of the mucosa by eosinophils is found on biopsy, particularly with the Luna eosinophil granule stain.[189] Strictures are rarely observed in eosinophilic esophagitis, and they respond to treatment.[190,191] Dilatations may be indicated even in cases of severe dysphagia without stenosis.[192] Eosinophilic esophagitis has been seen in patients previously operated on for esophageal atresia in whom reflux is common.[193] Oral corticosteroids,[183] fluticasone,[194,195] and eosinophil stabilizers like montelukast[196,197] are usually helpful in the management of this condition.[190] However, there seems to be a dissociation between the symptoms and the histologic findings during treatment.[198]

## Disorders of the Distal Esophagus

*Primary gastroesophageal reflux* involves both the failure of the gastroesophageal barrier and abnormal esophageal motility. The causes for the sphincteric failure are not completely understood, but there is increasing evidence of prolonged nondeglutitory relaxations as the main mechanism.[26,34,35] They permit the creation of a "common cavity" phenomenon

that allows the full action of the untoward gastroesophageal pressure gradients between the stomach and the esophagus. The gastric fluid refluxed into the esophagus must be pushed back to the stomach by peristalsis, but this second defensive mechanism is also damaged with the consequent risk of esophagitis. The proportion of peristaltic contractions after deglutition or reflux and the amplitude of the waves are decreased, particularly at the lower end of the organ.[40,43,57] Whether dysmotility in gastroesophageal reflux disease is a primary phenomenon or secondary to esophageal inflammation is unclear. There are solid clinical and experimental arguments to maintain that chronic esophagitis damages previously healthy peristalsis,[199,200] but at least in some cases motor function remains abnormal even after medical or surgical cure of reflux and esophagitis.[40,51,199,201,202]

The success of prokinetic treatment used extensively in the past decades illustrates the relevance of the dysmotility in GER disease. These drugs act by reinforcing the failing sphincter, hastening gastric emptying, and improving peristalsis.

The more characteristic motor disorder of the lower end of the esophagus is *achalasia* in which the LES is hypertonic and does not relax during deglutition. In addition, in part by dilatation of the esophagus and also because of primary hypoperistalsis, its propulsive function is totally ineffective. This condition is rare in young children and, although some cases have early onset, most are diagnosed in late childhood or early adolescence. Only a few pediatric studies include more than a limited number of cases,[81,203–210] and the largest multicenter series involves only 175 cases.[211]

The cause of achalasia is unknown, but there is increasing evidence of a progressive disturbance of the intrinsic innervation with reduced or absent nitric oxide synthase (NOS) activity.[19,23] This enzyme is in charge of synthesizing NO, the nonadrenergic-noncholinergic neurotransmitter of smooth muscle relaxation.[19] nNOS(−/−) mice with nitric oxide synthase disruption have hypertensive, nonrelaxing LESs.[212] Recent evidence indicates a correlation between paucity of c-kit positive interstitial cells of Cajal and depletion of neuronal nitric oxide synthase (N-NOS) immunoreactivity in the esophagus of patients with achalasia showing that these cells are in some way related to relaxation.[213] The progressive degeneration of the intrinsic innervation has some bearing with that seen in Chagas' disease, a South American parasitic condition caused by *Trypanosoma cruzi* that causes degeneration of the neural structures leading to megaesophagus[214,215] and abnormal esophageal function. However, in Chagas' disease the pressures in the LES are not increased but rather reduced.[216]

Achalasia may be associated with Allgrove syndrome, an autosomal recessive familial condition[217] caused by a mutation of the AAAS gene on chromosome 12q13[218–223] in which, in addition to the esophageal motor dysfunction, there are adrenocortical insufficiency and alacrima. This association is also addressed as ALADIN syndrome (alacrima, achalasia, adrenal insufficiency, and neurologic disorder).[224] Achalasia is more frequent in boys and is occasionally associated with Down syndrome.[130,131,225]

Achalasia patients complain of progressive dysphagia and regurgitation of food retained in the esophagus that should not be confounded with vomiting. Some have retrosternal pain that may become distressing. They lose weight and often have foul breath and respiratory symptoms like nocturnal cough or repeated pneumonia due to frequent microaspiration.[208,226,227] In cases of Allgrove syndrome there are also symptoms of adrenocortical insufficiency such as progressive pigmentation and asthenia and eventually absence of tears (alacrima), but these symptoms and other manifestations of neurologic disease[224] may appear later after the full clinical picture of achalasia has developed.

Barium meal is often diagnostic: The esophagus is large (megaesophagus) and contains stagnant fluid above the barium column. There is a marked aperistalsis and the esophagogastric junction is filiform, adopting a classical "bird's beak" shape.[208] The contrast progresses into the stomach after a long time, and most of it is retained in the esophagus for hours (Fig. 72-6). Radionuclide scintigraphy may depict the lack of progression of the esophageal content and allows more prolonged observation with less irradiation, but it is less informative of the shape of the distal esophagus.[130,228]

Fiberoptic endoscopy rules out the presence of stricture, and the instrument can be advanced in the stomach with relative ease. After suctioning of the retained fluid, a picture of esophagitis may be seen but it is secondary to fermentation of the stagnant fluid. pH-metry is not useful at this stage and can be misleading because this fluid is often acid and the probe reading may suggest GER, which is in fact impossible.

Manometry is the best diagnostic tool for achalasia: The sphincter is hypertonic and does not relax or does it incompletely during deglutition. The esophageal peristalsis is absent and the scarce contractions present, particularly during meals, are recorded simultaneously at all points of the lumen, which is in fact a common chamber (Fig. 72-7).[70,203,207] Twenty-four-hour ambulatory recordings performed with probes equipped with multiple solid-state sensors show that the aperistalsis is constant along the entire circadian cycle

**FIGURE 72-6** Barium meal in a 9-year-old patient with achalasia. The esophagus is enlarged and contained stagnant fluid before the contrast was given. Emptying is slow and the cardia has a typical pattern of "carrot" or "bird's beak" (*left*). Some feeble esophageal contractions are seen (*right*), but peristalsis is impossible because the esophageal walls remain widely separated.

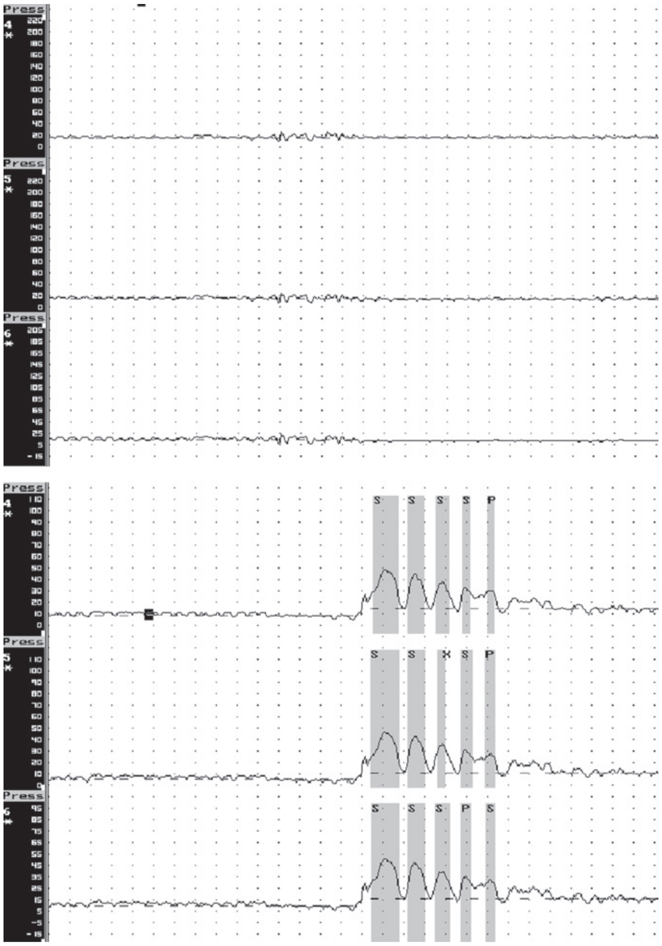

**FIGURE 72-7** Ambulatory esophageal manometry in an 8-year-old boy with achalasia. In the upper picture, the pressures at the upper (4), middle (5), and lower (6) levels of the esophagus are identical and no waves are seen. In the lower picture, corresponding to a meal, some waves are generated but they are simultaneous and nonpropulsive (time between vertical marks, 5 seconds).

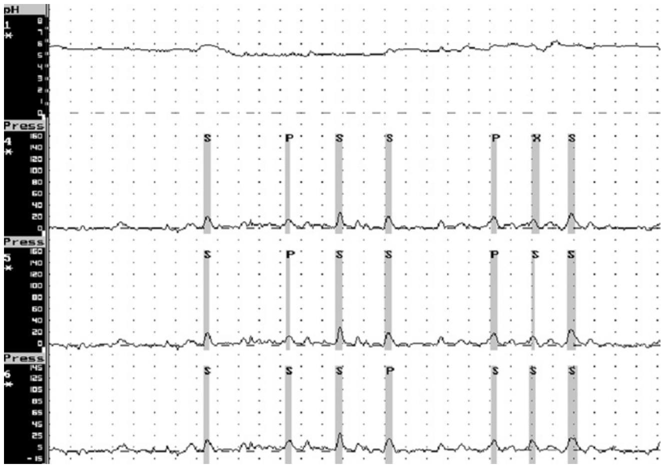

**FIGURE 72-8** Ambulatory esophageal manometry during meal in a 24-year-old woman 12 years after Heller myotomy for achalasia. She was asymptomatic, but esophageal motility remained poor. The motor waves at the upper (4), middle (5), and lower (6) levels of the esophagus showed peristaltic organization, but they were weak (<25 mm Hg, roughly half the normal). Time between vertical marks is 5 seconds.

including meals, when motor waves are normally more active.[81] Impedance studies confirmed and reinforced these data.[83]

The differential diagnosis includes extrinsic and intrinsic causes; in the latter group, acquired strictures and congenital stenosis from tracheobronchial remnants are usually easily eliminated by endoscopy. Leiomyomas and leiomyomatosis, either isolated or as part of Alport syndrome (hereditary X-linked nephropathy and deafness), may be suspected on endoscopy but require cross-sectional imaging with computed tomography or magnetic resonance imaging for confirmation.[228a]

Medication, particularly calcium channel blockers such as nifedipine, may alleviate the spasm in some cases,[229] but they cannot be relied on as a long-term treatment in children with achalasia.[124] Forceful balloon dilatation of the distal esophagus is often successful in adults, but this modality of treatment has not brought permanent relief in children,[203,204,230] although some favorable results were reported,[209,231] particularly older than the age of 6.[232] The local injection of botulinum toxin has been also tried in children, but its success has been limited as well.[226,233–236] Like in adults,[237] extramucosal Heller myotomy remains the best treatment at this age and it can be performed through either the thorax or the abdomen.[81,203,204,207,208,211,238] Perioperative lower esophageal manometry[239] or endoscopy[240] may ensure the completeness of the myotomy. An abdominal approach probably allows for a more complete myotomy on the gastric side and facilitates fundoplication. In fact, if sought after, reflux is rather constant after Heller myotomy and some form of fundoplication is probably indicated in children, whose long life expectancy after the operation supports the use of this procedure to prevent complications of GER.[81,204,206,207,226,241,242] A Nissen procedure may be inadequate due to the often large diameter of the thickened esophagus; the posterior Toupet or anterior Thal-Dor hemifundoplications are preferred.[81,207,242] Some authors prefer to omit antireflux procedures in these patients.[209,243] All these procedures can be performed laparoscopically, and this approach has become the gold standard.[209,238,242,244–247]

Postoperatively patients are relieved of their symptoms at once and they can feed properly and regain weight. However, the esophagus remains dilated for months or even years and its function only rarely returns to normal. Most patients maintain scarce and ineffective peristalsis in spite of the decrease in sphincteric pressure provided by myotomy (Fig. 72-8).[81,204,241,248,249] Some patients continue to have minor symptoms such as dysphagia and often require a few swallows of water during meals, but surgery brings back a good quality of life. Esophageal replacement has been reported in some rare cases of achalasia in which all other treatments failed.[250,251]

CHAPTER 73

# Gastroesophageal Reflux Disease

Michael E. Höllwarth

The esophagus is a rather simple organ with no digestive features but serves the function of conveying food from the pharynx to the stomach. Gastroesophageal reflux (GER) is the term used to describe the usually undetected backflow of gastric contents into the esophagus, rarely reaching the pharynx or the mouth, and causing regurgitation. It is a physiologic phenomenon and occurs in otherwise normal individuals several times during the day and night, especially postprandial after ingestion of fluids such as soup, tea, coffee, or milk. In healthy individuals a number of mechanisms such as resistance of the esophageal squamous epithelial layer, rapid clearance of the refluxed material by propulsive peristalsis, and buffering of refluxate by swallowed saliva ward off any negative effects of reflux on the esophagus.

Pathologic reflux or gastroesophageal reflux disease (GERD) is a situation in which reflux causes major symptoms and complications such as failure to thrive, disturbance of sleep, recurrent aspiration in very young infants, epigastric or retrosternal pain, heartburn, esophagitis, stenosis, or Barrett esophagus in older children. Problems concerning esophageal function and reflux disease have been extensively investigated, as evidenced by the 300 to 400 reports published each year. Epidemiologic data in adults show that approximately 20% of the Western population is affected and GERD is now the most common upper gastrointestinal disorder in the Western world.[1] Risk factors are either genetic (family history, monozygotic twins); demographic (pregnancy, age, body mass index); or behavioral (smoking, alcohol, drug therapy). Recent genetic investigations have shown collagen type III alpha I and the male gender to be risk factors for hiatal hernia.[2] Epidemiologic data concerning the incidence of GERD in children are scarce. According to Vandenplas, troublesome GERD occurs in 5% to 8% of infants.[3] In Italy 313 (12%) of 2642 infants (age range 1 to 12 months) had clinical symptoms of GER, but only 1 of 210 infants followed closely over a period of 24 months developed GERD.[4]

## Esophagogastric Junction

The esophagogastric junction is a complex system that effectively separates the abdominal compartment with its higher pressure from the thoracic compartment with a significantly lower pressure, thereby preventing constant reflux from the stomach to the esophagus. It consists of several structures such as the crura of the diaphragmatic hiatus, the angle of His with the mucosal flutter valve inside the stomach, and the lower esophageal sphincter (LES).

The crural diaphragm forms an oblique slit encircling the esophagus from cranial-ventral to dorsal-caudal and constitutes an external pinchcock mechanism.[5] The medial wall of the esophagus continues directly into the lesser curvature of the stomach while the lateral wall forms with the stomach a type of incisure—the so-called angle of His. Oblique muscle fibers of the stomach, located below the LES, are arranged in a C-like fashion with the open part toward the lesser curvature.[6] Corresponding to the external anatomy, a mucosal fold (flutter valve) lies within the lumen of the esophagogastric junction. The flutter valve is passively pressed against the end of the lower esophagus when the gastric fundus is filled (Fig. 73-1, *A* and *B*).[7] The flatter the angle of His, the less developed is the valve mechanism and the more readily a reflux occurs.

The LES lies within the diaphragmatic hiatus, which forms a firm tunnel in which the esophagus is secured by the phreno-esophageal membrane. Manometric studies show that its upper portion belongs to the thoracic cavity and its lower portion to the abdominal pressure zone (Fig. 73-2). Under normal circumstances, an abdominal section of the esophagus does not exist. The tone of the LES lies in the range of 12 to 15 to 25 mm Hg not only in adults but also in neonates and infants.[8,9] It is approximately 1 cm long in the newborn and 3 cm long in adults (Table 73-1). The LES maintains its basic tonus but relaxes with the ongoing peristaltic wave of the swallow and closes with a brief increase in tone to 35 or 40 mm Hg. It should be noted that, during propulsive peristalsis, the esophagus exhibits a longitudinal contraction of 3 to 5 cm and the LES moves upwards together with the esophageal body.[10] Thus a sleeve device is necessary to register the pressure of the sphincter over a longer distance in order to demonstrate the true relaxation on manometry.[11] LES tone and relaxation are modulated through the central nervous system via the vagus nerve.[12]

One specific characteristic of the LES is the fact that its tone relaxes through a propulsive peristaltic wave, and transient lower esophageal sphincter relaxations (TLESRs) of 5 to

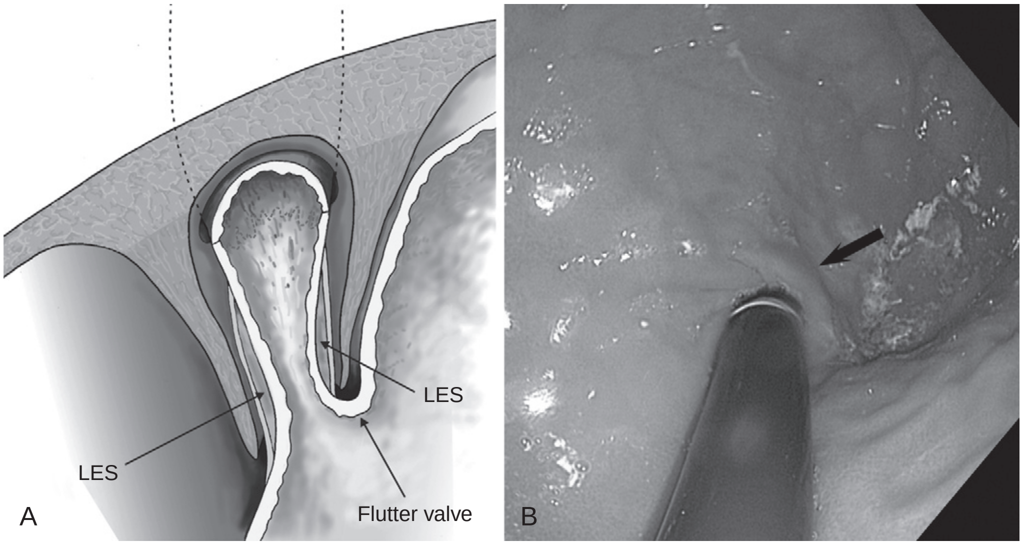

**FIGURE 73-1** **A,** Sketch of the anatomic structures of the esophagogastric junction. **B,** Endoscopic view of the mucosal "flutter valve" at the site of the angle of His. *(See Expert Consult site for color version.)*

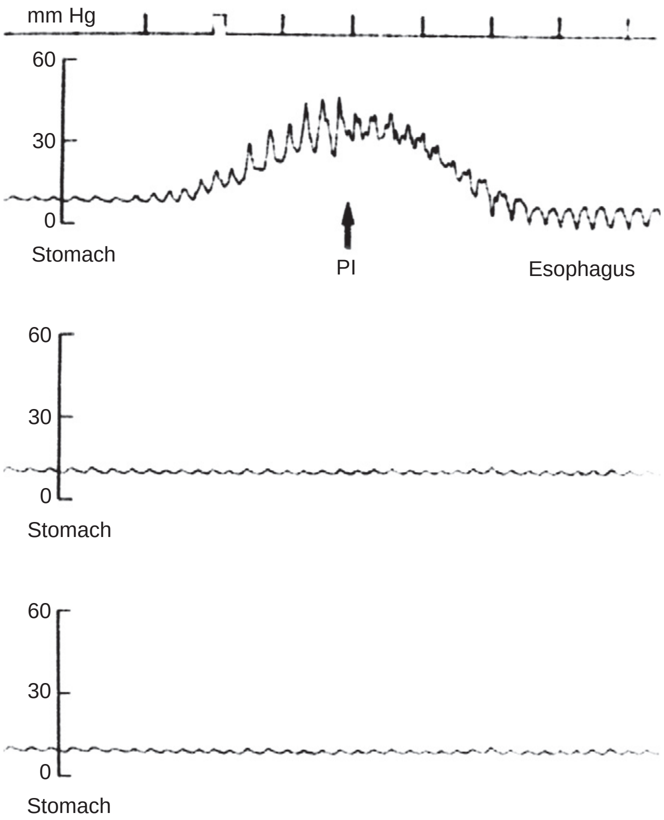

**FIGURE 73-2** Lower esophageal sphincter (LES) during a slow pull-through manometry in a newborn child. The LES lies within the hiatus with one part belonging to the abdomen and the upper part to the thorax. Except for the sphincter, there is no abdominal esophagus. *PI,* Pressure inversion.

30 seconds' duration occur even in the absence of any other esophageal peristalsis in healthy individuals.[13] A common space is created between the stomach and the esophagus and is seen on manometry as a sudden change of the typical esophageal tracing into an abdominal pressure curve, also known as the "common cavity phenomenon" (CCP) (Fig. 73-3).[14] Most of these relaxations remain unrecognized in healthy individuals because the refluxed material only reaches the lower esophagus. The volume is immediately returned to the stomach by a secondary peristalsis (volume clearance). Any drop in pH, however, that might accompany the refluxed gastric contents is neutralized only in a stepwise manner by the alkaline saliva during subsequent acts of deglutition (acid clearance) (Fig. 73-4). Therefore volume clearance is usually rather fast, whereas neutralization of the acidic reflux may take between 30 seconds and several minutes, the latter especially during sleep, because of the reduced frequency of swallowing.

Recent investigations show that nitric oxide is an important intramuscular transmitter for TLESR.[15] Glutamate is a different transmitter that affects the afferent vagal nerve. Its release can be inhibited by γ-aminobutyric acid ($GABA_B$) receptors, which exist on both ends of the neurons—at the gastric mechanoreceptors and the hindbrain control mechanisms—thereby achieving effective inhibition of TLESR.[16,17] Recently, metabotropic glutamate receptor 5 (mGluR5) antagonists were described as further potent inhibitors of TLESR.[18]

## Pathologic Reflux

TLESR is the primary pathophysiologic mechanism in all individuals with GERD. Relaxation is triggered by gastric mechanoreceptors that signal distension to the hindbrain. The latter generates motor signals to the LES and the esophagus via the vagus nerve. Additionally, these signals inhibit selectively the inspiratory contraction of the diaphragm suspending the pinchcock effect of the crura.[19] We have shown that the high incidence of GER in newborns and young infants is not caused by a low tone of the LES but by TLESR. Babies with pathologic reflux experienced more prolonged TLESR with CCP, significantly more often, but their LES pressure was normal (Table 73-2).[8,9] These findings were confirmed later by Omari.[20] Because any ingested fluid triggers TLESR by gastric distension, the largely liquid food (milk) given to infants is another factor that may cause more frequent TLESR.

**TABLE 73-1**
**Lower Esophageal Sphincter Tone and Length in Newborns and Small Infants**

| | n | *Age (days)* | *LES Tone (mm Hg)* $\dot{x} \pm SD$ | *LES Length (mm)* $\dot{x} \pm SD$ | *PS (n = 10)* |

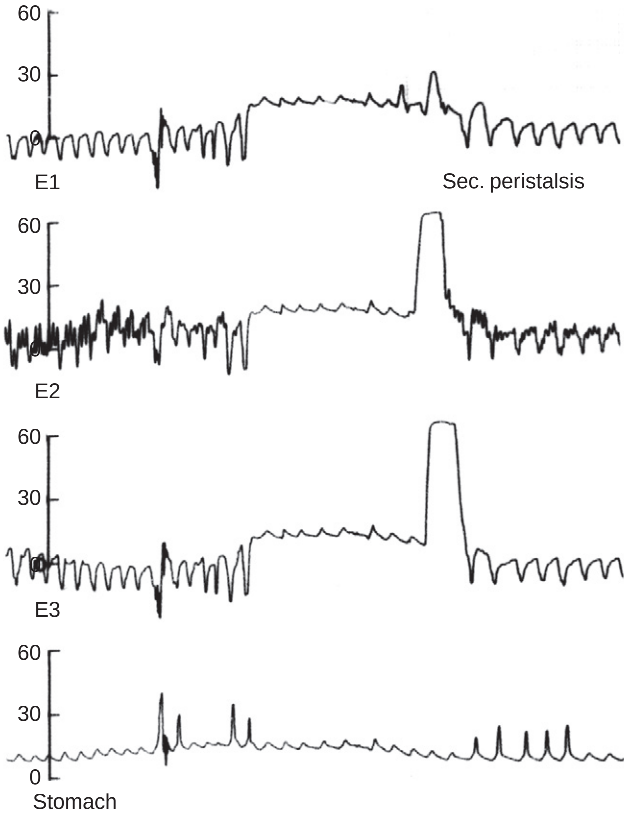

**FIGURE 73-3** Spontaneous pressure inversion of the esophageal tracings to an abdominal tracing indicating the opening of the lower esophageal sphincter due to a transient lower esophageal sphincter relaxation, the manometric "common cavity phenomenon." It is always terminated by a secondary propulsive peristaltic wave generated within the esophagus.

Furthermore, delayed gastric emptying with pathologic TLESR is observed in children with neurologic disorders and may increase the incidence of reflux episodes after a meal.[21] Given these functional disturbances in early infancy, as well as in children with neurologic disorders, we concluded that pathologic reflux may be regarded as a sign of delayed maturation or disturbed coordination of control centers in the hindbrain, disrupting the function of esophageal peristalsis, the LES, and in some patients also gastric motility.

The characteristic symptoms of pathologic reflux in infancy usually disappear at the age of 1 or 2 years. However, we and other authors have found that the disappearance of clinical signs does not necessarily mean that esophageal function has been normalized.[3,22–24] Orenstein studied prospectively a group of infants with histologically proven GERD but with no therapeutic intervention; although GER symptoms resolved in the majority of cases, the histopathologic results revealed a lack of improvement at the 1-year follow-up investigation.[23] Martin showed that infants with significant regurgitation on 90 days or more during their first 2 years had an increased risk of GER symptoms at the age of 9 years.[25] El-Serag interviewed a group of patients suffering from GERD in childhood (mean age, 10 years) to adulthood (mean age, 18 years): At least weekly, symptoms (heartburn or regurgitation) were reported in 46%, 94% of whom were taking proton pump inhibitors (PPIs) or other antisecretory medication. The authors concluded that approximately one half of young adults with a history of childhood GERD needed antisecretory therapy.[26] We recommend a 24-hour follow-up study in infants with a history of GERD even when the symptoms of reflux have disappeared at the age of 1 or 2 years, in order to identify children who still suffer from pathologic reflux. Our clinical experience confirms El-Serag's findings: Any pathologic reflux pattern that is still present at the age of 5 years will persist into adulthood.

## Symptoms of Gastroesophageal Reflux Disease

Mild regurgitation, a flaccid leak-out, or occasional vomiting as a sign of GER may be found in approximately one half of all newborns and young infants mainly fed on milk. The infants' subsequent development shows that the symptoms become less frequent after the first 4 to 6 months and are no longer observed at 12 months, when the child starts to receive solid food. Pathologic reflux at this age may be characterized by frequent regurgitation episodes, effortless leak-out of milk or food after meals, between meals, and when asleep. A moist pillow is another sign of reflux during sleep. Additional symptoms are restless sleep with sudden unexplained wake-up and excessive crying episodes. Reflux-related problems while feeding the baby may significantly disturb the interaction between mother and child.[27] In case of significant vomiting of food, the child may even develop malnutrition and fail to thrive. Further suspicious symptoms are developmental disorders, recurrent respiratory tract infections due to microaspiration, greater irritability, and agitation.[28] However, clinical symptoms in infants are not reliable indicators of GERD and are often poorly correlated with the results of 24-hour pH monitoring or histology.[29,30] Esophagitis is rare in newborns and infants as long as the babies are predominantly fed on milk, because gastric juices are largely buffered during the first 2 hours after feeding and the exposure time to acids is relatively short (Fig. 73-5).

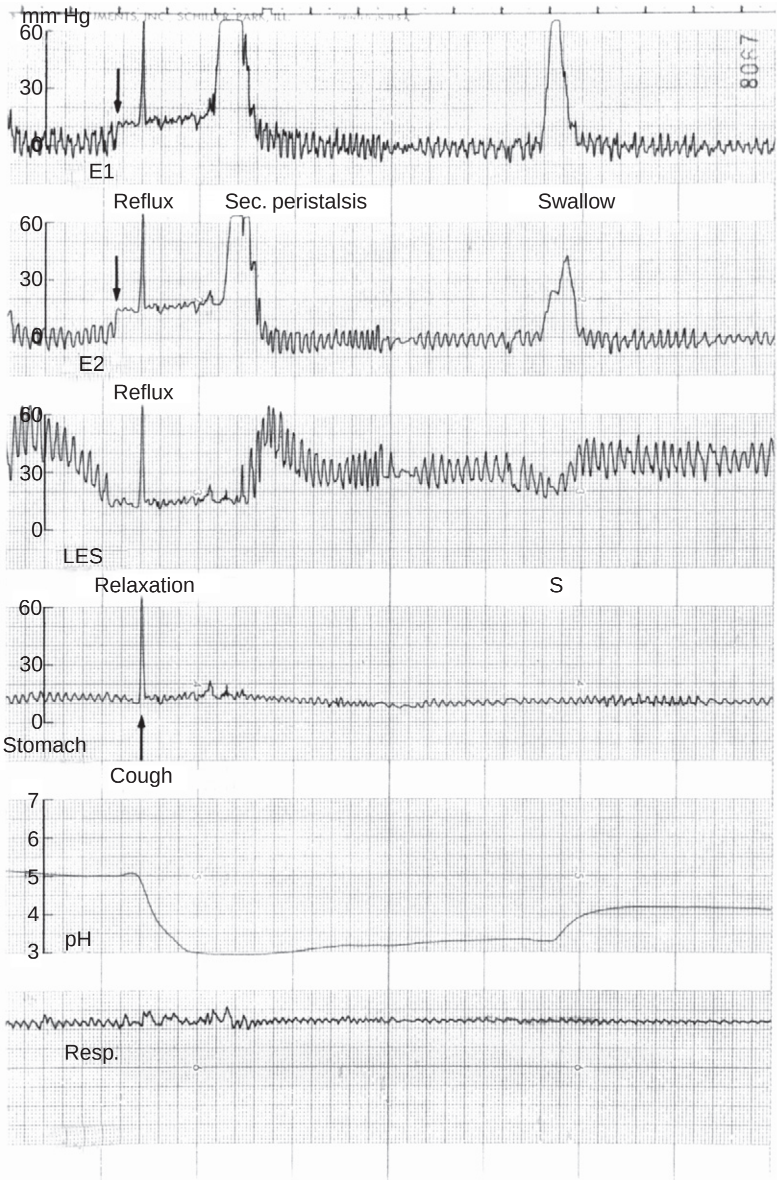

**FIGURE 73-4** Combined manometry and pH monitoring shows a 10-second "common cavity phenomenon" (CCP) with a fall of the pH from 5 to 3 and an increase with the next swallow to nearly pH 4. Note that a short cough during CCP indicates that reflux probably reached the pharynx and larynx.

**TABLE 73-2**

*Infants with pathologic reflux have a normal LES tone comparable with normal controls, indicating that the pathologic mechanism is not a weak LES pressure but a disturbed function with too many and too lengthy transient lower esophageal sphincter relaxations (TLESRs) indicated by more and longer CCPs ($P < 0.05$ compared with controls).

Apnea and sudden infant death syndrome (SIDS) are the most common causes of death between the age of 2 and 6 months. The association between reflux and apneic spells has been investigated with unequivocal results. There is no evidence that the typical apneic spells and near-miss events in infants between the ages of 2 and 6 months are caused by reflux events.[31,32] Although preterm infants had a higher rate of GER after feeding, a corresponding increase in apneic spells was not registered. In contrast, Wenzl showed a correlation between apnea and reflux in infants using the

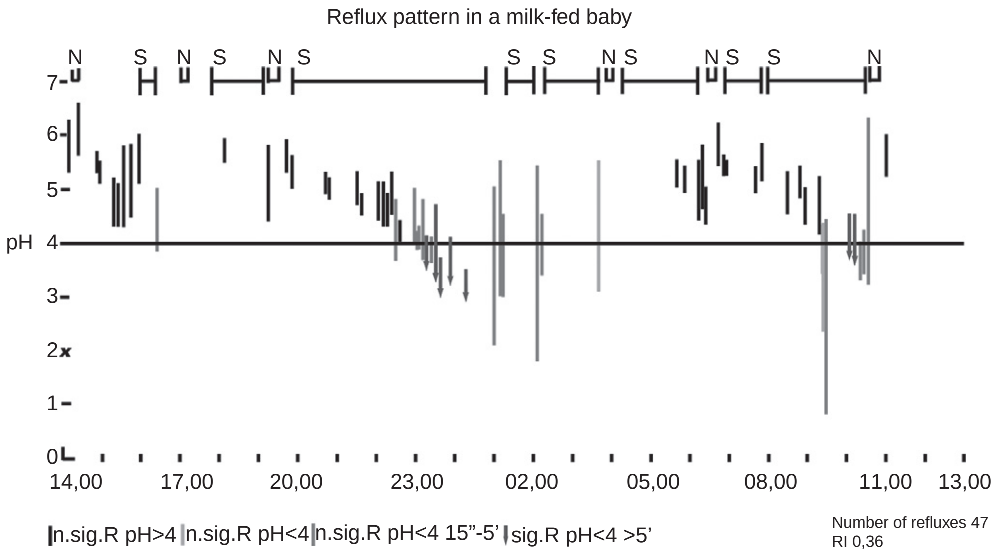

**FIGURE 73-5** Combined manometry and pH monitoring of a milk-fed 2-month-old infant. The lines indicate reflux episodes with the "common cavity phenomenon" and the related pH changes. In mainly milk-fed infants, gastric acid is effectively buffered and most of the reflux episodes for 2 to 3 hours after feeding do not fall lower than pH 4. *N,* Nutrition, *S,* sleep.

impedance technique. However, only 30% of the apneas were associated with reflux episodes while 70% were not.[33] Our investigations with manometry and simultaneous pH monitoring in infants with pathologic sleep apneas revealed no direct association between apneic spells and acidic refluxes. However, we did register a markedly delayed maturation of motor function of the esophagus in babies with sleep apneas or apparent life-threatening events (ALTEs).[34] Further studies have shown that infants with a pathologic sleep apneic pattern frequently suffer from pathologic reflux, whereas infants with a primary history of pathologic reflux have no remarkable prolonged apneic spells (Table 73-3).[35] These investigations support the hypothesis that infants with sleep apnea syndrome or ALTE suffer from a deeper localized underlying immaturity of the regulating hindbrain centers, whereas the causes for delayed maturation of esophageal motor function are located in higher brain regions and therefore not necessarily associated with disorders of respiratory regulation.

Symptoms in children beyond infancy are recurrent regurgitation of acid gastric juice, effortless vomiting, or night-time symptoms during sleep.[36] Recurrent respiratory tract diseases may occur due to microaspiration of reflux during sleep or may be complications of swallowing disorders in mentally handicapped patients. Clinical symptoms of esophagitis in most children are epigastric pain and, in adolescents, retrosternal pain or heartburn. Chronic inflammation of the mucosa may lead to microscopic bleeding and chronic anemia. If the inflammation spreads to deeper layers of the esophageal wall, it may eventually cause stenosis due to scarring. Late complications of GERD include replacement of the squamous epithelial layer by columnar epithelium, also known as Barrett esophagus. Chronic reflux in conjunction with unrecognized esophagitis, either with or without a hiatal hernia, may cause the Sandifer syndrome, which is characterized by behavioral problems such as spastic torticollis or dystonic body movements.

Hypopharyngeal refluxes at night with microaspiration may lead to laryngitis, laryngeal pseudopolyps and wheezing, chronic cough, pneumonia, or moderately severe symptoms of asthma. Recent clinical studies show that there might be a subgroup of patients with reflux-related airway problems who benefit from antireflux therapy, but chronic cough may also be unrelated to GERD.[37–40] The condition is difficult to diagnose except in those cases in which the radiologic investigation reveals aspiration of contrast material during reflux phases. Neither bronchoalveolar lavage nor nuclear medicine investigations are unequivocal. pH monitoring with one recording point in the upper and one in the lower esophagus discloses indirect signs when a large number of reflux episodes extend into the upper esophagus.[41] Other causes such as cystic fibrosis, aspirated foreign bodies, H-type fistulas, or malformations of the respiratory tract must be excluded. In children with a cerebral handicap, disruption of pharyngoesophageal transport—disturbed swallowing—is a common cause of recurrent aspiration.

**TABLE 73-3**
**Reflux and Apneic Spells**

| | n | *MA (sec/min)* | *LES Tone* | *Reflux* | *P:S* |
|---|---|---|---|---|---|
| Controls | 10 | 3,2 ± 1,3 | 21,6 ± 11,6 | 1 | 9,2 ± 1,6 |
| Infants with history of reflux | 12 | 5,5 ± 4,4 | 23,8 ± 10,4 | 8 | 8,4 ± 1,7 |
| Infants with history of sleep apnea | 21 | 13,7 ± 7,9* | 22,3 ± 7,0 | 14 | 7,5 ± 1,4 |

*Infants with a history of long sleep apneas also have more frequent reflux and an immature peristalsis when compared with infants with reflux or controls. *MA,* mean apneic time in sec/min; *P:S,* how many out of 10 induced swallows are followed by a propulsive peristalsis ($P < 0.05$ compared with controls).

## Diagnostic Investigations

Several diagnostic tests may be used to determine the extent of a pathologic reflux. However, the need for an extensive diagnostic workup depends on the nature of the underlying problem. The principal diagnostic tests to determine a pathologic gastroesophageal reflux are described in this chapter.

An *upper gastrointestinal series* is conducted to investigate the morphology and peristaltic function of the esophagus and exclude different pathologies such as pyloric hypertrophy and malrotation. Visualization of the gastroesophageal junction, demonstration of a sliding or fixed hiatal hernia, assessment of the angle of His, the course of esophageal peristalsis, and any remarkable features in the epithelium as signs of inflammation constitute the essential information that needs to be obtained. The actual evidence of reflux is less important because the radiologic exposure time is short and the true extent of reflux may be overestimated or underestimated. Indirect signs of a pathologic reflux include air reflux, a positive water siphon test (reflux after taking a large sip of water as provocation), and the level at which the reflux occurs.

*Twenty-four-hour pH monitoring* has long been the gold standard to evaluate the function of the esophagus. Ideally, multichannel probes are used and pH values in the stomach, lower esophagus, and upper esophagus are registered. Thus a pH drop in the esophagus may be correlated with the pH in the stomach, and the number of acidic refluxes that reach the upper esophagus can also be determined.[41,42] All pH drops below 4 of at least 15 seconds' duration (number of refluxes), the time required for normalization of pH and/or the time needed to increase the pH to 4 (reflux clearance), the number of reflux episodes with a clearance time of more than 5 minutes, and the longest reflux are assessed. We use a reflux index (RI) of 4% (percentage of time when pH < 4 in 24 hours) as a threshold in children and 3% in infants fed largely on milk because that takes into account the lower number of acid refluxes during which the pH drops below 4. The weakness of pH monitoring is that it provides a quantitative value of acid exposure of the esophagus but cannot demonstrate reflux episodes with a neutral or mildly alkaline pH.

*Combined multiple intraluminal impedance and pH monitoring* enable the investigator to determine all refluxes and the direction of bolus movement. Thus even neutral and alkaline refluxes can be recorded over 24 hours (Fig. 73-6).[43–45] Because microaspiration of nonacid refluxes plays an important role in recurrent respiratory tract infection, combined impedance/pH monitoring may well replace simple pH monitoring in the near future as the new gold standard of investigation.

*Manometric investigations* of esophageal function were introduced in the late 1960s, primarily to measure pressure in the LES. However, manometry is an excellent method to demonstrate the motor function and peristalsis of the esophagus as well. The manometric sign of TLESR is the CCP, which is marked by an increase in esophageal pressure tracings to abdominal pressure and a characteristic reversal of fluctuations that accompany respiration (see Fig. 73-3). Manometry combined with pH monitoring shows that the reduced pH due to reflux is normalized in a stepwise manner by swallowing saliva and permits analysis of acid, neutral, and alkaline refluxes (see Fig. 73-4). Thus the investigator can draw similar conclusions as those derived from impedance/pH studies. The disadvantage of manometry is that it is a motion-dependent investigation and requires a quiet child. Therefore it is not suitable as a routine method but may well be indispensable for specific questions.

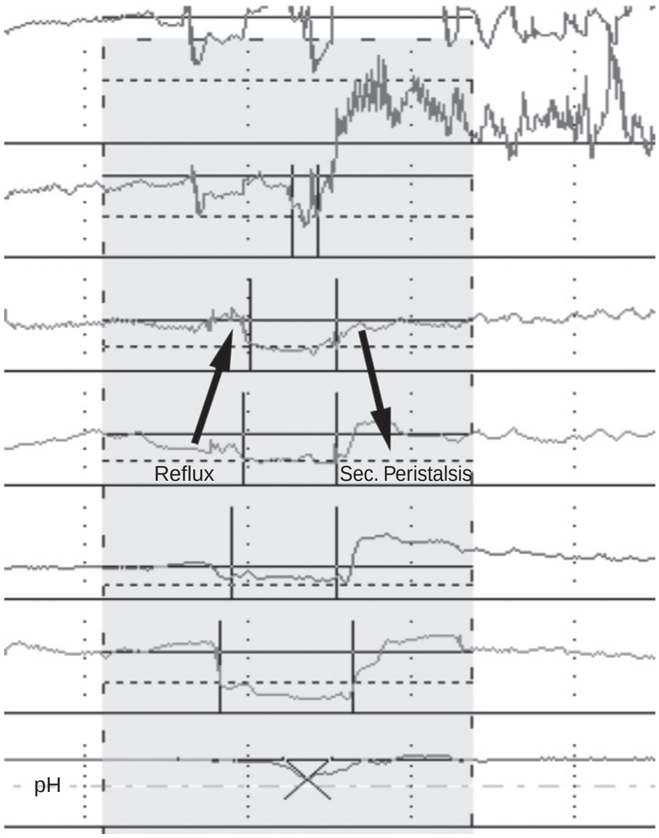

FIGURE 73-6 Combined impedance and pH monitoring shows a short reflux episode with a minimal decrease of the pH in the esophagus, which would not be detected by pH monitoring alone.

*Endoscopy and histology* are invasive investigations with flexible fiberoptic endoscopes and biopsies but an essential part of the diagnostic workup in GERD. Any endoscopic investigation is incomplete if the larynx is not inspected. Reddening, ulceration, or pseudopolyps on the vocal cords (Fig. 73-7) are typical signs of laryngeal reflux. Biopsy specimens are taken from the duodenum and the antrum of the stomach and tested routinely for *Helicobacter pylori*. The gastroesophageal junction is inspected by inversion of the tip of the endoscope in the stomach. Under normal circumstances the esophagus encloses the device tightly and the previously mentioned flutter valve can be seen at the lateral circumference. Sliding and paraesophageal hernias can be visualized (Fig. 73-8). The gastroesophageal junction and the Z-line can be accurately inspected by withdrawing the endoscope further. In normal cases the esophageal epithelium is smooth and milky red in color. In the presence of esophagitis one can quantify the degree of injury by using a scoring system such as the Savary-Miller interpretation: grade 1—erythema, grade 2—linear, noncircular ulceration, grade 3—confluent ulceration, grade 4—stricture. The more sophisticated Los Angeles classification of manifest esophagitis can also be used in children; it describes four grades of mucosal breaks, depending on the extension between mucosal folds.[46] It is essential to take several biopsy specimens, starting 1 to 2 cm proximal to the Z-line, upward into the upper esophagus. An optimal biopsy specimen includes

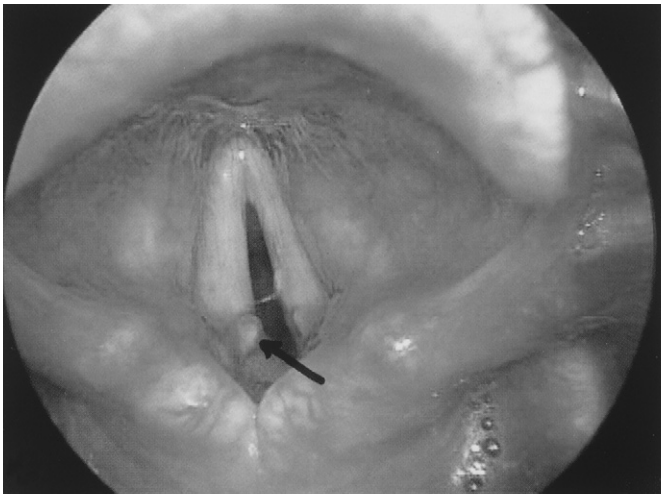

**FIGURE 73-7** Typical pseudopolyp on the vocal cord due to chronic reflux.

the entire epithelium with the basal cell layer. Hyperplasia of the basal cell layer and relative elongation of the papillae are signs of increased cell turnover due to reflux-related acid exposure or other pathologies. Dilated intracellular spaces are a relatively new parameter that is used in combination with other histologic features. Evidence of intraepithelial eosinophils then confirms the presence of obvious esophagitis, but it may be found even in the absence of corresponding symptoms.[47,48] On the other hand, the presence of more than 15 eosinophils per "high-power" field can be seen in infants with milk protein allergy and is a sign of a non-reflux-related allergic/atopic disease, also known as *eosinophilic esophagitis.*[49]

*Gastric emptying scans,*[51] *C-acetate breath test,* and *electrogastrography* have been used to evaluate gastric emptying time. However, doubts have been raised about their usefulness for the diagnostic workup of GERD.[28,50,51]

## Conservative Therapy of Reflux Disease

In infants, esophageal dysfunction and GERD resolve spontaneously in 90%. Therefore conservative measures are the treatment of choice. Former investigations have proposed the prone position, with the trunk raised as the most effective in preventing reflux because the hiatus is in the highest position.[52] However, the risk of sudden infant death is markedly increased in this position because vomiting during sleep may obstruct the nose and mouth, causing prolonged apneic spells and apparent life-threatening events (ALTEs). Currently, the supine position with the trunk elevated or the left-sided position during sleep and elevation of the head of the bed are given preference.[28,53] Additionally, frequent small-volume meals and thickening of food with rice gruel are recommended. However, the published literature provides no clear evidence of thickened formulas or specially manufactured milk formulas being effective in reducing the frequency of reflux events, but they do reduce visible regurgitation.[28,54–56] As mentioned earlier, the disappearance of symptoms does not necessarily mean that the reflux has subsided—it might just not reach the mouth. Therefore around the age of 2 years, a control 24-hour impedance/pH monitoring should be performed to prove or exclude persistent reflux.

In older children, there is no evidence of any specific change in food management reducing reflux. However, obesity, large-volume meals, and late eating have been associated with symptoms of GERD.[28]

$H_2$-receptor antagonists have been used for gastric acid buffering since the 1970s and have yielded beneficial effects in terms of providing symptomatic relief compared with placebo. Although their effect is inferior to that of a proton pump inhibitor (PPI), $H_2$-receptor antagonists are useful for PPI-intolerant patients.[57] Today, PPIs are the treatment of choice for curing GERD symptoms and esophagitis.[58] However, more studies are necessary to determine the specific symptoms and subgroups of juvenile patients who should be treated with PPIs.[58,59] Children on long-term PPI medication for GERD are exposed to a higher risk of acute gastroenteritis and community-acquired pneumonia, especially those with comorbidities such as diabetes or immunodeficiency.[60,61]

Although PPI therapy mainly reduces gastric juice acidity, a new and promising therapeutic option is the pharmacologic inhibition of TLESR by $GABA_B$ agonists such as baclofen. Recent experience with baclofen in adults and children with GERD has demonstrated a significant reduction in TLESR and reflux.[16,62–64]

Prokinetic therapy with cisapride has potential adverse effects (cardiac arrhythmias), and its clinical efficacy has not been conclusively established.[65] Domperidone and metoclopramide are other motility agents that are widely used, but their efficacy has not been demonstrated in randomized trials.[30]

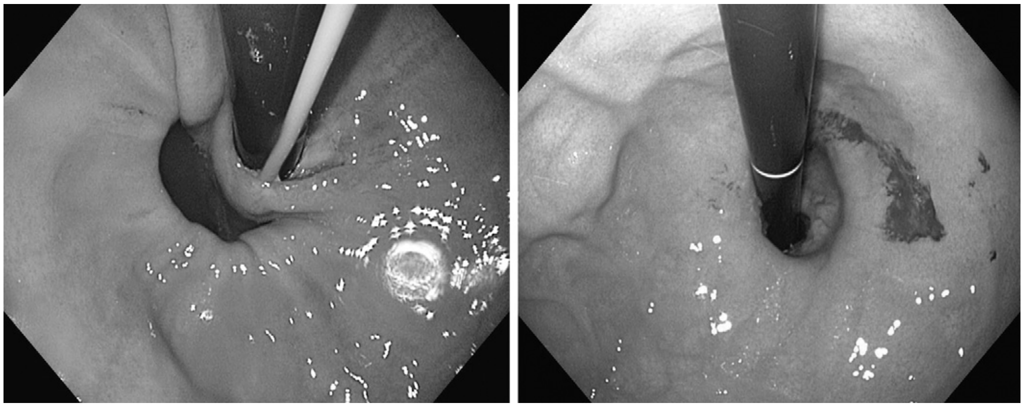

**FIGURE 73-8** *Left,* Typical paraesophageal hernia. *Right,* Axial hiatal hernia, with a view toward the higher-positioned lower esophageal sphincter.

## Surgical Therapy

Laparoscopic fundoplication is currently the treatment of choice. The procedure is safe and provides an excellent view due to magnification. Postoperative pain is significantly less, and the abdominal cosmetic aspect is clearly better when compared with a large laparotomy.

The most commonly used surgical procedures in children are the Nissen technique with a 360-degree wrap, the Toupet technique with a semicircular dorsal wrap, and the Thal technique with a semicircular ventral wrap.[66–68] The essential elements of all fundoplication techniques are mobilization of the gastroesophageal junction in order to achieve a 2- to 5-cm-long intra-abdominal esophagus (depending on the patient's age) and the creation of a partial or total fundus wrap around the esophagus over a large intraesophageal dilator (Figs. 73-9 to 73-11). When using the Nissen technique, the wrap should be loose and no longer than 1.5 to 2 cm in order to avoid complications such as the inability to belch or vomit and gas bloat. According to Nissen's original technique, the wrap must be created such that the surgeon can introduce his or her finger between the wrap and the esophagus.[66] Although a controversially discussed point, we advise fixation of the wrap to the esophagus with at least one suture and anchoring it to the diaphragm in order to prevent slippage or herniation. Most surgeons combine the technique with a hiatoplasty by approximating the crura with interrupted or figure-of-eight sutures to reduce the risk of wrap herniation into the thorax. We use onlay pledges to reinforce the hiatoplasty in cases of a large distance between the crura, or preexisting hiatal hernia. Great care should be taken to avoid injuring the vagus nerves. Modifications of Toupet's and Thal's techniques usually involve a 200- to 270-degree fundic wrap.

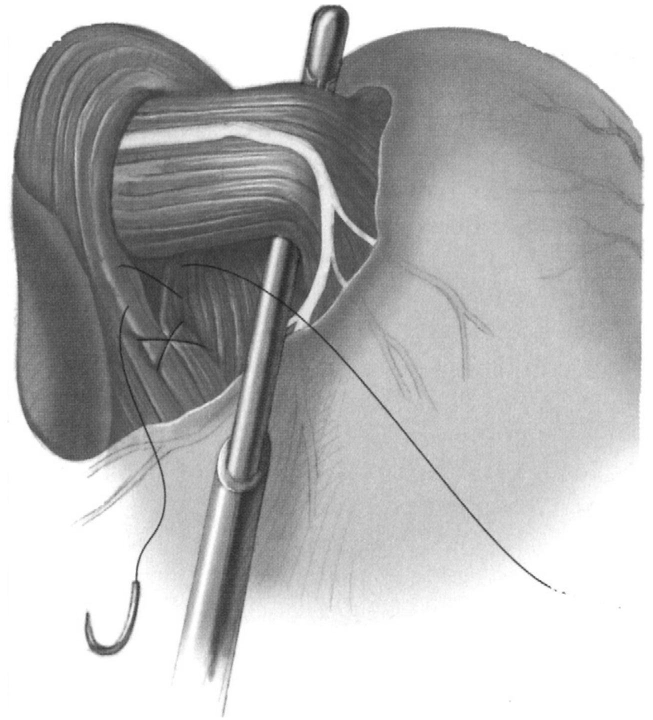

FIGURE 73-9 Laparoscopic Nissen. Hiatoplasty with figure-of-eight sutures. Great care should be taken to avoid closing the hiatus too tightly. ## Mechanisms of Antireflux Procedures

Manometric studies in adult patients before and after Nissen fundoplication have shown the following: (1) TLESR was substantially reduced to 50% of the preoperative rate, (2) the rate of TLESR accompanied by reflux was reduced from 47% to 17%, and (3) the mean residual pressure at the gastroesophageal junction during swallowing-induced relaxation increased significantly from 0.7 mm Hg to 6 mm Hg while the basal LES pressure was not affected.[69,70] Further investigations have shown that gastric distension causes an increased number of TLESRs in normal subjects and GERD patients, which is significantly attenuated by Nissen fundoplication, but gastric accommodation to the change in volume was similar in all groups.[71] Manometric studies comparing Nissen's technique with Toupet's showed that the resting tone of the sphincter was significantly higher in patients who underwent total wrap fundoplication, although there was no difference in the intra-abdominal length of the LES. The nadir pressure during LES relaxation was higher in those with a total wrap (6.5 vs. 2.6 mm Hg). However, the difference did not achieve significance. Significantly more CCPs occurred during TLESR by the Toupet technique after gas insufflation into the stomach. The authors concluded that partial dorsal fundoplication appears to restore gastroesophageal function more adequately, permitting air to be vented from the stomach without jeopardizing the antireflux barrier.[72] Studies on motor dysfunction of the esophagus show that it is not correlated with postoperative dysphagia and is not corrected by fundoplication, suggesting that it could be a primary phenomenon.[73–75]

## Results of Fundoplication

Antireflux surgery is a common procedure in the United States. From an analysis of 9987 records, it has been estimated that 48,665 procedures were performed in children between 1996 and 2003 (≈9 procedures per 100,000). The highest population-based procedure rate (45%) was performed in infants younger than the age of 1 year (≈101 procedures per 100,000 population).[76] Given the option of spontaneous maturation of esophageal function and the transient nature of reflux in infants younger than the age of 1 year, concerns have been expressed about the necessity of antireflux procedures. Hassall discussed failure rates and results of fundoplication in children and favors long-term medical treatment with PPIs; he recommends antireflux surgery only in selected patients.[77] It has been suggested that treatment algorithms should be reassessed in order to standardize the diagnosis, treatment, and follow-up of GERD in patients younger than 18 years of age in the United States.[78]

Tovar has convincingly shown that fundoplication with a floppy wrap is a powerful means of controlling reflux in appropriately selected children in whom medical treatment fails, or in symptomatic refluxers with specific comorbidities such as neurologic disorders or congenital anomalies.[79] A systematic review of randomized controlled trials of laparoscopic versus open fundoplication in adult patients showed a significantly lower operative morbidity, shorter postoperative stays, and less prolonged sick leave following the endoscopic approach.[80] In a randomized multicenter trial with a 5-year follow-up, antireflux surgery was more effective than omeprazole with respect to failure rates. However, when the dose of omeprazole was adjusted in cases of recurrent symptoms, the failure rate still revealed the superiority of surgery but the difference was not significant.[81]

Limpert compared the results of Nissen's procedure with Toupet's technique and came to the conclusion that, for most patients with normal or mildly disturbed esophageal motility, either procedure is effective. However, patients with a severe motility disorder are better served with a partial fundoplication.[82] In some studies, a lower rate of dysphagia was registered after the Toupet procedure, but in all other respects the results were of similar quality as those after a Nissen operation; others demonstrated no advantage of one procedure over the other.[75,83,84] Patients with aerophagy have fewer gas-related problems and less impairment of their ability to belch after a Toupet procedure when compared with Nissen fundoplication.[85] Long-term results of the laparoscopic Thal procedure also show favorable results; in one study, none of the children who were followed for more than 5 years had any symptoms of reflux.[86]

## Complications

A complication rate of 5.9% was recorded in 10,735 adults who underwent primary minimally invasive antireflux procedures between 1993 and 2000. The most common complication was wrap herniation (1.3%), the reoperation rate was 2.7%, and the mortality rate 0.08%.[87] Persistent dysphagia after laparoscopic fundoplication is usually related to the tightness of the wrap. It was speculated that division of the short gastric vessels permits the creation of a relatively loose fundoplication. However, it has been shown, in a randomized controlled trial, that routine division of short gastric vessels during total fundoplication did not improve the clinical or objective postoperative outcome.[88] In contrast, after analyzing more than 10,000 cases of laparoscopic fundoplication, Carlson and colleagues came to the conclusion that there might be a tendency to create a tighter wrap if the gastric vessels are not taken down. The overall incidence of dysphagia was 2.5% but was interestingly related to division (2.57%) or not (4.65%) of the short gastric vessels. The overall incidence of bloating was 9.4%, but the rates ranged from 0% to 45% (median, 2.4%).[87]

In childhood, recurrent gastroesophageal reflux disease (rGERD) is the most common problem after fundoplication. The majority of reoperations are performed within 12 months after the initial operation.[89,90] Failure rates to control reflux after fundoplication range between 2.5% and 10% but may be as high as 25% in patients with neurologic impairment.[91–93] Significant risk factors for recurrence are age younger than 6 years, preoperative hiatal hernia, postoperative retching, neurologic impairment, and postoperative dysphagia requiring esophageal dilatation.[91,94,95] A detailed analysis performed by Kimber revealed 9% redo procedures after 676 fundoplications; the majority of neurologically normal children had an associated anomaly such as esophageal atresia, while 60% of the redo patients had a neurologic impairment. Only 2 children out of the 66 who had to undergo repeat surgery had no associated medical conditions. The second Nissen procedure was

successful in 80%.[96] Analysis of the technical aspects of surgery revealed fundoplication herniations to be another common cause of failure.[97] Cephalad migration of the gastroesophageal junction above the hiatus may be due to inadequate esophageal lengthening into the abdomen. Thus in cases of a short esophagus, careful mediastinal mobilization is necessary to achieve a sufficient abdominal length. Inadequate hiatal closure may cause recurrent sliding or paraesophageal hernia, which occurs most frequently in children with hypertonic cerebral palsy.[96] This may be prevented by meticulous attention to accurate apposition of the crura during the initial procedure and/or the use of pledgeted sutures in wide or weak crural tissues.[96,97] In contrast to the open procedure, small bowel obstruction from adhesions is an uncommon event after laparoscopic fundoplication (4.8%).[98]

## Barrett Esophagus

Barrett esophagus (BE) is a condition associated with severe chronic reflux by which the squamous epithelium is replaced by columnar-lined epithelia of three different types: cardia-type epithelium, gastric fundic-type epithelium, and intestinal-type metaplasia including goblet cells (Fig. 73-12). The latter subtype can gradually progress through dysplastic stages to esophageal adenocarcinoma (EAC). Thus the term Barrett esophagus is used mainly for this histologic subtype with the highest risk for malignancy. The presence of dysplasia is often patchy; therefore biopsy guidelines recommend four quadrant biopsies every 2 cm in order to detect the development of high-grade dysplasia or early stages of EAC.[99] The risk of EAC in adult patients with BE is clearly elevated when compared with the normal population; however, the majority will not develop EAC.[100] So far it is unclear whether this holds true for pediatric patients with chronic reflux (e.g., children with esophageal atresia). Systematic reviews have shown that acid suppression therapy (surgery or drugs) has little or no effect on reversing BE, but antireflux surgery appears to reduce dysplasia and protects against development of high-grade dysplasia.[101] In contrast, recent studies show that antireflux surgery cannot prevent the development of EAC and therefore endoscopic follow-up examination should be continued after fundoplication.[102] A number of endoscopic therapies have been developed in recent years to eradicate the dysplastic epithelial lining (Neodymium Yag laser, Argon plasma coagulation, photodynamic therapy). Recent reviews show that radiofrequency ablation appears to be the most promising therapy, but long-term follow-up data are still necessary.[101]

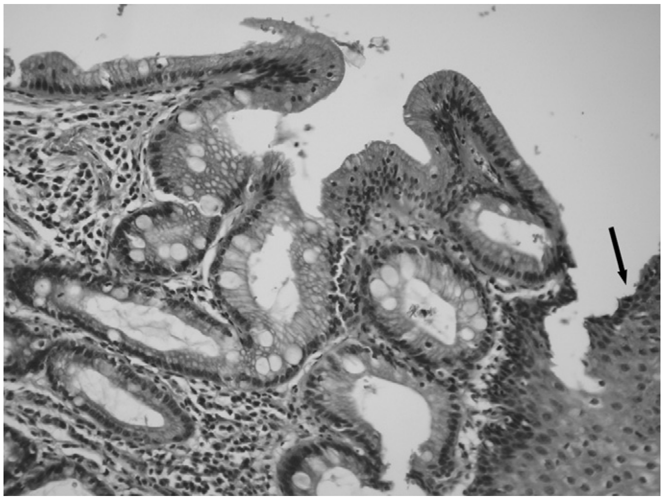

FIGURE 73-12 Barrett esophagus with intestinal metaplasia. On the right side of the histologic specimen is a part of the original esophageal epithelium visible (indicated by the *arrow*).

## Reflux in Children with Neurologic Impairment

Children with severe neurologic impairment (NI) frequently suffer from GERD, but the clinical symptoms may differ from those of neurologically normal children with reflux or may be concealed by more prominent symptoms such as recurrent respiratory tract infections. It has been shown that autoaggressive behavior and considerable agitation of these patients are valuable clinical signs of esophagitis and are significantly improved after successful surgical treatment.[103] Accordingly, analyses of quality of life proved the overall benefits of fundoplication and revealed fewer reflux-related short-term hospital admissions for aspiration pneumonia, GERD, and mechanical ventilation.[104,105] However, the rate of complications and recurrence after fundoplication was as high as 40%, with reoperation rates of 15% in long-term investigations.[106,107] Severe rumination and retching are known to be associated with reflux recurrence. Weber pointed to another important factor in these patients: Their preoperative nutritional status is a strong determinant of short- and long-term results, especially when steroids are administered additionally. He strongly recommends normalizing the child's nutritional status before performing any surgical procedure.[108]

Children with NI often suffer from oral motor impairment and need help with eating and drinking. Therefore a gastrostomy for feeding purposes with or without fundoplication is often necessary. Percutaneous endoscopic gastrostomy (PEG) is a useful procedure even in the presence of radiologic reflux.[109] Some studies have shown that PEG is associated with a greater frequency of symptomatic reflux and with significant complications, especially when combined with a laparoscopic antireflux procedure.[110,111] In other studies, good outcomes were reported with laparoscopic fundoplication and gastrostomy.[112,113] No randomized investigations have been performed to clarify whether it is better to combine gastrostomy with a fundoplication or with antireflux medication.[114] One study using decision analysis concluded that gastrostomy alone should be the favored approach in NI children without preoperative evidence of GER.[113] Experimental studies in cats have shown that gastrostomy causes a significant reduction in LES pressure, which can be prevented by preservation of the angle of His.[115] Technically, the gastrostomy should be performed in the lesser curvature or an anterior gastropexy should be added—both methods prevent flattening of the angle of His.[116,117]

Aspiration pneumonia is the most common cause of death in children with NI and GERD. Instead of fundoplication and

gastrostomy, a gastrojejunal feeding tube is used as an alternative treatment to reduce reflux episodes and provide adequate nutrition. However, an observational cohort study has shown that neither treatment option is clearly superior in preventing aspiration pneumonia or improving survival.[118] Bianchi described total esophagogastric disconnection as an alternative approach to treat NI children who are unable to swallow because it eliminates the risks of reflux and aspiration pneumonia.[119,120] Indications are either the inability to ingest food orally or recurrent respiratory disease and failure to thrive. Long-term results have shown that nutritional and metabolic complications including dumping and digestive malabsorption are common, and prolonged enteral nutrition is required.[121] This technique may be useful after failed fundoplication in NI patients.

## Impact of Delayed Gastric Emptying

Whether or not gastric emptying procedures are a valuable adjunct to fundoplication is controversial. Scintigrams with radioisotopes in the normal diet allow the investigator to quantify the magnitude of gastric retention before and after surgery. It has been estimated that 50% of children with GERD have delayed gastric emptying (DGE); the large majority suffer from disorders of the central nervous system.[122,123] It was speculated that children who develop complications after fundoplication (e.g., gas bloat, epigastric discomfort, recurrent reflux, paraesophageal hernia) may suffer from DGE.[122] Therefore gastric emptying procedures (GEPs) such as pyloroplasty or antroplasty have been proposed in addition to fundoplication, showing that recurrent reflux was significantly lower when a GEP was performed (18% vs. 35%) in children with GERD and DGE.[124] However, in Okuyama's investigation both GEPs were associated with a relatively high incidence of postoperative complications such as gas bloat, dysphagia, dumping, and wound infection.[123] In a carefully conducted study, Bais showed that the outcome of Nissen fundoplication was the same, regardless of whether the patient had a DGE or not. Patients with a DGE before the procedure had a normal emptying time after surgery, whereas patients with a normal emptying time had an increased rate of gastric emptying after surgery.[125] This study also showed that patients with a DGE do accumulate a greater portion of food in the fundus, which is normalized after fundoplication. Accordingly, recent investigations revealed no differences in outcome after fundoplication, regardless of whether a gastric emptying procedure had been performed in children with GERD.[126,127]

## Endoluminal Treatment of Gastroesophageal Reflux Disease

Although laparoscopic fundoplication remains the gold standard for surgical treatment of GERD, many new endoscopic techniques have emerged in recent times. The advantage of these purely endoluminal procedures is the fact that they can be performed on a day-clinic basis. The techniques can be divided into three groups: endoscopic suturing devices, endoscopic radiofrequency, and endoscopic implantation of inert material.

Endoscopic fundoplication has been performed thus far by using the *EndoCinch system* or the *EsophyX system*. The instruments introduced by the endoluminal approach permit construction of mucosal valves to prevent reflux.[128] The EsophyX system yielded good 12-month results in a multicenter trial and was approved by the U.S. Food and Drug Administration (FDA) in 2007.[129]

The *Stretta procedure* is a promising technique, delivering radiofrequency energy to the esophagogastric junction. Four small metallic prongs are embedded in the esophageal wall. Radiofrequency energy is applied to create small thermal lesions in the muscle wall at the LES. After FDA approval the procedure was tested in clinical trials, showing significant improvement in symptom scores and the use of PPI.[128] The procedure was successfully performed in 6 of 8 children.[130]

Endoscopic injection of *Enteryx,* an inert material at the esophagogastric junction, has also been associated with promising results. The material reduces the distensibility of the LES and decreases reflux events. A prospective multicenter trial showed excellent results in nearly 90% of patients who were able to discontinue PPI therapy, had improved symptoms, and had reduced esophageal acid exposure.[131]

## Hiatal Hernia

The history of hiatal hernia has dominated the reflux problem because it was synonymous with GERD until the 1970s.[132] It can be classified as axial—fixed or sliding—hernias, paraesophageal hernias, and mixed forms. An axial hiatal hernia is found in approximately 50% of adults older than 50 years of age.[133] Most individuals are asymptomatic or have nonspecific complaints within the spectrum of GERD. Reflux events occur due to delayed acid clearance and backflow of gastric juice during LES relaxations at the beginning of swallowing and after gastric distension.[133] Axial hernias in childhood are rare but can be observed in NI children or after surgical repair of an esophageal atresia with a long gap. The diagnosis can be established by radiologic procedures or even endoscopy after inversion of the scope. Surgical treatment consists of fundoplication with suture closure of the crura with or without reinforcing pledgets.

A paraesophageal hernia is a typical postoperative complication, with an incidence of 4.5% after fundoplication. It occurs less often after crural plication (3%) than without (10%).[134] It is generally believed today that children with asymptomatic paraesophageal hernias after fundoplication do not need surgical repair. However, patients with symptoms of dysphagia, postprandial pain, vomiting, or even gastric obstruction or strangulation need a laparoscopic redo fundoplication with closure of the hiatus.[134,135]

## Gastroesophageal Reflux Disease in Congenital Anomalies and Diseases

Gastroesophageal reflux is common in children after successful correction of esophageal atresia (EA). A recent survey of 132 adult patients who had undergone surgery for EA as newborns showed that 63% had reflux symptoms and 52%

reported dysphagia. Fifty-eight percent of 62 patients in whom endoscopy was performed suffered from reflux esophagitis, 42% had strictures, 11% had a Barrett esophagus, and one patient was diagnosed with a squamous cell carcinoma.[136] In the latter study it was concluded that patients older than 35 years of age and those with severe reflux symptoms are at high risk of having esophagitis or Barrett metaplasia. Specific problems associated with EA cause a significant reflux problem. First, many children with EA lack propulsive peristalsis in the distal segment of the esophagus, causing the ingested food to be transported by gravity. For this reason, the clearance time for refluxed gastric acid is significantly longer when compared with normal individuals, especially during sleep.[137,138] Second, experimental studies have shown that anastomosis of the esophagus under tension results in a significant decrease in LES pressure and length.[139] And third, nearly 20% of adult patients with EA as newborns have a hiatal hernia.[136] To avoid detrimental long-term complications and the development of Barrett esophagus, early investigations should be performed to assess esophageal function and the presence of reflux.[140] Around 30% of EA patients need an antireflux procedure. We give preference to the Toupet technique over the Nissen technique in order to avoid or reduce any additional barrier effect in the distal esophagus.

GERD occurs in up to 50% of children after repair of a congenital diaphragmatic hernia. This was found to be unrelated to the severity of the initial defect or the type of closure in some studies,[141,142] whereas wide defects requiring patch closure and need for extracorporeal membrane oxygenation (ECMO) were significant predictors of GERD in others.[143,144] The complex malformation of the diaphragm has an obvious detrimental effect on the anatomy and function of the esophagogastric junction. Investigations for GERD should be performed routinely during the follow-up of these patients.

Children with large congenital abdominal wall defects repaired in the neonatal period are known to suffer from pathologic reflux.[145] Children who have suffered caustic injury to the esophagus also show a higher frequency of GERD, which may be caused by a pathologic and prolonged acid clearance time due to disturbed peristaltic function of the esophagus or primary damage in the LES region.[146] GERD is also a major problem in the early life of children with cystic fibrosis but is known to improve with age.[147]

## Conclusion

Gastroesophageal reflux is common in neonates and infants. In most cases it is not caused by an insufficient LES but by delayed development of esophageal function and is characterized by several spontaneous relaxations of the LES. The mechanisms of reflux have been extensively studied in the past few decades. Esophageal function has been known to mature spontaneously by the end of 1 or 2 years in more than 90% of babies. Therefore unspecific and conservative lifestyle changes are usually sufficient. Reflux persisting into childhood requires sophisticated diagnostic procedures and close follow-up. If medical therapy fails, surgical correction is indicated. Fundoplication according to Nissen, Toupet, or Thal are the most commonly used procedures. Given the large number of postoperative complications, the patients should be followed for a long period of time.

CHAPTER 74

# Disorders of the Umbilicus

Robert E. Cilley

## History

Umbilical malformations have been depicted in art and sculpture since antiquity, but the developmental basis for these abnormalities was not recognized until the late nineteenth century. Surgical textbooks, such as that by von Bergmann in 1904, clearly describe the embryology responsible for persistence of the vitellointestinal duct as a fistula, sinus, or cyst.[1] The symptoms of fecal drainage ("congenital umbilical anus") and prolapse of the intestine were well known. The surgeon was advised to avoid pitfalls such as excision of an "umbilical tumor" that exposed two intestinal lumens because it would indicate that the vitellointestinal remnant had been excised in excess back to the ileum. An umbilical polyp representing a persistent remnant of the duct was referred to as an "enteroteratoma."

Surgical management has changed little in the past 100 years. Interestingly, then as now, granulomas of the umbilical cord were treated by silver nitrate cauterization. The embryologic basis of developmental abnormalities of the urachus was similarly recognized, and their surgical treatment was described much as it is today. The natural history of spontaneous resolution of most umbilical hernias was also understood at the end of the nineteenth century. External compression was often recommended, and the importance of preservation of the appearance of the umbilicus rather than excision was emphasized. Repair of umbilical abnormalities was recognized as formidable in small children, and little is known of the true operative morbidity and mortality in the hands of the surgical pioneers who first attempted their correction.

The most complete work on the umbilicus is the classic text by Cullen, published in 1916.[2] This encyclopedic work is still the most definitive work on the subject. Cullen's curiosity was originally stimulated by a case of cancer at the umbilicus, and it inspired him to explore the entire topic of umbilical pathology. He stated, "The study of the umbilicus, which in the beginning had seemed so unimportant, became so fascinating that I covered most of the literature on the subject."[2]

The vital functions of the umbilicus in utero and the structures that pass through it in normal development contrast with its lack of physiologic importance after birth. Its psychologic importance throughout life is attested to by individuals who have endured surgical loss of their umbilicus. Pediatric surgeons are the first to be consulted whenever there is an unusual finding of the umbilicus in newborns and older children. Umbilical herniorrhaphy is among the more commonly performed operations in childhood. In addition, the umbilicus serves as a portal of entry for most laparoscopic procedures, and it may be used as an intestinal or urinary stoma site. Cannulation of its vessels, either in their native location or transposed surgically, provides vascular access in neonates. The umbilicus is considered to be aesthetically important,[3] and it may be an object of display and adornment. Exposure of the umbilicus is commonplace, as is the use of jewelry and piercings to enhance its appearance.

## Normal Embryology

The classic description of the formation of the umbilicus indicates that the abdominal wall forms by a combination of lateral infolding and ventral flexion of the disk-shaped trilaminar embryo that begins in the fourth gestational week. However, the actual growth of the embryo does not truly involve "bending" and "folding" of structures but rather represents differential growth of tissues. Initially, the amnion is located in a dorsal direction, whereas the yolk sac occupies a ventral position. The embryo is attached to the chorion, the forerunner of the placenta, by a connecting stalk composed of extraembryonic mesoderm in which the umbilical vessels develop and into which the allantois grows (Fig. 74-1, *A*). The yolk sac maintains its ventral position but is divided into intracoelomic and extracoelomic portions (Fig. 74-1, *B*). The intracoelomic portion, derived from the roof of the yolk sac, becomes the primitive alimentary canal and maintains a connection with the extracoelomic portion through the vitelline or omphalomesenteric duct. This connection is normally lost by the fifth to seventh week of gestation.[2,4] Persistence of this connection, as a remnant of either the developing alimentary tract or the accompanying vitelline vessels, accounts for some of the abnormalities described in this chapter.

Early in the third week of gestation, a diverticulum called the *allantois* forms from the posterior wall of the yolk sac and extends into the connecting stalk of the embryo (Fig. 74-1, *A* and *B*). The allantois serves as a reservoir for the developing renal system in lower vertebrates but has no

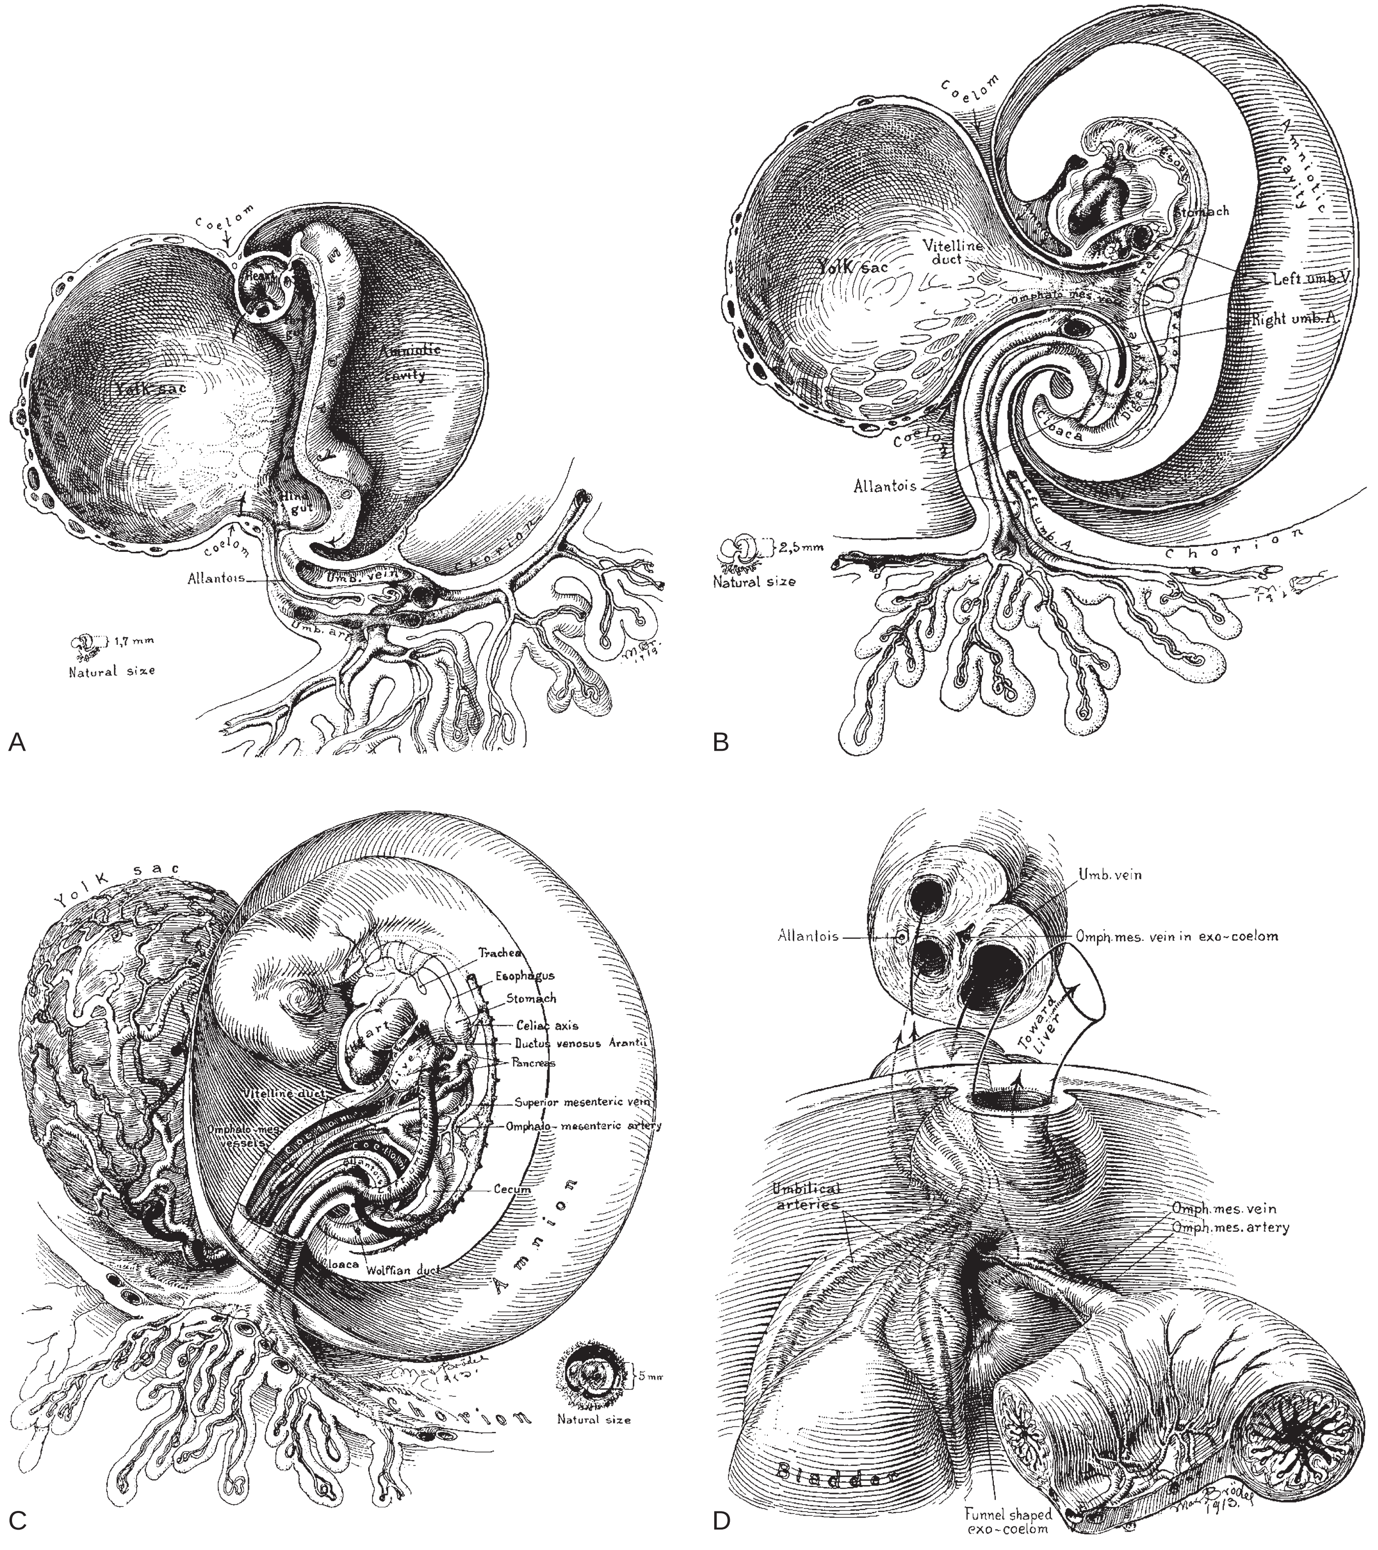

**FIGURE 74-1** **A,** A 1.7-mm embryo (third week). The primitive gut is not yet separate from the yolk sac. The amniotic cavity can be seen dorsally. The umbilical vessels develop in the extraembryonic mesoderm and connect the embryo to the developing placenta. **B,** A 2.5-mm embryo (fourth week). Infolding and flexion of the embryo draw the amnion around the body. The omphalomesenteric duct is part of the developing umbilical cord. (From Cullen TS: Embryology, Anatomy, and Diseases of the Umbilicus Together with Diseases of the Urachus. Philadelphia, WB Saunders, 1916.) **C,** A 5-mm embryo (fifth week) demonstrating a complete umbilical cord. The omphalomesenteric duct connection between the yolk sac and the alimentary tract is lost between the fifth and seventh weeks. **D,** A 45-mm embryo (10 weeks) viewed from inside. The intestines, which were extraembryonic coelomic (i.e., within the umbilical cord) between the sixth and tenth weeks, have returned to the peritoneal cavity.

known role in human development; it remains rudimentary as the transitory extraembryonic portion of the urachus. As the distal hindgut, or cloaca, partitions into the urogenital sinus ventrally and the anorectal canal dorsally, the developing bladder remains connected by the urachus to the allantois within the body stalk (see Fig. 74-1, *D*). The urachus is derived wholly from the developing bladder and may persist in various forms, which accounts for the abnormalities described later.

As the embryo develops, the amnion is drawn around it to surround the embryo and cover all the developing umbilical cord structures including the allantois, umbilical vessels, vitelline duct, and primitive mesenchymal tissue (Wharton jelly) (Fig. 74-1, *C*). During the period of rapid intestinal growth between the sixth and tenth weeks of gestation, the developing midgut is extracoelomic. As the body wall continues to develop, the intestines are incorporated into the coelomic cavity and intestinal rotation and fixation progress. The fibromuscular umbilical ring continues to contract and is nearly closed by the time of birth (Fig. 74-1, *D*). Persistence of the fascial opening as an umbilical hernia occurs frequently and is commonly seen in premature infants. Unlike other abdominal wall defects, umbilical hernias tend to resolve without specific treatment as a result of the ongoing development of tissues at the umbilical ring after birth. The fate of the structures that relate to the development of the umbilicus is shown in Table 74-1.

## Umbilicus at Birth

Modern obstetric practice uses plastic clamps that are placed a few centimeters from the umbilical skin during cord division at the time of delivery. Topical antimicrobials such as triple dye, bacitracin, silver sulfadiazine, povidone-iodine, chlorhexidine, hexachlorophene, alcohol, salicylic sugar powder, green clay powder, silver-benzyl-peroxide powder, and 1% basic fuchsin may be applied to the cord after birth.[5,6] All these agents are effective in reducing bacterial colonization rates, and their use is recommended when adequate cord care cannot be guaranteed. These agents may affect cord separation time, some cause discoloration, and repeated use of iodine-containing antimicrobials may result in systemic absorption of iodine and suppression of thyroid function. There is good evidence that, in developed countries, dry cord care, without the application of topical antibiotics, in association with routine soap and water bathing and meticulous hand washing practices is as effective as topical agents in reducing infection.[7] However, a recent randomized prospective study demonstrated fewer cord-related complications in infants treated with chlorhexidine powder compared with standard dry cord care.[8] In the undeveloped world, antiseptic cord cleansing with chlorhexidine may significantly reduce neonatal morbidity and mortality.[9]

Intestinal injury may result from injudicious placement of an umbilical cord clamp when an unrecognized small hernia of the umbilical cord (i.e., a small omphalocele) is present. Abdominal wall defects that relate to the umbilicus (i.e., gastroschisis and omphalocele) are covered in Chapter 75.

The normal time for separation of the umbilical cord after birth ranges from 3 days to 2 months.[10] Antimicrobial treatment may prolong cord separation by decreasing leukocyte infiltration. Delayed separation of the umbilical cord has been associated with heritable neutrophil mobility defects and widespread infections that are often lethal.[11] The abnormal neutrophils lack a membrane glycoprotein, which results in abnormal attachment, chemotaxis, and phagocytosis.[10] Although persistence of umbilical cord attachment beyond 3 weeks of age has been suggested to be a sign of such immunologic abnormalities, recent studies that have included more than 600 newborns have demonstrated the range of normal newborn cord separation to be broad (3 to 67 days), with a mean of 14 to 15 days.[10,12] In these studies, nearly 10% of normal newborns underwent cord separation after 3 weeks of age, thus indicating that delayed cord separation is not a reliable indicator of immunologic disease. If prolonged cord separation is associated with umbilical infection, leukocyte adhesion deficiency disorders should be suspected and an immunologic evaluation performed.[6,13,14]

**TABLE 74-1**
**Fate of Structures Related to the Developing Umbilicus**

| *Structure* | *Fate* | *Remnants, Pathologic Condition* |
|---|---|---|
| Urachus (connects the bladder to the allantois) | Obliterates | Median umbilical ligament, patent urachus, sinus, cyst |
| Omphalomesenteric duct (connects the midgut to the yolk sac) | Obliterates | Meckel diverticulum, patent omphalomesenteric duct, sinus, cyst, bands, polyp |
| Omphalomesenteric arteries | Most regress; fuse to form the celiac, superior mesenteric, and inferior umbilicus | Dominant artery may accompany Meckel diverticulum, fibrous band to the mesenteric arteries |
| Omphalomesenteric veins | Plexus around the duodenum becomes the superior mesenteric and portal vein (contribution from both the left and right vein) | Preduodenal portal vein if the ventral portion of the plexus persists |
| Umbilical arteries | Obliterate after birth | Medial or lateral umbilical ligaments* |
| Umbilical veins | Right obliterates; left returns placental blood to the inferior vena cava through the ductus venosus | Falciform ligament |

*Atlases and anatomy texts variably refer to the obliterated umbilical arteries as the *medial* or *lateral umbilical ligament*. When called the *medial umbilical ligaments*, the epigastric vessels are called the lateral umbilical ligaments. When called the *lateral ligaments*, the epigastric vessels are referred to as the *epigastric folds*.

After separation of the cord, the umbilicus may have many appearances. A normal umbilicus is characterized by a depression in which may be found the mamelon (a central eminence that contains the remnants of the solid portion of the umbilical cord) and the cicatrix (dense scar where the intraembryonic and extraembryonic coelom were in continuity). The cushion is the slightly raised margin that surrounds the umbilical depression. Cullen described more than 60 "normal" configurations of the umbilicus.[2]

# Umbilical Abnormalities

## ACQUIRED

### Umbilical Granuloma

After cord separation, a small mass of granulation tissue may develop at the base. These granulomas consist of true granulation tissue with fibroblasts and abundant capillaries; the granulomas range in size from 1 mm to approximately 1 cm. The surface often has a pedunculated appearance. Umbilical granulomas may be treated by cauterization with one or more applications of silver nitrate until the area epithelializes. Alternatively, the granuloma may be excised and silver nitrate or absorbable hemostatic material applied.[15] If the mass does not respond to cauterization, a true umbilical polyp or sinus tract must be suspected (see later). Care must be taken with silver nitrate application because burns and skin injury may occur.[16]

### Umbilical Infections

Although modern perinatal practice has dramatically reduced the incidence of omphalitis, infections of the umbilicus still occur with alarming morbidity and mortality, particularly in undeveloped countries.[17] Rigorous asepsis, hand washing, and cord care (either dry cord care or topical antimicrobials) have reduced the incidence of umbilical infections to less than 1% in hospitalized newborns.[18] Before the institution of such practices, the mortality rate for omphalitis was 65%. The primary pathogens implicated in these infections were *Staphylococcus aureus* and *Streptococcus pyogenes*. Currently, gram-negative bacteria play an important role in the pathogenesis of umbilical infections. Severe infections are often polymicrobial. Omphalitis may be manifested as a purulent umbilical discharge or periumbilical cellulitis. Delivery at home, low birth weight, use of umbilical catheters, and septic delivery are risk factors. Tetanus infection occurs on rare occasions. Intravenous antibiotic therapy is effective in eradicating most infections. Omphalitis is a common problem in developing countries, where it accounts for more than a quarter of neonatal hospital admissions.[19,20]

Cellulitis may progress to fasciitis, and such progression may be subtle. Signs of necrotizing fasciitis include abdominal distention, tachycardia, purpura, blistering, pyrexia, hypothermia, leukocytosis, and progression of cellulitis despite antibiotic therapy. Bacteriologic cultures demonstrate polymicrobial flora.[21] Necrotizing fasciitis and umbilical gangrene may be lethal and require immediate wide surgical debridement for patient survival.[18,22–27] Excision should be performed immediately on recognition; all infected skin, fat, and fascia should be excised back to viable, bleeding abdominal wall musculature. The umbilicus is obligatorily excised. Excision of preperitoneal tissue including the umbilical vessels and urachal remnant may be critically important to achieve eradication of the infection because these tissues harbor invasive bacteria and may provide a route for the progressive spread of infection seen after less extensive surgical debridement.[22] The defect may require a temporary prosthetic patch for closure, but ultimate fascial closure and umbilical reconstruction may leave an acceptable appearance. Hyperbaric oxygen therapy has been advocated as adjuvant therapy, but it is not of proven benefit.[26] The overall reported mortality associated with necrotizing fasciitis in collected series is 81%.[18,22–27]

Umbilical drainage resulting from chronic infection of umbilical remnants such as umbilical artery remnants has also been reported.[28] Excision and debridement are curative. Omphalitis can result in necrosis and breakdown of the umbilical stump with spontaneous evisceration within the first 2 months of life and may be associated with portal venous thrombosis and subsequent extrahepatic portal hypertension.

## CONGENITAL

### Omphalomesenteric Remnants

Remnants of the vitelline or omphalomesenteric duct account for a wide variety of umbilical abnormalities that may require surgical correction.[28a] These remnants include fistulas, sinus tracts, cysts, mucosal remnants, and congenital bands. Typical variations of the pathologic varieties are illustrated in Figure 74-2, *A* to *F*.[2,29,30]

If the omphalomesenteric duct is patent from the terminal ileum to the umbilicus, fecal umbilical drainage will be noted (Fig. 74-3, *A*). Although this event is dramatic to parents, the problem is immediately recognizable on examination and parents may be reassured that prompt surgical correction is curative. Prolapse of the proximal and distal ileum through the patent duct has a characteristic appearance. Although contrast injections are of interest, they do not change the surgical approach (Fig. 74-3, *B*). Anatomically unusual conditions such as an unexpected origin of the omphalomesenteric duct from the appendix will be recognized at the time of operation (Fig. 74-4).[31,32] Unless another, more serious medical condition exists, a patent omphalomesenteric duct should be excised promptly. A mechanical intestinal preparation is not necessary, although we customarily stop formula feeding; perioperative intravenous antibiotics are also given. The operation may be performed through the umbilicus itself or through an incision below the umbilicus. Full exploration and identification of all umbilical structures including one vein, two arteries, and the urachal remnant are indicated. The omphalomesenteric duct is traced to the ileum and divided. The ileum is closed, and care must be taken to control any dominant vitelline vessels that may be present. After the fascia is closed, umbilicoplasty is performed.

Small duct remnants and sinuses may have less characteristic drainage. Injection of contrast material may be helpful in delineating the nature of the problem in these instances, but surgical exploration remains the definitive diagnostic test. It is important that a full exploration is performed and that all umbilical structures including the intraperitoneal undersurface of the umbilicus are visualized to identify and remove any bands attached to the small intestine. If a Meckel diverticulum is attached to an omphalomesenteric band discovered at exploration, it is excised. Cystic remnants of the omphalomesenteric

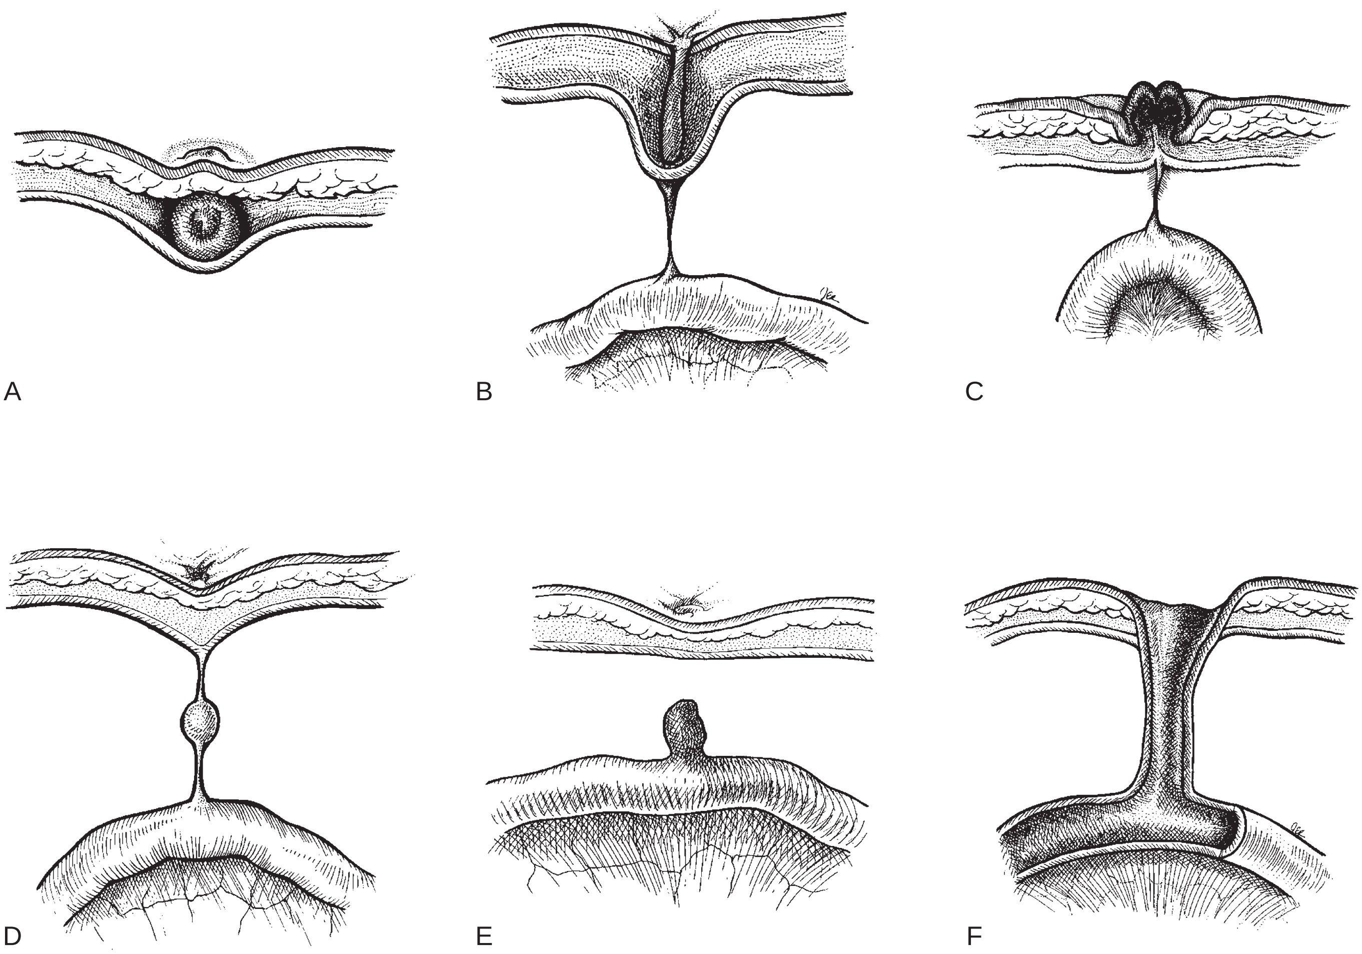

FIGURE 74-2 Various omphalomesenteric duct remnants. **A,** Umbilical cyst containing intestinal tissue. **B,** Umbilical sinus with a band. **C,** Umbilical polyp covered with intestinal mucosa. **D,** Fibrous band containing a cyst. **E,** Meckel diverticulum. **F,** Patent omphalomesenteric duct. Other varieties and combinations exist.

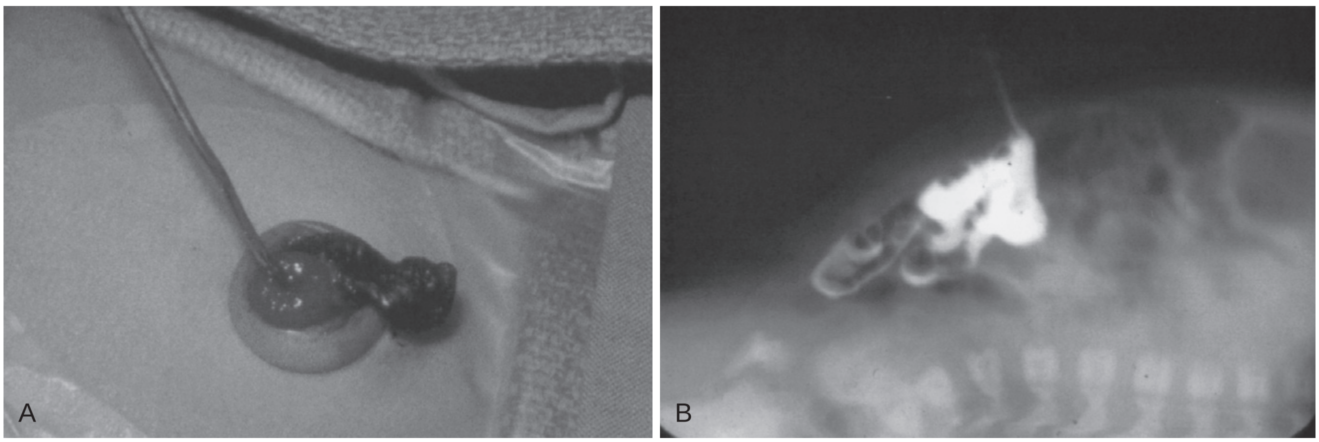

FIGURE 74-3 **A,** This photo of a newborn demonstrates probe patency of an omphalomesenteric duct into the ileum. **B,** A radiograph with contrast medium injected into a patent omphalomesenteric duct demonstrates filling of the small intestine. Studies of this sort are not usually necessary.

duct may become infected and cause acute symptoms, even in older individuals. If an abscess has formed, it may require surgical drainage; excision of any remnant may be accomplished at a later time. The omphalomesenteric duct or any remnant attachments between the abdominal wall and the intestine may cause angulation, volvulus, or herniation of intestinal loops, thereby resulting in mechanical intestinal obstruction. The nature of the obstruction will be discovered during laparotomy.

Rarely, spontaneous regression of a patent omphalomesenteric duct may occur.[33,34] In one case the defect was

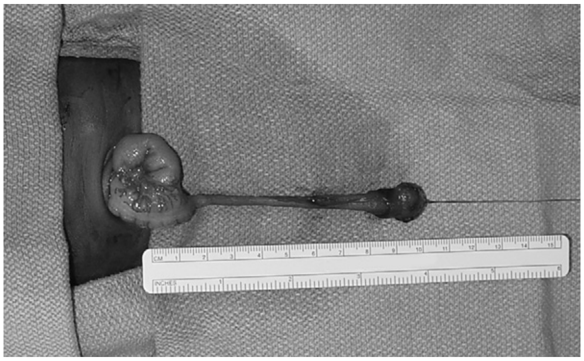

FIGURE 74-4 An unusual omphalomesenteric duct in continuity with the appendix. Presentation was as a large umbilical polyp. Correction was performed through the umbilicus.

documented by a fistulogram shortly after birth, but it was not operated on until the patient was 3 months of age. At that time, only a Meckel diverticulum was found, but it had no connection to the umbilicus, thus indicating that some regression had occurred in the interim. The Meckel diverticulum and its treatment are discussed in Chapter 84.

## Urachal Remnants

Various abnormalities of the urachus have been described.[2,35,36] The typical abnormalities are depicted in Figure 74-5. A patent urachus is associated with drainage of urine from the umbilicus. Clear drainage from the umbilicus should always raise suspicion of a patent urachus. Although the definitive anatomy is discovered during laparotomy, frank drainage of urine from the umbilicus requires an investigation of the urinary tract to look for bladder outlet obstruction in which the urachus is functioning as a relief valve (Fig. 74-6).[37] Such conditions are rare. A patent urachus may be approached either through the umbilicus or through an infraumbilical incision. It is important to identify all the umbilical structures for a definitive diagnosis. The patent urachus is ligated and transected at the level of the bladder; broad-based connections are closed in two layers with absorbable sutures. Excision of urachal remnants using laparoscopic techniques has been described.[38,39]

FIGURE 74-6 Radiograph with contrast medium injected into a patent urachus demonstrates filling of the bladder. (From Jona JZ: Umbilical anomalies. In Raffensberger JG [ed]: Swenson's Pediatric Surgery, 5th ed, Norwalk, Conn, Appleton & Lange, 1990. Used with permission.)

Urachal sinuses may give rise to umbilical drainage or be discovered on examination. Urachal cysts most often cause an infection manifested as a painful mass localized between

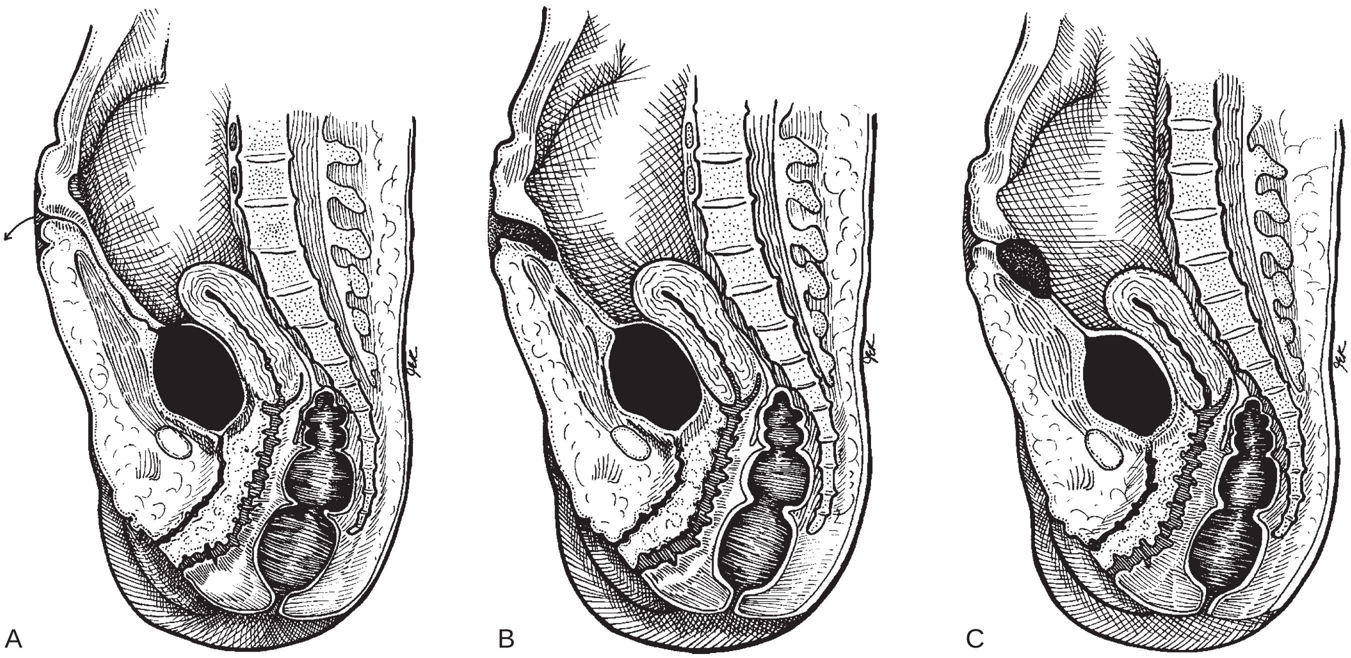

FIGURE 74-5 Various urachal remnants. **A,** Patent urachus with communication between the bladder and umbilicus. **B,** Urachal sinus. **C,** Urachal cyst, which is usually associated with infection.

the umbilicus and the suprapubic area. Ultrasonography or computed tomography may be helpful to confirm the diagnosis. Other unusual manifestations have been reported including a lateral mass.[40] The urachus has also been described as exiting from the midline below the umbilicus.[41,42] In addition, a patent urachus may be one of the causes of a giant umbilical cord in the newborn.[43] When a urachal cyst becomes infected and develops into an abscess, drainage of the acute process is required. After the abscess is drained, complete healing may take place. It is unknown whether subsequent operation to remove any residual cyst remnants is necessary.

Urachal remnants may cause complications later in life. Abnormal epithelium including colonic, small intestine, and squamous may be present in incidentally removed urachal remnants.[44] The fate of these tissues is unknown, but many different malignant tumors have been reported to originate from the urachus. A partial list of tumors in adults arising from the urachus is shown in Table 74-2. Pediatric tumors including rhabdomyosarcoma and neuroblastoma may originate from urachal remnants as well.[45,46]

Pain plus retraction of the umbilicus during micturition has been described as a sign of a urachal anomaly.[47,48] Resection of the urachal remnant is curative.

Diagnostic imaging including ultrasound, contrast injections, computed tomography, and magnetic resonance imaging may occasionally be helpful in diagnosing and treating umbilical abnormalities.[49] An infant with umbilical discharge caused by both a persistent urachus and an omphalomesenteric duct has been reported.[50]

### Umbilical Dysmorphology

A single umbilical artery may occur in conjunction with many syndromes and is associated with congenital abnormalities in a third of cases. Such abnormalities include trisomy 18 and renal and cardiac anomalies. Children with dysmorphic features may have characteristic findings that aid in diagnosis. Minor abnormalities that lack medical significance can nonetheless provide insight into the nature and timing of dysmorphologic events that occur during development.[51] Commonly, dermatoglyphics, hair patterning, auricular shape, and genital configuration are part of such observations. Minor abnormalities of the configuration of the umbilicus may be useful in the classification of dysmorphologic findings. For example, an umbilicus that is situated unusually high on the abdominal wall at the level of the lower rib cage and is flat and poorly epithelialized indicates Robinow syndrome, which is also characterized by a flat facial profile, mesomelic shortening, and genital hypoplasia. If the umbilicus is broad and prominent with a large stalk and redundant periumbilical skin, Rieger syndrome should be suspected, especially if these umbilical abnormalities occur in conjunction with goniodysgenesis and hypodontia. If the umbilicus is prominent with a button-like central portion in a deep longitudinally oriented ovoid depression or flat with radiating branches of the cicatrix, Aarskog syndrome, a condition classically characterized by short stature, facial dysplasia, syndactyly, and genital anomalies, is indicated.[52]

## OTHER CONGENITAL AND ACQUIRED PATHOLOGIC CONDITIONS OF THE UMBILICUS

Suprapubic dermoid sinuses usually extend from the skin overlying the pubis and pass over the superior surface of the bladder to the umbilicus alongside the urachus.[53,54] The embryologic origin of such a sinus tract remains unclear, although it may be a variant of a dorsal urethral duplication.

Children with bladder and cloacal exstrophy may have an omphalocele or a low-set umbilicus incorporated into the upper portion of the open bladder plate, along with diastasis of the lower abdominal wall musculature and diastasis of the symphysis pubis.[55] Variants of exstrophy include superior vesicointestinal fissure, duplicate exstrophy, and pseudoexstrophy, in which the bladder is intact and only the musculoskeletal abnormalities are present.

Numerous unusual protrusions have been described at the umbilicus. Ectopic pancreatic tissue including islets is best explained by the pluripotential nature of cells of the vitelline duct.[56] Abnormal portions of liver connected to the main lobes of the liver have been described and probably represent entrapment by closure of the umbilical ring.[57] A giant, 10-cm hamartoma originating from the umbilicus without intra-abdominal involvement has been excised without incident.[58] The appendico-omphalic explanation of a fistula between the appendix and the umbilicus was noted earlier ("Omphalomesenteric Remnants"). Entrapment of the appendix in the umbilicus such as in a small omphalocele may also explain some fistulas from the appendix to the umbilicus.[59,60] Keloid formation has been observed after umbilical cord separation.[61] A giant umbilical cord may contain urachal remnants and ectatic vessels and may mask a small omphalocele. Care should be exercised during application of the cord clamp whenever the appearance of the cord is abnormal.

The umbilicus may be affected by any disease of hair-bearing skin including dermatoses and infections. It may be the site of ectopic tissue including endometriosis, as well as numerous primary and metastatic tumors, in addition to those of urachal origin (see Table 74-2). Many acquired pathologic conditions of the umbilicus are summarized in Table 74-3.

### Umbilical Piercing

Umbilical piercing is common and may present dilemmas in management. Trauma surgeons should be familiar with the opening mechanisms of body piercings to facilitate radiology studies and as needed for emergency procedures.[62] Removal of the piercing device is not necessarily recommended if infection occurs.[63] Local infections can be treated by warm compresses and antibiotic ointment. If infection persists, oral

antibiotics are prescribed. The site is cleansed with antibiotic soap, and the jewelry rotated and left in place to allow drainage. Infections that require surgical drainage or debridement are rare. Navel piercing jewelry may be temporarily removed during surgery while preserving the piercing sinus tract. A plastic intravenous catheter is placed in the sinus when the piercing is removed.[64]

### UMBILICAL LINT

The origin of umbilical lint has been a subject of curiosity and speculation. Experimental shaving on the periumbilical hair eliminates lint formation. Lint collected from the umbilicus after colored cotton shirts were worn by subjects with intact abdominal wall hair matched the color of the shirts indicating the source of the lint. Presumably umbilical lint collects as a direct result of the whorled umbilical hair acting on clothing-derived material. Hair encircles the umbilicus, and the keratin scales overlap with their bases pointing toward the hair follicle. This arrangement imposes direction on the random movement of the clothing lint that occurs when the material rubs back and forth across the abdomen with body movement. The periumbilical hairs act in a ratchet-like fashion to move the lint into the depths of the umbilicus.

## Umbilical Hernia

### ANATOMY

At birth the umbilicus is surrounded by a dense fascial ring that represents a defect in the linea alba. The umbilical opening is reinforced by strongly attached remnants of the umbilical arteries and urachus in an inferior direction and the more weakly attached umbilical vein in a superior direction. A layer of fascia (Richet fascia) derived from the transversalis fascia supports the base of the umbilicus. The peritoneum forms an intact undersurface of the umbilical ring, and skin overlies the umbilicus after the cord has separated. When the supporting fascia of the umbilical defect is weak or absent, a direct hernia results.[65] An umbilical hernia in children is surrounded by the dense fascia of the umbilical ring, through which a peritoneal sac attached to the overlying skin protrudes. The umbilical ring continues to close over time and the fascia of the umbilical defect strengthens, which accounts for the spontaneous resolution of this defect in most children.

An indirect umbilical hernia has also been described in which the peritoneal contents herniate from a point immediately superior to the umbilical ring. The hernia follows the umbilical canal along the umbilical vein, the linea alba in

an anterior direction, and a thin layer of preperitoneal fascia in a posterior direction.[66] This form of herniation has been suggested to cause proboscoid hernias in children; in this defect, the umbilical cicatrix is displaced progressively in an inferior direction as the hernia enlarges. This defect may also be responsible for umbilical hernias in some adults.

The umbilical hernia of childhood is distinguished from a "hernia of the umbilical cord," in which there is a defect in the peritoneum, as well as an open fascial defect at the umbilicus. Intestines herniate into the substance of the umbilical cord itself and are covered only by amnion. A hernia of the umbilical cord is, in effect, a small omphalocele.

## INCIDENCE AND NATURAL HISTORY

There is no doubt a molecular basis for umbilical ring closure.[67] Genetic heterogeneity accounts for the presence of an open umbilical ring in some children at the time of birth, whereas in others, the ring is essentially closed at the time of cord separation. Unlike inguinal and epigastric hernias, which have no real tendency to close after term, the umbilical ring is programmed to continue closure in many children for weeks, months, or years after birth.

Umbilical hernias in childhood occur with equal frequency in boys and girls. Numerous reports document a high incidence in African and African American infants.[68–70] The umbilical ring is open throughout most of gestation but becomes progressively smaller as gestation progresses. Most umbilical hernias in infants are recognized after cord separation in the first few weeks of life, and almost all are noted by 6 months of age. Most undergo spontaneous closure during the first 3 years of life. Umbilical defects are found in many premature infants after cord separation. Although umbilical hernias are commonly found in low-birth-weight infants (75% of infants weighing $< 1500$ g), most will resolve.[71] The lack of accurate longitudinal studies of children with umbilical defects does not allow definitive conclusions to be drawn about their natural history.[72] Umbilical hernias with a small ring diameter ($<1$ cm) are more likely to close spontaneously and close sooner than those with a large ring diameter ($>1.5$ cm). The diameter of the umbilical defect is prognostically important, whereas the length of the protrusion is not. Some umbilical hernias that are present at 5 years of age will close spontaneously without an operation.[73,74] The relationship between umbilical hernias that become symptomatic later in life and childhood umbilical defects is unknown. The protruding portion of the hernia generally remains unchanged while the fascial ring closes until it is too small to admit any contents into the hernia sac. The hernia thus tends to disappear abruptly.[74] Umbilical hernias are commonly observed in patients with Down syndrome, trisomy 18, trisomy 13, mucopolysaccharidoses, and congenital hypothyroidism. Umbilical defects (hernia or omphalocele) are part of the Beckwith-Wiedemann syndrome. Incarceration of intestine or omentum, strangulation, perforation, evisceration, and pain are rare events in the natural history of umbilical hernias in children. The most difficult task of the pediatric surgeon is to convince the family that observation alone will be successful in most cases and that an operation is not indicated for their child, especially in infancy. The large conspicuous skin-covered hernia sac with its characteristic and unsettling appearance is often associated with a small fascial defect. It may be helpful to demonstrate the size of the actual fascial defect to the parent.

Uncorrected umbilical hernias can become symptomatic at any time in life. Rupture and evisceration are rare but can occur.[75,76] Incarceration is rare, but the small bowel is most commonly affected when it does occur. Conditions that increase intra-abdominal pressure increase the likelihood of complications. Repair of umbilical hernias in patients with ascites is hazardous. Umbilical hernias may also become symptomatic during pregnancy, and if incarceration occurs, surgery is required. Unusual contents of umbilical hernias include uterine fibroids and endometrial elements.[77,78]

## SURGICAL INDICATIONS

Although repair of childhood umbilical hernias has been advocated to prevent the complication of incarceration in adults, the relationship between the two events is unclear.[79,80] Rare events such as incarceration requiring reduction, strangulation, perforation, and evisceration are absolute indications for surgery. In the absence of these absolute indications, persistence and appearance are relative indications for operative repair in developed countries. Infants with giant proboscoid hernias in whom the umbilical ring does not narrow during serial observations may be considered for repair in the first 2 years of life. Typical umbilical hernias should be observed at least until age 2. If there is no improvement in the size of the umbilical fascial ring, consider repair. Ample evidence supports the decision to postpone repair until later in childhood. Large defects ($>1.5$ cm) that persist past the age of 5 should be repaired. Evidence-based guidelines are lacking, and the decision may be individualized on the basis of such considerations as family history, parental desires, and local practices. The appearance of a hernia often drives families to insist that the hernia be repaired. In less developed parts of the world, it may be appropriate to actively observe umbilical hernias, with operation reserved for those with complications such as incarceration.[81,82]

If the child has a tender umbilical mass, the hernia may be reduced by milking the air out of the incarcerated loop of intestine and applying firm, steady pressure on the incarcerated mass. Admitting a patient for observation to rule out peritonitis and performing the operation the next day are appropriate. If the incarceration resists reduction, an emergency procedure is required. In an infant with an inguinal hernia and a concomitant umbilical hernia, the umbilical hernia should generally be left alone because it will probably close spontaneously.

## SURGICAL TECHNIQUE, RESULTS, AND COMPLICATIONS

Procedures described for the repair of umbilical hernias in children range from multiple layers of closure after opening the peritoneum to closed techniques in which the peritoneal sac is inverted or treated like an inguinal hernia sac and ligated with sutures.[83,84] Absorbable and nonabsorbable sutures have been advocated. The redundant skin of a large defect may be left in place and improves in appearance over time. Some have advocated excision of the skin and reconstruction when a large proboscoid hernia is present (see later). However, the fundamental technique of umbilical hernia repair has changed little since the 1953 description by Gross.[85] Secure closure of the fascia, usually in a transverse fashion, and preservation of the appearance of the umbilicus are common to all repairs. Strapping and taping of the defects have been discredited.[65,86]

Repair of an umbilical hernia is performed as an outpatient procedure with the patient under general anesthesia. Local anesthesia may be infiltrated into the wound before or after the procedure, but paraumbilical infiltration avoids distortion of tissues by the anesthetic.[87] Administration of local anesthesia before the incision conforms to the principles of preemptive analgesia. An infraumbilical skin crease incision is made (Fig. 74-7). The incision may be hidden within the umbilicus itself. Subcutaneous dissection is performed to circumscribe the sac. The sac is transected and may be dissected from the undersurface of the umbilical skin, but extensive and time-consuming dissection is unnecessary. Leaving a small remnant of the peritoneal sac on the undersurface of the umbilical skin causes no complications. The sac may be trimmed to a strong fascial edge or simply folded inward to allow placement of interrupted absorbable sutures in a transverse orientation. To ensure accurate placement of sutures, they are tied after placement is complete. A second layer of closure is unnecessary. Inversion of the umbilical skin is maintained with fine absorbable dermal suture between the underside of the umbilicus and the midportion of the fascial closure. The skin is closed with intradermal absorbable sutures and covered with a small dressing. Some surgeons apply a pressure dressing; however, a recent randomized study showed no benefit from application of a pressure dressing in standard childhood umbilical hernia repair.[88] Although infection predisposes to recurrence of the hernia, such complications are rare. Visceral injuries are possible but should not occur if the fascial edges are kept in view during the procedure.

Epigastric hernias can occur immediately adjacent to the umbilicus and may be difficult to distinguish from an umbilical hernia. Careful examination reveals a bulge at the upper margin of the umbilicus or just above it. A supraumbilical incision permits repair of an adjacent epigastric hernia and simultaneous repair if both umbilical and epigastric hernias are present.

## Use of the Umbilicus

Cannulation of the umbilical arteries and umbilical vein is commonly performed in sick neonates and provides a convenient means for intravascular access and monitoring.

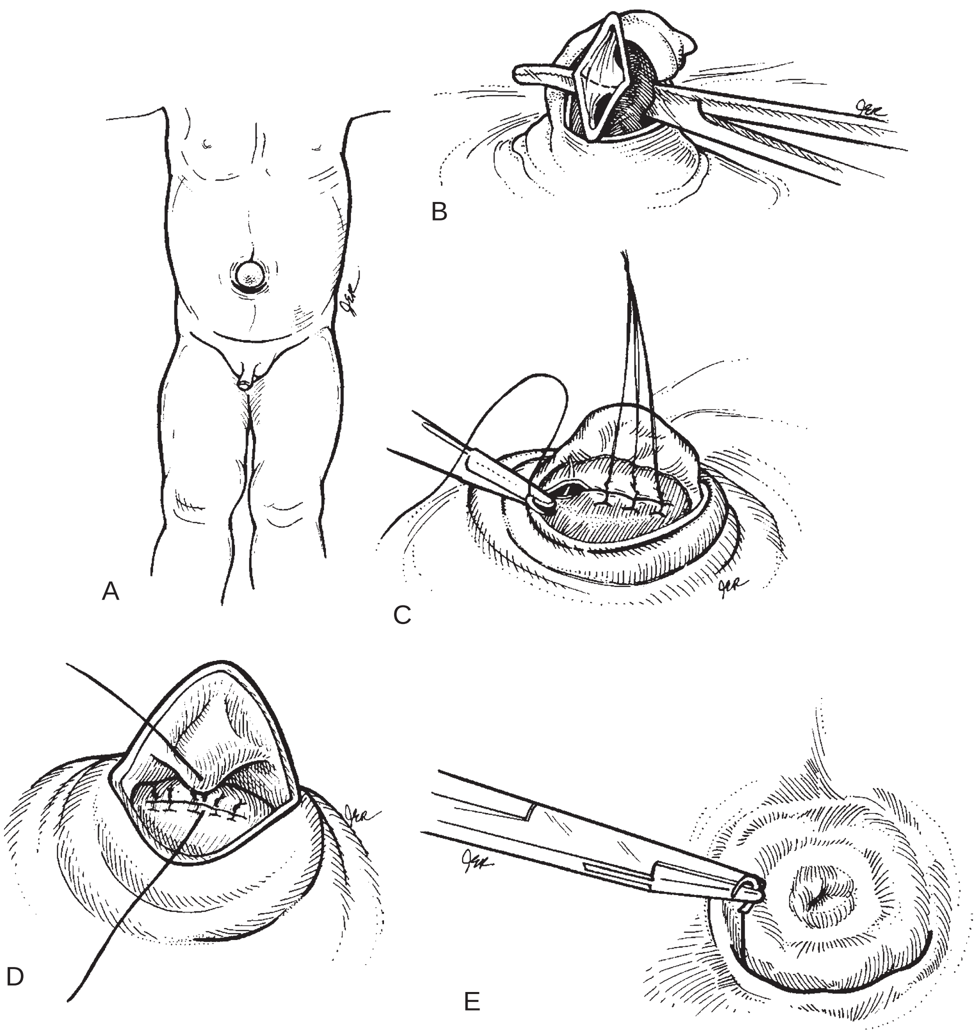

FIGURE 74-7 Repair of an umbilical hernia. **A,** An infraumbilical, curvilinear incision is marked. **B,** The sac is encircled and opened. **C,** The fascia is closed transversely. **D,** A tacking suture is placed between the undersurface of the umbilical skin and the fascia. **E,** Final result.

Associated risks are related to infection, vascular thrombosis, and direct injury from catheters.[89] There is insufficient outcome-based evidence to either refute or support the use of prophylactic antibiotics when umbilical artery or venous catheters are inserted in newborns.[90,91] There is little evidence that heparin coating of the catheter or catheter material lowers complication rates.[92] The umbilicus is frequently used as the entry site for laparoscopic equipment. The center of the umbilicus may be opened and the fascial ring probed and spread for access in infants, small children, and those with a shallow umbilicus. This technique leaves almost no detectable incision. In patients with a deep umbilicus, a separate infraumbilical incision may be preferable. The umbilical port is most often used as the primary site for placement of the viewing camera. Closure of the fascial defect after removal of the port is necessary to reduce the risk for formation of a hernia. Single-port laparoscopic procedures using the umbilicus as the only access site are gaining popularity in both pediatric and adult surgery.[93] The umbilicus has also been used to mask the abdominal incision used for pyloromyotomy in cases of hypertrophic pyloric stenosis.[94] This approach results in an almost undetectable scar.

The umbilicus can also be used as a stoma site.[95] No studies have compared the complication rate for intestinal stomas brought out of the umbilicus with those brought out from other locations in the abdominal wall; however, complications of umbilical stomas were reported by one study to be common.[96] After closure, the umbilicus is reconstructed and a nearly normal appearance is achieved. We have used the umbilicus as a temporary ostomy site and have found it satisfactory. Though providing no physiologic benefit, it leaves the patient with one less obvious incision site.

The umbilicus has also been used as an exit site for urinary diversion. In premature infants, a temporary cutaneous vesicostomy brought out of the umbilicus functions well and can be closed with excellent cosmetic results.[97] Intestinal conduits for urinary diversion have also been brought out of the umbilicus.[98]

# Reconstruction and Preservation of the Umbilicus

The umbilicus is aesthetically and psychologically important, and its abnormal appearance or absence may cause distress. Absence of the umbilicus may even be a source of grief and depression. The appearance of the umbilicus should be acceptable to the patient and family. A T-shaped or oval umbilicus with a superior hood may be the most aesthetically appealing configuration.[3] A broad or protruding umbilicus may be perceived to be less acceptable. One of the goals of all umbilical surgical procedures is to maintain or restore as normal an appearance as possible. Multiple techniques of surgical reconstruction or re-creation of the umbilicus have been described as noted later. Standard umbilical hernia repair produces minimal distortion of the umbilicus and generally results in a satisfactory appearance. Omphalomesenteric and urachal remnants can usually be excised through the umbilicus as noted earlier. After laparoscopy via the umbilicus, if the umbilical skin is secured to the fascial closure, a satisfactory umbilical depression is maintained. Patients may seek surgical correction for the perception of an unfavorable appearance of the umbilicus such as protrusion. Umbilicoplasty to address the appearance of the umbilicus has become a niche within the discipline of plastic and reconstructive surgery.

## UMBILICOPLASTY FOR GIANT HERNIAS WITH REDUNDANT SKIN

When large hernias (giant proboscoid hernias) are repaired, the redundant skin results in an unnatural appearance. Some improvement may occur with the passage of time, but a broad, flat, protruding configuration may persist. Reconstruction by a variety of techniques may improve the immediate and long-term appearance.[99–104] We have found the "tripartite umbilicoplasty" based on the technique described by Reyna and colleagues to be satisfactory for immediate reconstruction of giant umbilical hernias.[103] None of these described techniques has been widely adopted and shown to be superior in long-term follow-up.

## UMBILICOPLASTY FOR ABDOMINAL WALL DEFECTS AND CREATION OF A NEO-UMBILICUS

The umbilicus may be retained or reconstructed during the repair of abdominal wall abnormalities. The structures of the umbilical cord may be incorporated into a reconstruction of the umbilicus, or a neo-umbilicus may be fashioned.[105–111]

In gastroschisis and omphalocele, fascial repair may be performed through the circular skin defect that remains after the umbilical structures have been excised. This is the case for both primary and staged closures. The circular skin defect may then be closed with an intradermal purse-string suture that is incorporated into the middle of the fascial closure (Fig. 74-8, A).[106] Even if the fascial defect is enlarged for the application of a Silastic chimney, the lower portion of the defect can be closed in a similar circular fashion to create the appearance of an umbilicus.[105] Others have advocated preservation of the umbilicus in the repair of abdominal wall defects and leaving the umbilical remnants in place in continuity with the skin closure.[108,110,111] There is a trend toward preservation of the native umbilicus in gastroschisis repair (Fig. 74-8, *B*).

The umbilicus is abnormally located in all children with bladder exstrophy and is often associated with a small omphalocele defect. It may be transposed more cephalad at the time of bladder closure to create a more normal appearance.[112] In children with prune-belly syndrome, the umbilicus may be preserved on a vascularized pedicle and located appropriately after the removal of excess skin.[113]

In some circumstances a new umbilicus must be constructed when it is absent as a result of previous surgical removal or treatment of an abdominal wall defect. The normal location for the umbilicus is at the level of the iliac crests, overlying the third or fourth lumbar vertebrae. Umbilical reconstruction should create a round or oval depression with steep walls that

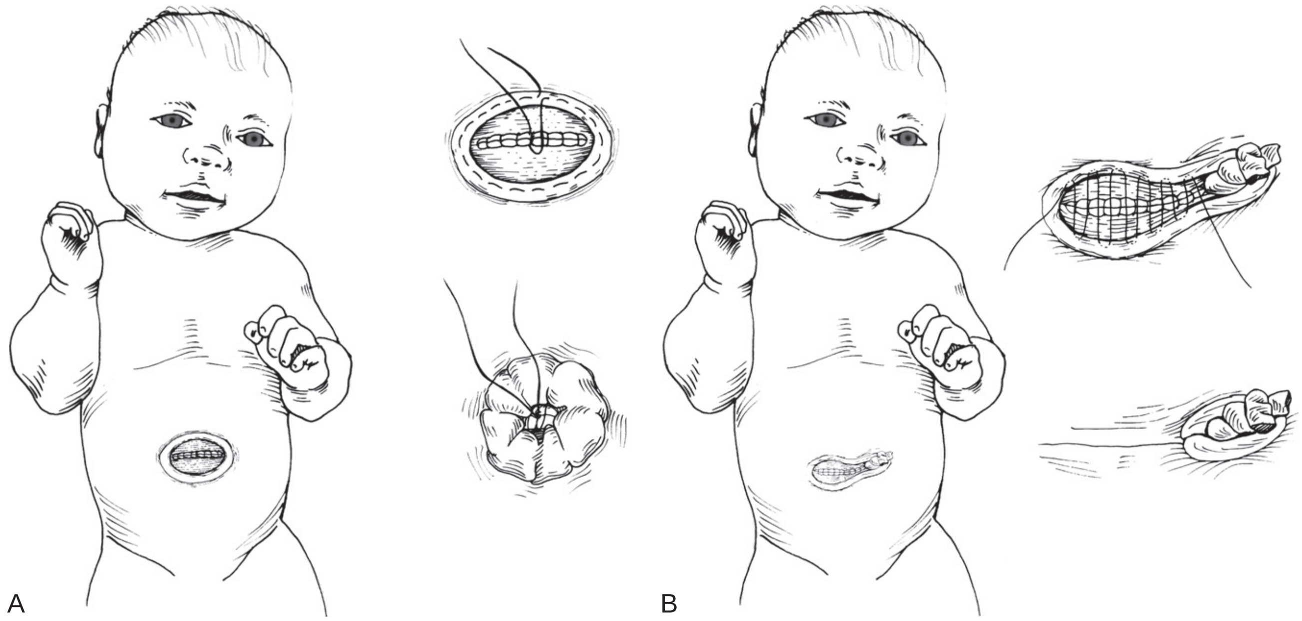

FIGURE 74-8 Technique of umbilicoplasty after excision of the cord structures or when a procedure is performed through the umbilicus (e.g., surgical repair of gastroschisis or a small omphalocele, excision of an omphalomesenteric remnant through the umbilical ring, excision of a urachal remnant through the umbilicus). **A,** Child with gastroschisis after fascial closure. Placement of a circumferential purse-string dermal suture is shown. Note that the suture passes through the fascia. **B,** Retention of the umbilical cord after repair of gastroschisis.

FIGURE 74-9 Creation of a neo-umbilicus using a tubularized defatted skin pedicle in a patient with a giant omphalocele in conjunction with abdominal wall reconstruction.

is centrally fixed to the abdominal wall fascia (Fig. 74-9). Some umbilical reconstructions tend to flatten over time. Tubularized skin reconstructions may be more durable and may also mimic the "cushion" or slightly raised area that surrounds the umbilical depression. Many techniques have been proposed to reconstruct an absent umbilicus.[106,109,114–122] They vary considerably in their complexity, but none have proved superior in long-term follow-up. Several techniques have been specifically described to reconstruct an absent umbilicus after exstrophy repair.[112,123–126]

CHAPTER 75

# Congenital Defects of the Abdominal Wall

Michael D. Klein

## History

Newborns with abdominal wall defects were reported in the first century AD by Aulus Cornelius Celsus, a Roman physician, and then by Paulus Aegineta in the fifth century.[1] Omphalocele is described in the sixteenth century printed works of Ambrose Paré,[2] and Lycosthenes may have been the first to describe gastroschisis at about the same time.[3] Taruffi introduced the term *gastroschisis* in 1894.[4] For many years gastroschisis was confused with an omphalocele that had a torn sac.[5] Moore and Stokes are credited with limiting it to the specific clinical entity as we understand it today,[6] although they give credit to earlier authors who used the term, such as Bernstein,[7] but not to the earliest collected series of Massabuau and Guibal.[8]

The first successful repair of omphalocele was reported by Hey in 1802.[9] In 1873 Visick described the successful repair of gastroschisis.[10] Ahlfeld[11] in 1899 described painting an omphalocele sac with alcohol to produce an eschar and awaiting contraction and epithelialization. The use of mercurochrome for painting the sac was popularized by Max Grob.[12–14] Toxic effects of mercurochrome were described later.[15–17] A modern version was introduced by Ein and Shandling, who used an adhesive semipermeable artificial membrane.[18] Olshausen in 1887 first reported skin flap coverage of defects after removal of the membrane,[19] and Gross further demonstrated its effectiveness and popularized the technique.[20] Staged closure of the resultant hernia could be difficult because of failure of the abdominal cavity to grow without the impetus of the intestines within it, and because of intestinal adhesions to the skin flaps. For this reason, the skin was sometimes closed over an intact omphalocele sac.[21,22]

In 1967 Schuster introduced staged reduction of large omphaloceles with prosthetic material because he noted that the abdominal cavity did not grow with skin closure alone.[23] The fact that no operative technique has achieved universal success or acceptance is attested to by the many ingenious methods that continue to be devised including skin grafting,[24,25] pneumoperitoneum and tissue expanders to stretch the abdominal wall in preparation for closure,[26–28] partial hepatectomy,[29,30] lateral relaxing incisions in the fascia,[31] and division of the rectus abdominis muscles.[32]

## Spectrum of Clinical Congenital Abdominal Wall Defects

The clinically important defects are all umbilical with intact rectus abdominis muscles (Table 75-1). Omphalocele is a large defect (>4 cm) covered by amniotic membrane that contains midgut and other abdominal organs including the liver and often the spleen and gonad (Fig. 75-1). One unusual form of omphalocele is the cephalic fold defect, or pentalogy of Cantrell, in which the abdominal wall defect is supraumbilical and the heart is in the sac through a defect in the pericardium and the central tendon of the diaphragm.[33] The other elements of the pentalogy are an intracardiac defect and a sternal cleft. Ectopia cordis thoracis (when the heart is outside the chest with no pericardial covering as opposed to being inside the omphalocele sac) might be considered a form of a cephalic fold defect (Fig. 75-2).

Another unusual omphalocele is the caudal fold defect, cloacal exstrophy, in which the defect is infraumbilical and accompanied by exstrophy of the bladder, epispadias, diastasis of the pubic rami, and imperforate anus (see Chapter 120). The ileum prolapses between the two halves of the exstrophied bladder.

Gastroschisis is less than 4 cm in diameter, has no covering membrane, and usually contains only the midgut with the stomach and possibly a gonad. It is almost always to the right of the umbilical cord, although exceptions do occur (Fig. 75-3).[34] Occasionally, a skin bridge may be present between the cord and the defect, but the abdominal wall and its muscles are normal. At birth the bowel can appear perfectly normal, but more than 20 minutes after birth, the extruded intestine may be thickened and covered with a fibrinous exudate matted together so that individual loops cannot be distinguished. There have been several reports of gastroschisis with a small remnant of midgut appearing above a defect that has essentially closed, most likely caused by antenatal volvulus.[35,36] Most authors recognize patients with gastroschisis and an associated gastrointestinal condition such as atresia, perforation, necrosis, or volvulus as a separate entity with a poorer

**TABLE 75-1**
**Comparison of Congenital Abdominal Wall Defects**

| *Defect* | *Site* | *Sac* | *Contents* | *Frequency* | *Associated Anomalies* | *Outcome* |
|---|---|---|---|---|---|---|
| Omphalocele—lateral fold | Umbilicus | Yes | Liver, intestine, spleen, gonad | Common | Chromosomal, cardiac | Good (depending on associated anomalies) |
| Omphalocele—cephalic fold (pentalogy of Cantrell) | Superior umbilicus | Yes | Liver, intestine | Rare | Cardiac, sternal cleft, pericardial defect, central tendon diaphragm defect | Poor |
| Omphalocele—caudal fold (cloacal exstrophy) | Inferior umbilicus | Yes | Intestine | Rare | Bladder exstrophy, imperforate anus, epispadias | Fair |
| Umbilical cord hernia | Umbilicus | Yes | Intestine | Unusual | Uncommon | Good |
| Gastroschisis | Right umbilicus | No | Intestine | Common | Intestinal atresia | Good |
| Ectopia cordis thoracis | Midline sternum | No | Heart | Rare | Cardiac | Poor |

**FIGURE 75-1** Omphalocele.

**FIGURE 75-2** Ectopia cordis.

**FIGURE 75-3** Gastroschisis.

**FIGURE 75-4** Umbilical cord hernia.

outcome.[37] This is usually called *complicated gastroschisis*. Gastroschisis in the fetus is probably associated with intrauterine distress. Neonates with gastroschisis are more frequently premature and commonly have respiratory problems. Even term babies with gastroschisis are more likely to be small for gestational age[38–40] and to have younger mothers.[41]

Umbilical cord hernia is least common. It is also less than 4 cm and contains only the midgut, but it is covered by a membrane (Fig. 75-4). It is often confused with omphalocele. The differences are that it contains only midgut, never liver, and the abdominal wall above the defect is normal, with the rectus muscles meeting in the midline at the xiphoid. Few associated anomalies are reported with this defect. Like all abdominal defects in which the midgut has not returned to the abdominal cavity before birth to allow for rotation and fixation, these patients have malrotation, although it is not usually a cause of intestinal obstruction.

Umbilical hernia is distinguished from these anomalies by two features: (1) The defect is covered by normal skin, and (2) it is only rarely present at birth, instead usually

becoming apparent in the first weeks or months of life. In the literature before 1970 and in the literature outside pediatric surgery even today, these three forms are often confused, particularly omphalocele/gastroschisis and omphalocele/umbilical cord hernia.

Infants with congenital abdominal wall muscular deficiency, or prune-belly, syndrome have all the normal layers of the abdominal wall but little muscle in the loose areolar tissue. Much of the morbidity is related to similar muscular deficiency in the genitourinary and gastrointestinal tracts.

Other abdominal wall defects, often incompatible with life,[42–44] have been described in humans[45,46] including true absence of abdominal wall structures with evisceration of bowel.[47,48]

# Embryology

## EMBRYOLOGY OF THE ABDOMINAL WALL

At 3 weeks' gestation the flat disk of the embryo develops four folds that will enclose the body cavities (Fig. 75-5, *A* and *B*). Two lateral folds form the pleuroperitoneal canals once they meet anteriorly in the midline. The cephalic fold brings down with it the developing heart, which actually began distal to the brain, but now takes its place within the anterior chest wall. It also carries the septum transversum, which continues posteriorly and divides the pleuroperitoneal canals into the pleural and peritoneal cavities. The caudal fold brings with it the developing bladder or allantois, which started off distal to the anus. During this process the gut tube has formed along the length of the embryo with a communication at the umbilicus to the yolk sac; the yolk sac will eventually disappear, sometimes leaving a vitelline duct remnant on the distal ileum. At about 5 weeks' gestation, this gut tube elongates and develops within the umbilical coelom (Fig. 75-5, *C*), a cavity in the body stalk on the anterior surface of the embryo. At about 10 weeks' gestation the gut returns from the space within the umbilical stalk to the peritoneal cavity and undergoes rotation and fixation.

## EMBRYOGENESIS OF THE DEFECTS

Omphalocele represents a failure of the body folds to complete their journey.[49] Most omphaloceles are lateral fold defects and are always at the umbilicus. The rectus muscles often insert far apart on the costal margins and for this reason cannot be

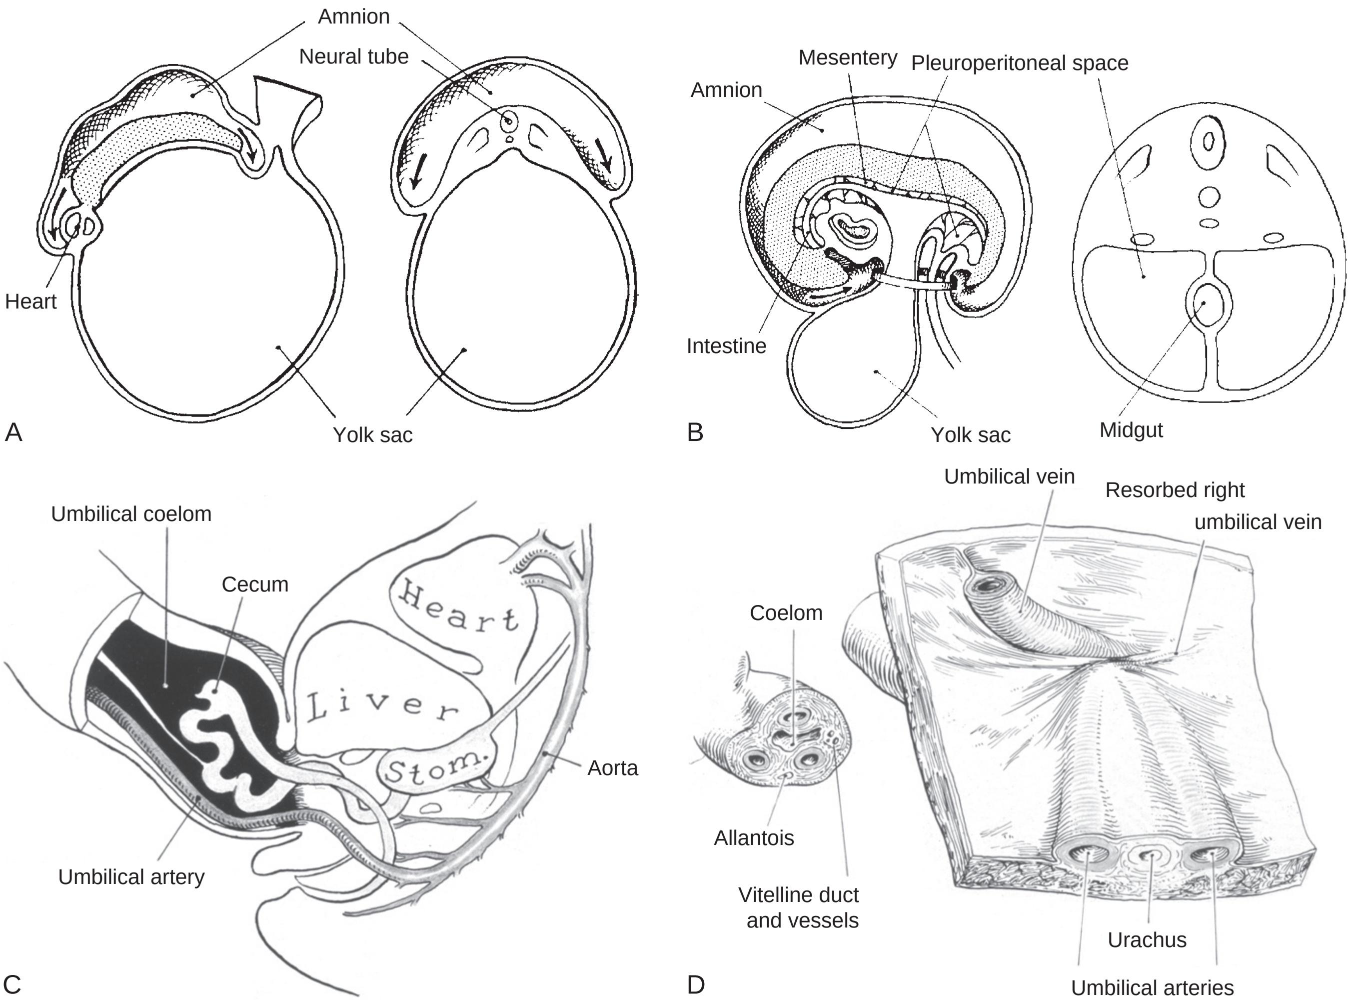

**FIGURE 75-5** Embryology of the abdominal wall. **A,** Two-week embryo as a flat disk before folding to form the body cavities. **B,** At 4 weeks the folding is complete. The gut tube is about to be pinched off the yolk sac. **C,** At 6 weeks the elongating midgut enters the umbilical coelom. **D,** A view from inside the abdominal cavity showing the relatively unsupported right side of the umbilicus as a result of resorption of the right umbilical vein.

brought entirely together in a repair. Whatever the insult may be that causes it, this aberration occurs early in embryogenesis and is thus likely to affect other organ systems as well, so children with omphalocele frequently have associated anomalies. Cephalic fold defects result in ectopia cordis or the pentalogy of Cantrell, whereas caudal fold defects cause bladder and cloacal exstrophy. Gastroschisis, antenatal exposure of the viscera, is probably caused by failure of the umbilical coelom to develop.[50] The elongating intestine then has no space in which to expand and ruptures out the body wall just to the right of the umbilicus, possibly because the right side of the umbilicus is relatively unsupported as a result of resorption of the right umbilical vein at about 4 weeks' gestation (Fig. 75-5, *D*).[51] An alternate explanation that the yolk sac and associated vitelline structures fail to incorporate into the umbilical cord, thus allowing the midgut to exit the abdomen at the point they exit, is also reasonable.[52] Thus gastroschisis has no covering membrane. In gastroschisis the bowel is usually thickened, matted, edematous, and covered with a fibrinous peel. Some have explained the latter appearance on the basis of the change in amniotic fluid electrolyte composition with the onset of fetal kidney function.[53–56] Evidence from studies in animals indicates that the peel forms in utero[57–59] and that it is a postnatal event.[60] Some investigators have related the condition of the bowel to the presence of meconium from the fetus in the amniotic fluid.[19,61] In a recent clinical study, neonates delivered with meconium staining had a fibrinous peel, whereas those without staining had none.[55] Our clinical observation of more than 50 deliveries indicates that the appearance of the bowel is most often a postnatal event (Fig. 75-6). At the moment of birth, the bowel in gastroschisis is usually quite normal. Twenty minutes later it begins to acquire the characteristic changes. These changes may be due to exposure to air, but more likely they are related to mesenteric venous occlusion at the level of the abdominal wall defect with resultant edema and transudation of proteinaceous fluid.

Umbilical cord hernia is a simple failure of the midgut to return to the peritoneal cavity at 10 to 12 weeks. Thus this defect contains only midgut and is covered by a membrane. Such hernias are much smaller than omphaloceles and have a better outlook. Distinguishing umbilical cord hernia from omphalocele both embryologically and clinically is important in managing patients and reporting results. Margulies[61] first translated the embryologic work of Pernkopf[62] and Politzer and Sternberg[63] into English, which permitted Benson, Penberthy, and Hill[64] to recognize it as a separate clinical entity.

**FIGURE 75-6** Gastroschisis at delivery. The bowel does not appear matted, edematous, and coated with a fibrinous peel.

Alternative explanations for these various defects, especially gastroschisis, have been presented, but none have been generally accepted. Some have thought that gastroschisis must represent "failure of mesodermalization" with actual absence of abdominal wall components.[65,66] Although such anomalies have been reported, they are usually stillborn monstrosities. Nearly all live-born children with abdominal wall defects have intact abdominal walls with normal muscle layers. More recently there has been speculation that decreased blood flow in the omphalomesenteric artery might be a cause.[67] This has resulted in many studies on the use of vasoconstrictive agents in the first trimester. Because the omphalomesenteric artery supplies intestine and not the abdominal wall, it is difficult to see how this has gained such credence.

There are many reports of abdominal wall defects induced in animals by exogenous agents. In a comprehensive review of the literature gastroschisis was induced by 22 teratogens, omphalocele by 9, and umbilical cord hernia by 8.[68] Such studies raise the issue of whether the apparent increase in incidence of gastroschisis since 1970 might be due to new environmental teratogens. Studies of abdominal wall defects in animals might not necessarily be relevant. One recent example is the superb work of Brewer and colleagues on the mouse knockout model of congenital abdominal wall defects.[69,70] These investigators demonstrate that the AP-2a transcription factor is important for the normal development of the mouse abdominal wall. They provide beautiful illustrations of the development of the normal abdominal wall and its abnormal development in the knockout model. Yet their careful description allows the clinician to conclude that the defect presented does not represent any of the clinical defects pediatric surgeons see.

Possible causes of abdominal wall defects have also been investigated in clinical material that has recently been reviewed.[71] For gastroschisis, demographic risk factors for which there is more than isolated evidence include young maternal age, low socioeconomic status, absence of the maternal father, poor maternal prenatal care, and primigravida status. Nutritional factors are low levels of glutathione and α-carotene, high levels of nitrosamines, absence of supplemental vitamin intake during pregnancy, folic acid fortification, and general, poor nutrition. Maternal obesity was actually found to be protective. Most, but not all, studies show no familial or genetic risk factors. There is little evidence that living near chemical plants, farms, landfills, or other specific sites is a risk factor. Vasoconstrictive agents are repeatedly reported as related risk factors. Many studies confirmed that use of illegal drugs including cocaine, methamphetamine, and marijuana during pregnancy was a risk factor. Risk factors for omphalocele are different from those for gastroschisis. Demographic factors include both advanced and very young maternal age and maternal obesity. Nutritional factors are failure to use multivitamins during pregnancy (especially Vitamin B 12), lack of folic acid fortification, and alterations in glycemic control. No strong evidence is found for medication, illegal drug, or lifestyle factors, although maternal history of febrile illness and in vitro fertilization do appear to be risk factors.

### GENETICS AND FAMILIAL OCCURRENCE

Although rare, reports of abdominal wall defects, mainly omphaloceles, occurring in families and even in twins have occurred.[72–74] No specific genes have been identified with gastroschisis, but omphalocele is associated with chromosomal anomalies (especially Trisomy 18), and candidates have been reported for specific genes including PITX2, CDKN1C, MTHFR, and 677C-T (folate). OEIS is closely related to caudal fold omphalocele and may be related to a specific gene.[72] Many syndromes include abdominal wall defects. Beckwith-Wiedemann syndrome (congenital abdominal wall defect, macroglossia, and hypoglycemia with a propensity for the development of abdominal tumors later in life) is the most common.[73,74] It is remarkable that the abdominal wall defect in Beckwith-Wiedemann syndrome can be any of the three aforementioned entities, and yet we presume that they all have a different embryogenesis. This syndrome also appears to be associated with assisted reproductive technologies.[75] Other syndromes that include omphalocele are displayed in Table 75-2.

## Antenatal Considerations

### ULTRASOUND

Today, the diagnosis is usually made antenatally by ultrasound (US).[76] Omphalocele can be distinguished from gastroschisis by the presence of a sac and from umbilical cord hernia by the presence of the liver in the defect. The diagnosis allows for antenatal counseling, which given the generally good prognosis, can be reassuring. In a report from 11 European antenatal US registries in 2001, the sensitivity for detecting omphalocele was 75% (range, 25% to 100%), and that for gastroschisis was 83% (18% to 100%).[77] The first age at which omphalocele was detected was 18 ± 6 weeks, and gastroschisis, 20 ± 7 weeks. Only 41% of fetuses with omphaloceles detected antenatally were live-born. Twenty-two percent were fetal deaths, and in 37% the pregnancies were terminated. Fifty-nine percent of fetuses with gastroschisis were live-born, with 12% being fetal deaths and 29% terminations. Recent reports show no significant changes.[78,79]

**TABLE 75-2**
**Omphalocele Syndromes**

| *Name* | *Description* | *Inheritance* | *OMIM #* |
|---|---|---|---|
| Shprintzen omphalocele syndrome | Malformation syndrome that includes mildly dysmorphic facies, omphalocele, scoliosis, learning disabilities, and pharyngeal and laryngeal hypoplasia | Autosomal dominant | 182210 |
| Omphalocele–cleft palate syndrome | Lethal syndrome associated with uterus bicornis in one case, uvula duplex and hydrocephalus internus in another, omphalocele, and cleft palate | | 258320 |
| Beckwith-Wiedemann syndrome (also known as exomphalos-macroglossia-gigantism syndrome [EMG syndrome] and Wiedemann-Beckwith syndrome [WBS]) | Pediatric overgrowth disorder involving a predisposition to tumor development. The clinical presentation is highly variable; some cases lack the hallmark features of exomphalos, macroglossia, and gigantism. Abdominal wall defects common, as well as visceromegaly including liver, spleen, pancreas, kidneys, and adrenals | Inheritance of BWS is complex. Possible patterns include autosomal dominant inheritance with variable expressivity, contiguous gene duplication at 11p15, and genomic imprinting resulting from a defective or absent copy of the maternally derived gene | 130650 |
| Gershoni-Baruch syndrome | Large/giant omphalocele containing liver and intestines. Also associated with diaphragmatic hernia and radial ray defects | Autosomal recessive hypothesis in one case | 609545 |
| C syndrome (Opitz trigonocephaly syndrome, Trigonocephaly syndrome) | Unusual facies, polydactyly, cardiac abnormality, large omphalocele in a few cases | Autosomal recessive mostly, autosomal dominant in a few cases; disruption of the CD96 gene involved with encoding a member of the immunoglobulin family | 211750 |
| Donnai-Barrow syndrome (Faciooculoacousticorenal syndrome) | Facial anomalies, ocular anomalies, sensorineural hearing loss, and proteinuria. Some cases include omphalocele as an associated anomaly | Autosomal recessive; mutation in the LRP2 gene | 222448 |
| Thoracoabdominal syndrome (THAS) | Diaphragmatic and ventral hernias, hypoplastic lung, cardiac anomalies, cleft palate, omphalocele, sporadic pentalogy of Cantrell | X-linked dominant | 313850 |
| Manitoba oculotrichoanal syndrome (MOTA) (Marles syndrome) | Hypertelorism, unilateral eye malformations, aberrant anterolateral scalp hairline, nasal and anal anomalies. Omphalocele noted in several cases | Autosomal recessive | 248450 |
| Craniosynostosis–mental retardation syndrome of Lin and Gettig | Midline craniosynostosis, agenesis of the corpus callosum, severe mental retardation, unusual face, contractures, camptodactyly, hypospadias, hypogonadism, small omphalocele, and multiple small bowel atresias | | 218649 |

*Continued*

**TABLE 75-2**
**Omphalocele Syndromes—cont'd**

| *Name* | *Description* | *Inheritance* | *OMIM #* |
|---|---|---|---|
| Chromosome 9p deletion syndrome | Trigonocephaly, flattened occiput, prominent forehead, broad flat nasal bridge, anteverted nares, malformed external ears, hypertelorism, hypertonia. Omphalocele rare anomaly | | 158170 |
| PAGOD syndrome (agonadism with multiple internal malformations) | Agonadism, hypoplasia of the right pulmonary artery, hypoplasia of the right lung, isolated dextrocardia with complex cardiac malformations, and diaphragm hernia or omphalocele | | 202660 |
| Acrocephalopolydactylous dysplasia (Elejalde syndrome) | Excessive birth weight, swollen globular body with a thick neck, apparently short limbs, polydactyly, craniosynostosis with acrocephaly, omphalocele, and abnormal face | Most likely autosomal recessive | 200995 |
| Popliteal pterygium syndrome (lethal type) (Bartsocas-Papas syndrome) | Popliteal pterygium with a cord containing nerves and vessels, synostosis of hand and foot bones with digital hypoplasia and syndactyly, facial clefts, ankyloblepharon and filiform bands between the jaws, omphalocele, aplasia of the urethra | | 263650 |
| Malpuech facial clefting syndrome (Facial clefting syndrome, gypsy type) | Mental and physical growth retardation, hypertelorism, facial clefting, urogenital abnormalities, eye abnormalities, hearing loss, omphalocele, caudal appendage, umbilical hernia | Autosomal recessive (kindred highly inbred) | 248340 |
| Cerebrocostomandibular syndrome | Severe micrognathia, rib defects, mental retardation, microcephaly, histologic anomalies, omphalocele | Both autosomal dominant and autosomal recessive have been described | 117650 |
| Fryns syndrome | Diaphragmatic hernia, abnormal face, distal limb anomalies* | Autosomal recessive | 229850 |
| OEIS complex | Omphalocele, bladder exstrophy, imperforate anus, and spinal defects | | 258040 |

Data from references 194–198.
*Omphalocele is not reported in OMIM but is noted in several case reports. The first reference also points to other syndromes not noted by OMIM.

Antenatal US also detects associated anomalies.[80] In gastroschisis these anomalies are usually intestinal atresias.[81,82] In omphalocele one study reports a 25% incidence of the detection of major associated anomalies.[83] The frequency of associated cardiac anomalies in omphalocele makes antenatal echocardiography helpful.[84]

Given the poor outcome of all forms of ectopia cordis, termination could be a reasonable alternative when US demonstrates the heart outside the chest. Some ultrasonographers have attempted to correlate the bowel problems of gastroschisis with the antenatal appearance on US,[85,86,90] but this has not been successful in all centers including more recent experience.[82,91,92]

Routine use of antenatal US has not been definitively shown to improve perinatal morbidity or maternal outcome, although there may be some survival benefit for a fetus with a life-threatening anomaly. There may, however, be a cost savings, if the mother chooses termination of pregnancy. Such has not been the case for either omphalocele or gastroschisis,[93] although termination rates for these treatable anomalies can be high (63% in one study).[94] A recent report demonstrated that multidisciplinary prenatal care for mothers carrying pregnancies with gastroschisis produced infants with higher birthweights and greater gestational age, although there was no difference in the outcome for gastroschisis or the likelihood for a successful vaginal delivery.[95]

### AMNIOTIC FLUID AND SERUM TESTS

Elevated alpha fetoprotein (AFP) in both maternal serum and amniotic fluid and elevated amniotic fluid acetylcholinesterase (AChE) have been correlated with abdominal wall defects when there is no myelomeningocele.[96] In a study of 23 pregnancies with gastroschisis and 17 with omphalocele, second-trimester serum AFP was 9.42 times greater than normal in gastroschisis and 4.18 times normal in omphalocele.[97] Another study found elevated amniotic fluid AFP in 100% of pregnancies with gastroschisis and in only 20% of those with omphalocele. AChE was elevated in 80% of pregnancies with gastroschisis and 27% of those with omphaloceles.[98]

## Obstetric Delivery

Intuitively, it may seem appropriate to deliver these patients by cesarean section to avoid injury to the bowel or tearing of the omphalocele sac, and some reports claim a benefit for cesarean section.[99–101] There is also, however, a report of two patients with gastroschisis whose bowel was injured during cesarean section delivery.[102] The more recent obstetric literature finds no benefit of cesarean section.[103–110] Some reports even show no benefit with referral of the mother for delivery in a pediatric surgery center.[111,112] One must conclude that the mode of delivery is a decision to be made by

the obstetrician on the basis of obstetric indications, not on the presence of an abdominal wall defect.

The belief that the condition of the bowel in gastroschisis is due to a relatively late (33 weeks) intrauterine event has led some to recommend preterm delivery.[113] Because we think that the condition of the bowel is a postnatal event, we do not believe that it is worth the risks of prematurity. It seems most likely that the good results observed with preterm delivery by planned cesarean section are related to the fact that it allows for immediate repair and avoids the venous congestion of the mesentery and its effect on the intestine. Others have also found no benefit of preterm delivery,[99] and a recent study shows increased morbidity with preterm delivery.[114]

Antenatal counseling and coordination with the obstetric team are essential. Because the condition of the bowel in gastroschisis and distention of the bowel and size of the liver in omphalocele are often related to the time between delivery and repair, it is important to make arrangements for repair as soon as possible after delivery.[72]

# Clinical Features

## INCIDENCE AND ASSOCIATED CONDITIONS

### Omphalocele

Before 1970, omphalocele was the most common of the abdominal wall defects; it is now the second after gastroschisis. The overall incidence is 1 to 2.5 per 5000 live births[8] with a male preponderance.[115]

Conditions associated with omphalocele are listed in Table 75-3. Up to 45% of patients with omphalocele have been reported to have a cardiac abnormality including ventricular septal defect, atrial septal defect, ectopia cordis, tricuspid atresia, coarctation of the aorta, and persistent pulmonary hypertension of the newborn.[116] Chromosomal abnormalities can be found in up to 20%, and an association with Down syndrome has also been reported.[117] Patients with omphalocele are more likely to be large for gestational age (macrosomia or > 4 kg in birth weight).[118] Musculoskeletal and neural tube defects are also reported in greater than expected incidence.[119,120] Gastroesophageal reflux is more likely, with 43% being affected in one study.[121]

### Gastroschisis

Gastroschisis has become the most common of the abdominal wall defects over the past 30 years.[122–124] This may be related to the increased incidence of prematurity and the increased survival of premature infants in general, or to the fact that it was not until the 1970s that the distinction between gastroschisis and omphalocele was regularly made.[44] The incidence is about 2 to 4.9 per 10,000 live births,[122,125–127] with a male preponderance.[28,115]

The anomalies associated with gastroschisis are usually related to the midgut, with the most common being intestinal atresia (see Table 75-3).[128] In the first year of life infants with gastroschisis are likely to have gastroesophageal reflux (16%)[72] and undescended testicle (15%), although the latter often corrects spontaneously.[129,130] Many reports recognize congenitally short or dysmotile bowel with gastroschisis.[131] Although neither condition has been quantified in terms of severity or incidence, they are certainly lower than the incidence of atresia (<5%).

**TABLE 75-3**
**Associated Conditions**

| *System* | *Gastroschisis (%)* | *Omphalocele (%)* |
|---|---|---|
| Cardiac | 2-12 | 7-47 |
| Respiratory | <1 | 1-4 |
| Central nervous system | 2-10 | 4-30 |
| Musculoskeletal | <1-10 | 4-25 |
| Gastrointestinal | 5-40 | 3-20 |
| Genitourinary | 3-10 | 6-20 |
| Facial | 1-3 | 1-14 |
| Chromosomal | <1-3 | 3-20 |

### Omphalocele

***Initial Care*** Although the bowel in omphalocele is protected by the sac, operation is still urgently needed to increase the chance for primary closure. A nasogastric (NG) tube should be placed early to decompress the intestines. A rectal examination aids this with evacuation of meconium. Maintenance of body temperature is especially important. Ventilator support and supplemental oxygen should be supplied as needed.

Because of the frequency of associated heart defects, cardiology evaluation and echocardiography are in order, although the results will not delay repair.[132] Intravenous fluids are provided at maintenance rates, best through an upper extremity. If not done at birth, 1 mg of vitamin K should be administered, as well as prophylactic antibiotics

The value of primary closure has been debated. Some believe that staged closure is so successful that it is preferable to avoid the possible complications of increased abdominal pressure, which include respiratory compromise, decreased venous return with decreased urine output and cardiac output, compromise of the blood supply to the intestine, and acidosis related to kinking of the hepatic veins as the liver is reduced. Nonoperative initial treatment (painting the sac with an antiseptic) is still useful when operative closure is not possible.[133]

***Operative Closure*** In the operating room the sac and abdomen are prepared with an antiseptic and excess cord is removed. If the patient is hypoxic or unstable, we cannulate and preserve the umbilical artery or vein (or both) for transplantation to the lateral abdominal wall for postoperative monitoring, but this is rarely necessary.[134] We always use plastic adhesive edge drapes to preserve heat. We first attempt to reduce the abdominal contents with the sac intact, as a number of reports suggest.[135–137] Such reduction is often impossible either because the abdominal cavity is too small or because the sac is adherent to the liver and falciform ligament. We then incise the skin a few millimeters from the sac circumferentially around the defect and elevate skin flaps until the rectus muscles can be identified. At this point the sac is excised with ligation of the umbilical vessels and urachus. Any sac adherent to the liver is divided such that some remnants are left on the liver.

If the viscera cannot be reduced, it is helpful to stretch the abdominal wall manually in a posterior-to-anterior direction. The intestine is replaced first and then the liver. The liver

effectively holds the intestine in place, and if skin flap closure should be necessary, the secondary operation will be much safer. For primary closure, mattress sutures are placed through all layers of the abdominal wall except the skin. It is important to place these sutures through the rectus abdominis muscles and not just through the midline fascia, which may result in a postoperative hernia. It will not be possible to appose the rectus muscles in the upper portion of the incision because they insert broadly on the costal margin. It is also not necessary because the liver fills this space. Turning anterior rectus fascial flaps to cover this defect has been suggested, but we have not found this to be necessary. It is best to place the abdominal sutures without tying them and then pull alternate sutures to either side to see how the patient will tolerate fascial closure. If the anesthesiologist can ventilate the patient with peak inspiratory pressures of less than 25 cm $H_2O$, closure is safe. The skin is closed with a running suture, and in most patients this makes a scar that looks like an umbilicus. Several methods have been described for performing a cosmetic umbilicoplasty at the initial operation.[138–141] It often suffices to close the skin incision in a subcuticular purse-string fashion with absorbable suture material while taking every second or third bite to the fascia. However, frequently not enough skin is available for these procedures. In many cases the skin will have a tenuous vascular supply and appear blanched. Adhesive tape should not be used for a wound dressing.

Other methods have been suggested to determine whether the fascial closure is too tight: a saphenous vein intravenous line that will not drip by gravity or intravesical or NG tube pressure greater than 20 cm $H_2O$.[32,142] Splanchnic perfusion pressure (calculated as mean arterial pressure minus intra-abdominal pressure measured either intragastric or intravesical) has been suggested as being an even better predictor.[143] If the fascial closure is judged to be too tight, one can consider only skin closure, but in our experience, if the closure is still too tight after the maneuvers suggested, the skin closure will also probably be too tight. In this case the viscera can be covered with a prosthetic silo that will allow slow reduction of the abdominal viscera over a 1-week period. The simplest of these devices is the preformed Silastic chimney with a spring-loaded ring at the bottom, which is placed though the defect beneath the edges of the abdominal wall (Fig. 75-7).[144] The surgeon can suture this ring to the abdominal wall to prevent the ring from extruding as pressure is applied to reduce the viscera. Antibiotic ointment is applied around the edges as a dressing. If this device is not available, one can use 0.007-inch-thick Dacron-reinforced Silastic. We suture one piece to each side of the abdominal wall so that the knots are on the outside and the edges of both the fascia and Silastic face out. We then separately suture up the inferior and superior edges and over the top (Fig. 75-8).

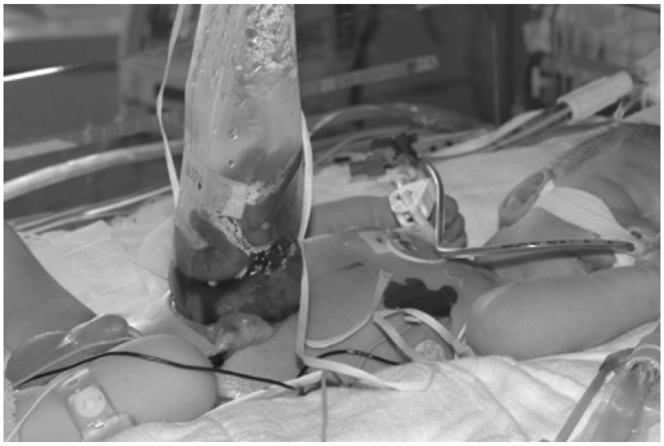

FIGURE 75-7 Gastroschisis with bowel contained in a preformed Silastic silo.

FIGURE 75-8 Gastroschisis with bowel contained in a hand-sewn Silastic silo.

We do not perform a Ladd procedure or appendectomy. If a testicle is present in the sac, it can be placed in the abdominal cavity because in most cases it will be in the scrotum in a year. If an obvious atresia is present, we may bring out a single stoma through normal abdominal wall or simply leave the atresia in the abdomen and wait at least 6 weeks before reoperating.

Most pediatric surgeons agree that giant omphalocele is a separate category of defect that is particularly difficult to treat and which has a much poorer outcome than the usual lateral fold defect.[145] As eloquently described by Campos and colleagues, there is no standard definition of this entity in terms of size or amount of herniated viscera.[146] It simply consists of a degree of visceroabdominal disproportion that defies treatment with fascial or even skin closure whether applied primarily or after a staged closure. A recent report from the Children's Hospital of Philadelphia[147] defines both in utero and newborn giant omphalocele as one with 75% or more of the liver in the sac. Unfortunately they did not present a technique for determining the volume of the liver, so this may also be open to individual interpretation. It is often accompanied by respiratory symptoms.[148] The Philadelphia series is valuable in documenting 31 patients in a 6-year period with 25 survivors. Seventy-one percent required intubation in the first hour of life, and 40% of survivors had chronic lung disease. More than half of the survivors had associated anomalies, more than half had neurodevelopmental disability at 1 year of age, and three fourths had feeding problems.

Giant omphalocele requires some imagination and creativity to treat.[149] Suggestions have included painting the sac with antiseptic,[150] the use of skin flaps with grafting to the open areas remaining,[151] use of tissue expander,[152] and split-thickness skin grafting.[153] We have tried on several occasions to use Gore-Tex and then place skin flaps or grafts over the Gore-Tex, with failure on each occasion as a result of

sepsis and sloughing. However, it has been possible to use flaps or grafts on the granulating surface that occurs after removing the Gore-Tex, and the underlying pseudocapsule seems to stabilize the abdominal wall. Using an absorbable material covered by a VAC sponge dressing is an appealing alternative.[154,155] The use of tissue expanders to either expand the abdominal cavity or obtain more skin in older infants is also an option.[28,156]

***Postoperative Care*** With primary closure, most patients require assisted ventilation initially, but over a period of several days the abdominal wall accommodates the abdominal contents. Intravenous fluids are administered at 150 mL/kg/hr or more to maintain urine output at 1 mL/kg/hr. A central intravenous line is placed for parenteral nutrition. Short-term antibiotics are administered if primary closure has been performed, but antibiotics are continued until completion of staged closure with a prosthesis. The wound is managed with antibiotic ointment, and the sutures are removed at 3 weeks. We keep a 10-French sump NG tube on low intermittent suction until there is evidence of bowel function including stooling, decreased distention, and reduced NG tube output. The tube is then removed, and 12 hours later feedings are begun gradually. It is not unusual for the appearance of bowel function to be delayed. If intestinal function has not resumed in 3 weeks, a small bowel contrast study may be indicated.

If a prosthesis has been used, it is usually appropriate to initiate reduction of the abdominal contents on postoperative day 1. Reduction is accomplished simply by manual manipulation, which can then be secured in many ways: applying long clamps suspended by umbilical tape to the overhead warmer, applying a TIA 90 stapler, running a suture back and forth, or using umbilical cord clamps (Fig. 75-9). A particularly ingenious method is a ringer mechanism,[157] but it is not commercially available. Simply tying the prosthetic sac with umbilical tape leaves a larger circular defect than closing it side to side does. One might consider adding several sutures to each side outside the prosthesis when it is applied. These sutures can then be tied once the prosthesis is flat to further appose the edges.

**FIGURE 75-9** Reduction of intestine contained in a preformed Silastic silo.

Despite Schuster's original hypothesis, it is unlikely that the abdominal wall grows during reduction.[23] It is more likely that the edema of the bowel wall resolves and the intestinal contents are emptied while the abdominal wall is simply stretched.

The several methods of measuring intra-abdominal pressure discussed earlier were originally used to monitor primary closure and then reduction of a prosthesis. The most important lesson learned from these studies is that we had been reducing the abdominal contents too slowly, usually every other day. It is important to be aggressive. Most often the prosthesis can be removed and the abdominal wall closed in 7 days. If it is not performed by 14 days, the prosthesis may begin to separate from the abdominal wall. Recently, Jona suggested that active reduction may not be necessary.[158] In his small series no pressure was applied to the silo, and the abdominal contents spontaneous reduced by day 8.

If skin flaps have been used, the definitive repair can be done at any time, depending on the patient's general condition. If the intestine begins to grow into a large skin sac instead of stretching the abdominal cavity, an abdominal binder can be used to direct forces inward. When it is time to bring the fascia together, the skin can be dissected off the liver with little trauma other than some mild bleeding that will stop with pressure. If the edges of the muscular abdominal wall cannot be brought together, a prosthetic mesh patch can be used as long as it can be entirely covered by healthy skin. If a part of it must be left exposed, it is unlikely to be incorporated and will become infected or extruded. If one can predict that skin flap closure will not be possible initially, it is probably best to avoid dissecting flaps so that that tissue will be healthier when it is time for the final repair.

If a postoperative hernia occurs, it can usually be repaired at 1 year of age without the use of a prosthetic patch. In occasional patients the hernia resolves spontaneously.

## Ectopia Cordis Thoracis and Cephalic Fold Defect

Operative repair of ectopia cordis thoracis and cephalic fold defects is especially challenging. It is difficult to replace the heart in the thoracic cavity without kinking the great vessels or the pulmonary veins. Coverage with soft tissue to gain time can result in cardiac tamponade, so wide intrathoracic dissection around the heart and great vessels has been advocated to increase the space within the chest. The fascia of the abdominal wall is closed once cardiorespiratory stability has been achieved. In ectopia cordis thoracis, it is also important to provide a rigid covering for the heart. This has been performed with rib struts between the sternal halves and with prosthetic material. Reported repairs of these difficult clinical problems emphasize creative use of available tissue and individual anatomic features.[159–162] In the cephalic fold defect (pentalogy of Cantrell), the sternal cleft and pericardial defect need no special treatment. We have used immediate skin closure of the omphalocele and allowed the patient to grow and have the intracardiac defect treated later. A Gore-Tex patch can then be used to close the central tendon of the diaphragm with no tension so that the heart can extend somewhat into the abdomen. With growth the patch becomes taut and elevates the heart slowly into the chest, which can grow to receive it. A valuable recent review of the literature has been published.[163]

### Caudal Fold Defect

This complex problem is more completely dealt with in Chapter 120. Initial management might consist of closure of the omphalocele and creation of a colostomy. Preservation of intestinal length including salvage of any colon that might be attached to the bladder plate before creating a colostomy is especially important. Lund and Woo have reviewed this topic well.[164,165]

### Gastroschisis

***Initial Care*** Two features of gastroschisis make initial care somewhat different from that of omphalocele. The patient is frequently premature, and closer attention must be paid to heat preservation, respiratory support, and the large surface area of exposed intestine. The latter is also responsible for increased fluid needs and heat loss. Perhaps the best way to control this problem is to place most of the infant immediately in a plastic drawstring bowel bag to control evaporative heat and fluid loss.[166] Because in most cases the intestine will be perfectly normal immediately after delivery whether the delivery is vaginal or cesarean, the faster the bowel can be reduced, the more likely primary closure can be achieved and the less bowel wall edema and fibrinous coating will accumulate.

Previously we chose to deal with this issue by operating immediately after delivery[167] because our obstetricians preferred cesarean delivery for all children with abdominal wall defects. As more obstetricians become convinced by the literature that the route of delivery does not affect outcome in gastroschisis, fewer cesarean sections are scheduled. A review of our more recent data indicates that rapid transfer from the delivery room to the operating room (<1 hour) will also lead to a greater likelihood of primary closure.[167a] When the delivery room and the pediatric operating room are in the same hospital, this is much easier to arrange.

***Operative Technique*** Time is taken to wipe the vernix caseosa carefully from most of the baby to facilitate many of the subsequent maneuvers. If there is no immediate respiratory distress, an intravenous line is started, monitoring equipment is applied, and the patient is intubated. It is helpful to evacuate meconium from the rectum by anal dilatation. It has generally been assumed that patients with gastroschisis will have a volume deficit because of the large surface area of the mass of eviscerated intestine. Yet a recent Canadian study suggests that limiting preoperative fluid resuscitation will improve outcomes.[168] While the anesthesiologist is involved with these activities, the surgeon holds the umbilical cord up and, loop by loop, reduces the intestine. In most cases, by the time that the patient is ready for skin preparation, the bowel has been totally reduced. Other operative maneuvers and postoperative care are similar to that described for omphalocele. A satisfactory cosmetic closure can be obtained for gastroschisis by leaving the entire umbilicus intact during the initial stages of the procedure (Fig. 75-10). The vessels and urachus can be divided at the level of the peritoneum after trimming the cord. A subcuticular skin closure is then performed with the umbilicus being the left edge of the midportion of the incision, or often the entire incision, because the defect can often be quite small with gastroschisis or umbilical cord hernia.

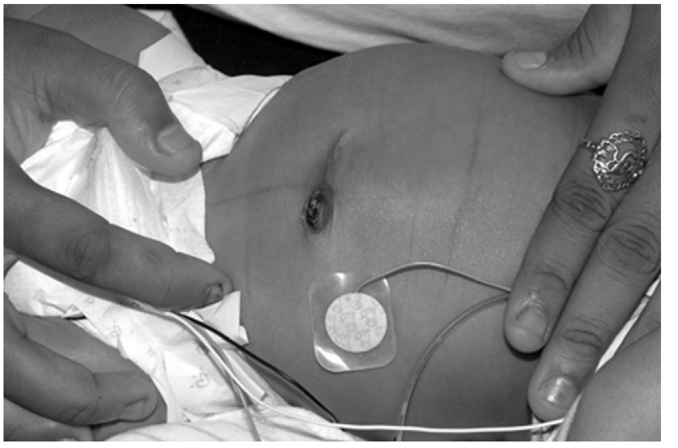

**FIGURE 75-10** Gastroschisis with cosmetic closure obtained by preserving the umbilicus.

In several centers the spring-loaded preformed Silastic pouch (Bentec bag) is frequently placed at the bedside on arrival of the patient.[169,170] Reduction can then be performed also at the bedside, and the patient is taken to the operating room only for final closure. Kidd and colleagues have found that with this technique, they perform fewer primary closures (34% vs. 84%) and have a somewhat longer length of stay (38 days vs. 30 days), but the mortality (3% excluding those with lethal associated anomalies) and time until full feeding are no different.[171] They did, however, report fewer ventilator days, infections, strictures, reoperations, and episodes of necrotizing enterocolitis. Bianchi and colleagues have also shown that waiting several hours to reduce the intestinal mass may not be as deleterious as has been supposed.[172,173] In a 2008 multicenter prospective trial comparing bedside placement of the silo to primary closure, there was a trend to fewer days on the ventilator for the bedside silo group, but no difference in days on TPN, length of stay, incidence of sepsis, or incidence of necrotizing enterocolitis.[174] A study from Stanford showed good results with sutureless closure, which is performed either initially with reduction of the bowel or secondarily after reduction of the Bentec bag.[175] The umbilical cord is laid over the small residual defect and held in place with an adhesive, microporous dressing.

Management of complicated gastroschisis must be individualized.[128] Often an atresia can simply be placed in the abdominal cavity and repaired 6 weeks after the abdomen has been closed with native tissue, whether skin or fascia. A stoma can also be brought out through normal abdominal wall lateral to a prosthesis. This usually requires sewing on Silastic sheets because the spring-loaded ring of the Bentec bag will interfere with stoma placement. The most shrunken nubbins of bowel can be surprisingly useful 2 to 3 months after residence in the abdominal cavity.[176] If they cannot be exteriorized, perforations and other complex wounds can be treated with a VAC sponge dressing.[177]

### Umbilical Cord Hernia

This defect is easily reduced by holding the sac upward and gently massaging the bowel into the peritoneal cavity. The fascia can always be closed primarily, and a cosmetic umbilicoplasty is nearly always feasible.

# Complications

Complications may be related to prematurity (in gastroschisis), associated anomalies (in omphalocele), gastrointestinal tract anomalies (in gastroschisis), and a closure that is too tight. Mention has already been made of the increased fluid needs and delayed recovery of bowel function. It is important to be prepared to treat the problems of prematurity including heat loss, respiratory failure, hyperbilirubinemia, hypoglycemia and hyperglycemia, and hypocalcemia. In managing respiratory distress it is important to obtain blood for capillary blood gas analysis from the upper extremities because the lower extremities are likely to be edematous and congested. Patients with gastroschisis and ruptured omphalocele are frequently hypovolemic. Philippart and colleagues studied fluid resuscitation in patients with both gastroschisis and omphalocele by using muscle pH as an indication of adequate perfusion and resuscitation.[178] They found that all infants needed at least 25% of estimated blood volume during surgery (17 to 80 mL/kg in 45 to 120 minutes) and required 82 to 312 mL/kg in the first 24 hours of life. Urine output is a good monitor of volume in neonates. Treatment of most of the gastrointestinal tract anomalies can be delayed. In omphalocele, the bowel may be normal enough to sustain an anastomosis, but edema accumulates in all tissues and the liver expands with the length of the operation.

A closure that is too tight can lead to ventilatory compromise, decreased venous return and low cardiac output, and oliguria. The remedy is to return the patient to the operating room to remove the fascial sutures and perform skin closure only. One may need to add a prosthesis. If a prosthesis has been used initially, it may be possible to open it at the bedside and reclose it more loosely. In omphalocele, postoperative metabolic acidosis can develop as a result of kinking of the hepatic veins from reduction of the liver. In this case, removal and refashioning of the prosthesis may be necessary.

All these patients tend to have a slow onset of bowel function, no matter how quickly the defect is reduced or how normal the bowel appears. Bowel function seems to return faster in patients with omphalocele than in those with gastroschisis.[179]

# Outcome

## SHORT TERM

The survival rate for gastroschisis is 90% in most series.[121,180] In a registry study in Texas, the survival rate of infants with gastroschisis was 93% in 1995-1997.[181] In a study from Manchester, United Kingdom, a 94% gastroschisis survival rate was obtained.[182] Of the seven patients who died, five died of overwhelming sepsis. Primary fascial closure was achieved in 80%. The median time to feeding was 30 days (range, 5 to 60 days), and the median length of stay was 42 days (range, 11 to 183 days). Those who required a silo or had associated intestinal atresia (8 of 91 patients) required more time until feeding and had a greater length of stay, but no increased mortality. In a 2010 report based on 2490 patients in the Pediatric Health Information System (PHIS) database created by the Child Health Corporation of America (Kansas City, Mo.) the overall survival was 96.4%. Associated conditions included cardiovascular 15%, intestinal resection 12.5%, intestinal atresia 11%, ostomy formation 8.3%, and pulmonary 5%.

Survival rates for omphalocele range from 70% to 95%, with most of the mortality being related to the associated cardiac and chromosomal anomalies.[180] In a report from Los Angeles, there was no difference in mortality from omphalocele for birth weight, size of the defect, or type of initial closure.[183] They also reported no significant change in mortality from 1960-1970 (23%) to 1970-1980, when it was 19%. Mortality was mainly related to associated anomalies. For their patients with gastroschisis, survival rates did increase in the more recent decade to 91%, and mortality was attributed to prematurity, bowel complications, and *Candida* sepsis associated with total parenteral nutrition.

Few patients survive any form of ectopia cordis,[184,185] but Groner does report one normally active 12-year-old who wears a plastic shield to cover the as yet unreconstructed bony defect.[186] O'Gorman and colleagues reported seven patients with pentalogy of Cantrell, of whom four survived and three were free of a ventilator.[187] Nearly all patients with caudal fold defects survive, although bowel and urinary tract function vary.[165]

## LONG TERM

In a report from The Netherlands in 2009 on 111 patients with omphalocele treated between 1971 and 2004, 20% of the patients died, almost all related to associated congenital anomalies.[188] Readmission was required at some time in 70%. The most frequent later operations were inguinal hernia, tonsillectomy, adenoidectomy, myringotomy tubes, fundoplication, bowel obstruction, malrotation, orchidopexy, and cosmetic revision of abdominal scars. Thirty percent of patients were still taking medication of some sort. Only 3 patients ever had the feeling that omphalocele interfered with their choices of activities or professions, and 10 reported that omphalocele did affect some social relationships (teasing).

Davies and Stringer interviewed 25 of 35 patients who underwent surgery for gastroschisis between 1972 and 1984 and survived longer than 1 year.[44] Their median age was 16 years. Ninety-six percent were in good health and experienced normal growth, and 35% required further surgery related to gastroschisis, two for small bowel obstruction and three for scar revision. Fifty-seven percent reported that absence of an umbilicus caused them some distress during childhood. In 25 school-aged children with gastroschisis reported from Oregon, 7 were held back a grade or enrolled in special classes, but all participated in normal physical activities.[180] Eighty-four percent of these patients reported normal bowel movements. Those with abdominal complaints were usually evaluated as nonspecific or functional. Of 22 patients who required bowel resection at the initial operation, 10 had bowel complications, whereas only 2 of the 68 without a bowel resection had such complications. Ten percent of all patients underwent further surgery for abdominal wall hernia, scar revision, or undescended testis. In 2009 the Canadian Paediatric Surgical Network reported a contemporary survival of 95%.[109]

In a combined series of omphalocele and gastroschisis reported from Oklahoma City, 94 patients had an 88% survival rate.[189] There was long-term follow-up in 61 patients for a mean of 14.2 years. Nineteen needed 31 reoperations, mainly for abdominal wall hernia and intestinal atresia. Eighty percent described their quality of life as good, but 40% were

concerned about their height and felt inadequate in sports and social activities. Many also expressed concern about the absence of an umbilicus. Another combined series with a mean age at follow-up of 8.8 years was reported by Lindham from Sweden.[190] He noted several episodes of bowel obstruction in the first year of life, recurrent abdominal pain without a specific abnormality, and some concern in girls about the scar and absence of an umbilicus. Growth and development, however, were normal.

In a study from the United Kingdom, patients with gastroschisis averaged the 32nd percentile for weight at 5 years of age and the 52nd percentile after that.[191] With complicated gastroschisis (such as gastroschisis associated with intestinal atresia), they reached only the 25th percentile. The group from Stanford[192] found that most survivors of omphalocele and gastroschisis had poor weight gain. None had gastrointestinal or metabolic problems at 3 years of age on the basis of imaging studies, fecal fat excretion, and serum chemistry. One third had IQ lower than 90, and this was related to the length of hospitalization and nongastrointestinal anomalies.

Koivusalo and colleagues from Finland sent detailed questionnaires to 75 patients older than 17 years with congenital abdominal wall defects (16 with omphalocele, 11 with gastroschisis) and received a response from 76%.[193] The only illness found more frequently than in the general population was rheumatoid arthritis in 7%. Thirty-seven percent reported some morbidity related to the scar and absence of the umbilicus, 51% had functional gastrointestinal disorders, and 12% had low self-esteem. Still, 88% reported that they were in good health, and their quality of life and educational levels were no different from that of the general population.

Adverse late cardiorespiratory and pulmonary effects are seldom found in patients with either omphalocele or gastroschisis.[179] Many children do express concern later in life about the absence of an umbilicus. Although both the short-term and long-term outlook for patients with ectopia cordis and both cephalic fold and caudal fold omphaloceles is guarded, patients with lateral fold omphalocele, umbilical cord hernia, and gastroschisis have an excellent survival rate and long-term prognosis. Most problems are related to associated conditions, not to the abdominal wall defect or its repair.

# CHAPTER 76

# Inguinal Hernias and Hydroceles

Philip L. Glick and Scott C. Boulanger

## History

Inguinal hernias have been recognized at least as far back as 1500 BC. What appears to be an inguinal hernia has been found on an ancient Greek statuette, and Egyptian writings describe groin bulges elicited by coughing (the Papyrus of Ebers, ca 1552 BC).[1] There is also evidence to suggest that surgery for hernias had been performed as early as 1200 BC. The Roman physician Celsus is credited with some of the earliest surgery for inguinal hernia, circa 50 AD.[1] About that same time Galen described the anatomy of the processus vaginalis; however, he believed that hernias were the result of "rupture" of the peritoneum with stretching of overlying muscle and fascia.[1] This is where the slang term for hernia, "rupture," may have had its derivation.

Modern hernia surgery began in the nineteenth century when an accurate understanding of the anatomy of the inguinal canal became available.[1] Richter, Camper, and Scarpa, among others, contributed to the field during this period. Cooper in 1804 described the transversalis fascia and pectineal ligament, or Cooper ligament. In 1811 Colles described the reflection of the inguinal ligament, and in 1817 Cloquet described the processus vaginalis and noted that it was rarely closed at birth. With a thorough understanding of inguinal anatomy, modern hernia surgery had only to await the development of aseptic techniques of surgery.

In 1870 Lister introduced the concept of antisepsis in surgery, and in 1896 Halstead began operating with gloves.[1] In 1904 Von Mickulicz took aseptic surgery one step further. These developments allowed rapid progress to be made in hernia surgery. In 1871 Marcy described an operation still in use by pediatric surgeons to this day: high ligation of an unopened sac through the external ring and tightening of the internal ring. This technique, however, had an unacceptably high recurrence rate in adults.[2] In 1887 Bassini reported his results using a technique involving opening the external oblique, high ligation of the sac, tightening of the external ring, and reconstruction of the posterior inguinal floor.[2] Along with Halsted, Bassini is credited with the development of the modern hernia repair.

## Incidence

Inguinal hernia repair remains the most common operation performed by pediatric surgeons. The reported incidence of inguinal hernia in children ranges from 0.8% to 4.4%.[3]

### AGE

Inguinal hernia most commonly presents during the first year of life with a peak during the first few months. Approximately one third of children are younger than 6 months of age at the time of operation.[3] The highest incidence of hernia is found in premature infants, 16% to 25%.[4,5] This correlates fairly well with the patency rates of the processus vaginalis. At birth 80% are patent and the rates decrease dramatically by the first 6 months of age.[6] However, all indirect hernias, regardless of age at presentation, are likely secondary to failure of the processus vaginalis to close completely during fetal and newborn development.

### SEX

Males are much more likely to have hernias, with the reported male-to-female ratios between 3:1 and 10:1.[3] Although premature infants have a higher incidence of hernia, there does not appear to be a significant gender difference at this age.[7–9]

### SIDE

Approximately 60% of hernias are right sided.[10] This is true for both males and females. In males, this is possibly the result of later descent of the right testicle than the left, but this does not explain the observation in females. Bilateral hernias are present approximately 10% of the time.[10] It has been suggested that patients with left-sided hernias are more likely to develop a right-sided hernia than vice versa.[11,12] More recent data, however, suggest that this may not be true.[13–15]

### FAMILY HISTORY

Approx 11.5% of patients have a family history.[3] There is an increased incidence in twins as well, about 10.6% in males and 4.1% in female twins.[16]

## Embryology

Indirect inguinal hernias are fundamentally the result of failure of closure of the processus vaginalis (Fig. 76-1). The processus vaginalis is an evagination of the peritoneum through the internal ring, which can first be identified during the third month of fetal life.[17] Some have suggested that formation of the processus vaginalis is a result of intra-abdominal pressure,[18] whereas others believe this to be an active process.[19,20] The intra-abdominal testis passes through the processus during the seventh to ninth months of gestation. During this time the processus elongates. Following this, the portion of the processus vaginalis lying above the testicle obliterates, closing the internal inguinal ring, while the distal portion persists as the tunica vaginalis. Failure of this to occur results in patency of the processus vaginalis and potentially an indirect inguinal hernia (if bowel or other organs can enter the processus) or a hydrocele (peritoneal fluid only). In females the canal of Nuck corresponds to the processus vaginalis and communicates with the labia majora, the female homologue of the scrotum. The canal of Nuck normally closes around the seventh month of gestation, earlier than in males.

The exact timing of closure is uncertain. Studies have suggested that up to 80% to 100% of infants are born with a patent processus vaginalis and that closure, if it occurs, is most likely to happen within the first 6 months of life.[6,21] After 6 months of age, patency rates fall more gradually and plateau generally around age 3 to 5. It also appears that the left side closes earlier than the right. Where in the processus closure begins (i.e., proximal, middle, or distal) is unknown. After closure of the processus, it persists as a cord, which subsequently disappears and becomes incorporated into the external spermatic fascia. The high rate of patency associated with undescended testis suggests that closure most commonly occurs only after descent of the testicle or that these processes are linked.

The biologic mechanisms that signal and induce descent of the testicle through the inguinal canal and obliterate the processus are for the most part unknown. Androgens appear to play a role because patency of the processus is common in androgen insensitivity syndrome. However, the processus itself has no androgen receptors. Work from Hutson and colleagues has implicated the genitofemoral nerve (GFN) and calcitonin gene–related protein (CGRP) in both testicular descent and obliteration of the processus vaginalis.[17] They have suggested that reduced CGRP release from the GFN prenatally may result in undescended testis, whereas reduced CGRP postnatally may lead to hernias and hydroceles.

Although it is clear that a patent processus vaginalis is a prerequisite for an inguinal hernia, it is not sufficient and other factors are involved. Table 76-1 provides a list of other contributing factors that have been identified.

## Clinical Features

Inguinal hernias (unless otherwise indicated in this chapter, inguinal hernia refers to an indirect inguinal hernia) are generally found by parents at bath time or during well-child examinations by their pediatricians. There is typically a history of intermittent bulge in the groin, labia, or scrotum. It is most often apparent when there is increased intra-abdominal pressure such as during episodes of crying or straining. When taking the history of present illness, it is important to sort out inguinal hernias from communicating hydroceles, undescended testis, and inguinal adenopathy. Hernias may present at birth or not until days, weeks, months or even years later, but the defect to a variable extent has been there since birth. This point becomes important to remember when asymptomatic hernias are found, in terms of the timing of surgery (i.e., not an emergency) and the activities children should be allowed to participate in while awaiting repair (i.e., no restrictions if asymptomatic).

**TABLE 76-1**
**Factors Contributing to the Development of an Indirect Inguinal Hernia**

| |
|---|
| Urogenital |
| Undescended testis |
| Exstrophy of bladder |
| Increased peritoneal fluid |
| Ascites |
| Ventriculoperitoneal shunt |
| Peritoneal dialysis |
| Increased intra-abdominal pressure |
| Repair of exomphalos or gastroschisis |
| Severe ascites (e.g., chylous) |
| Meconium peritonitis |
| Chronic respiratory disease |
| Cystic fibrosis |
| Connective tissue disorders |
| Ehlers-Danlos syndrome |
| Hunter-Hurler syndrome |
| Marfan syndrome |
| Mucopolysaccharidosis |

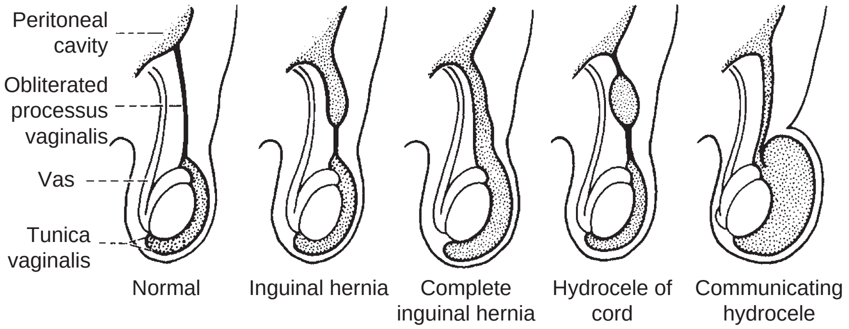

**FIGURE 76-1** The most common variants of hernias and hydroceles arising from failure of complete obliteration of the processus vaginalis.

Hernias are usually asymptomatic. Because hernias often appear during episodes of infant distress, parents often feel the hernia is the cause of these symptoms. Unfortunately, many of these perceived symptoms persist after the repair. Older children often complain of groin or inguinal "pain" during exercise.

Incarcerated hernias result from entrapment of bowel or other viscera within the hernia sac. Debate has continued as to whether "entrapment" occurs at the internal or external ring. The answer is that it can occur at both, but predominately at the level of the internal ring. This can cause intermittent pain and irritability. Subsequently, signs of bowel obstruction result, such as distension, vomiting, and obstipation. If the hernia is not reduced, blood supply to the incarcerated organ may be compromised to the point of infarction, "a strangulated inguinal hernia." The patient may present with peritonitis at this point. This process can occur in as little as 2 hours. Incarceration occurs most commonly in the first 6 months of life and after age 5 is relatively rare.

The concern in this younger population is that they are preverbal and their caretakers may not recognize the signs and symptoms of an incarceration in a timely manner. We instruct our families of preverbal infants with hernias waiting for elective surgery that the differential diagnosis of a crying baby includes (1) needs to be fed, (2) needs a diaper change, (3) needs a nap, and (4) "needs an operation" (may have an incarcerated hernia). We also instruct the families of the signs and symptoms to be aware of.

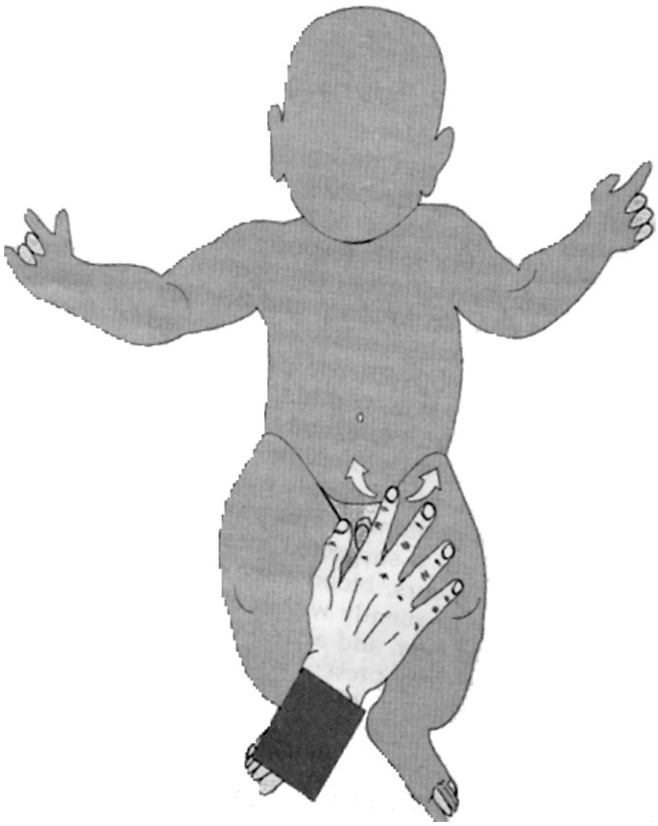

**FIGURE 76-2** Examination for an inguinal hernia. A single finger is laid over and parallel to the inguinal structures, and the finger is rubbed across the cord from side to side at the level of the pubic tubercle.

## Examination

To examine for an inguinal hernia, the patient is placed supine and undressed on an examining table in a warm room. The examiner first observes for an inguinal mass or asymmetry of the groins. The testis should be "trapped in the scrotum" with a finger across the top of the scrotum to account for both testes and to sort out true inguinal bulges from retractile testis. If no mass can be identified, the older child should stand and perform a Valsalva maneuver. An infant may be allowed to strain or cry to provoke an inguinal bulge to appear. If a mass is still not present, the spermatic cord can be palpated to determine thickening (the silk glove sign).[22] This is performed by laying a single finger over the spermatic cord at the level of the pubic tubercle. The finger is lightly rubbed over the cord from side to side over the pubic tubercle (Fig. 76-2). A positive silk glove sign indicates that the cord structures within the inguinal canal are thickened compared with the normal side. The examination imparts to the examiner the sensation of rubbing two pieces of silk together or the sensation of feeling a plastic bag with a few drops of water in it ("plastic baggy sign"), but these signs are not completely accurate and are subjective.

If a hernia is not demonstrable on physical examination, some surgeons will still operate if the hernia has been seen previously by a physician or if the parents give a thorough history.[23] However, with parental education, follow-up examinations, or modern radiologic techniques, unnecessary surgery can be avoided in equivocal cases. Additionally, advantage can be taken of photographic documentation by the parents. Kawaguchi and Shaul (2009)[24] found that they could accurately diagnose an inguinal hernia in equivocal cases using parents' digital images.

## Radiologic Investigations

In most cases the diagnosis of an inguinal hernia can be made by history and physical examination alone. However, in a small subset of patients radiologic testing may be of value. Previously, the technique most commonly used had been contrast herniography, but this has now been replaced by inguinal ultrasonography (US).

Herniography is performed by injecting water-soluble contrast material into the peritoneal cavity via an infraumbilical fluoroscopic-guided injection.[25] Gravity will allow the contrast material to pool into the hernia sac, which is identified by plain radiographs taken at 5, 10, and 45 minutes apart. Hydroceles can be identified by this technique, and femoral hernias can be differentiated from inguinal hernias. This test is also useful for detecting contralateral hernias or in postoperative patients with recurrent ipsilateral groin symptoms. It has no value, however, for incarcerated hernias because the neck of the sac is occluded in those cases. Complication rates for this technique are rare and include intestinal perforation, intramural intestinal hematoma, and allergic reactions to the contrast media.[25,26] Despite this, herniography had not found widespread use.

US has gained some popularity as an adjunct to the physical examination. It has the advantage of being rapid,

noninvasive, and complication free. Chen and colleagues[27] performed US on 244 boys presenting with either unilateral or bilateral hernias. US was performed on both groins. They noted an accuracy of 97% when using 4 mm as the upper limit of the normal diameter of the inguinal canal. In a series of 642 children, Erez and colleagues[28] noted that a preoperative measurement of the inguinal canal of $3.6 \pm 0.8$ mm was associated with normal findings at surgery, whereas $4.9 \text{ mm} \pm 1.1$ mm was associated with a patent processus vaginalis and $7.2 \pm 2$ mm or greater was associated with a true hernia.[28] Therefore using appropriate measurements, US is a reliable tool for diagnosing hernias when a good history is present, but the examination is equivocal and is potentially useful for preoperative evaluation of the contralateral groin in patients presenting with unilateral hernias (Fig. 76-3).

# Management

An inguinal hernia will not resolve spontaneously, so surgical closure is always indicated. Because of the high risk of incarceration, particularly in young infants, repair should be performed expeditiously. Some reports suggest 90% of complications can be avoided if repair is undertaken within 1 month of diagnosis.[29,30] More recently Langer and colleagues found that repair undertaken within 2 weeks decreased the rate of incarceration by half compared with a 30-day wait. Furthermore, most patients can be done safely in an ambulatory setting. Exceptions include premature infants and older children with significant risk factors such as cardiac or respiratory problems. Choice of anesthetic type varies with the patient. Although most patients are treated under general anesthesia with endotracheal intubation or laryngeal mask, several other options exist and the choice of technique depends on several factors including age and significant comorbidities.

## ANESTHESIA

As mentioned earlier, numerous techniques exist for patients undergoing inguinal hernia repair. They can be classified as general, regional, or local techniques. Healthy full-term infants and older patients are generally treated under general endotracheal anesthesia, and this has been found to be extremely safe. However, others, particularly premature infants (>36 weeks gestational age and gestational age plus chronologic age younger than 60 weeks) (see later), require a more varied approach. Regional techniques (spinal, epidural, or caudal anesthesia) are often chosen in these situations. Although each has its proponents, none has been shown to be definitively superior. A recent review of the Cochrane database found several small trials comparing regional versus general anesthesia. No statistical difference was demonstrable in the proportion of premature infants having postoperative apnea/bradycardia, respiratory rate, or postoperative oxygen desaturations. However, the total enrolled number of patients in the trials was only 108.[31]

Postoperative pain control has also been a matter of some debate. Caudal blocks are routinely performed in some centers, whereas other centers use instilled local anesthetic. A recent randomized prospective trial comparing instillation of 0.25% bupivacaine without epinephrine (2.5 mg/kg) versus caudal block found no difference in the level of postoperative

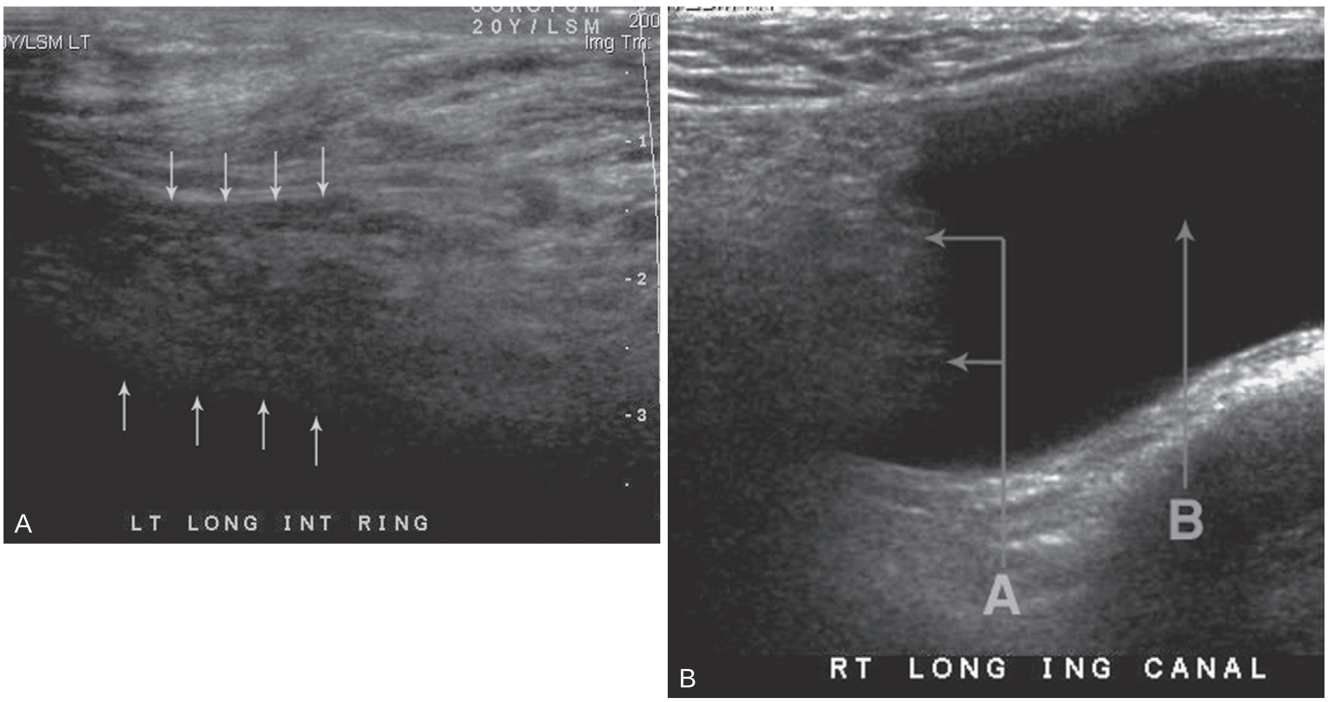

**FIGURE 76-3** Ultrasound examination of the inguinal canal. **A,** No hernia. The arrows outline the normal inguinal canal. The strands are the vas deferens and cord structures. Using Doppler imaging, signals to the scrotum and venous signals to the IVC would be seen. **B,** Inguinal hernia. The double arrow points to the leading edge of incarcerated viscera. If it were bowel, peristalsis would be evident; if it were omentum, it would not. The single arrow is fluid in the hernia sac.

pain.[32] Additionally, instillation of local anesthetic (so-called *splash technique*) is as effective as injection into the wound.

Recently concerns have been raised about the effect of anesthesia in the developing brain. Most research has been in animal models and has clearly shown the anesthetics can induce brain cell apoptosis. However, conclusions about effects on humans have been mixed. In 2009 Wilder and colleagues[33] looked at a population of children and identified that learning disabilities were more common in children younger than age 4 who had undergone general anesthesia. Similar results were found the same year by DiMaggio and colleagues[34] in children younger than age 3 undergoing inguinal hernia. This will likely remain an active area of debate for some time and affect the timing of surgery, particularly hernia repair, which is the most common general surgical procedure in this age group.

## AGE FOR OVERNIGHT STAY

Most full-term infants and older children undergo same-day hernia surgery. The age at which an ex-premature infant can safely have same-day hernia surgery is debatable. One study showed preterm infants younger than 41 to 46 weeks postconceptual age and with a history of neonatal apnea were at greater risk of postoperative apnea.[35] Another large study, using sophisticated monitoring techniques for monitoring postoperative breathing disturbances, found that infants younger than 44 postconceptual age were at increased risk of clinically significant episodes of postoperative apnea.[36] In 1995 a combined analysis from eight prospective studies was performed and concluded that the incidence of postoperative apnea was not less than 1%, with 95% statistical confidence, until 56 weeks for a 32-week premature infant and 54 weeks for a 34-week premature infant.[37] In our center we routinely use 60 weeks' postconceptual age as the cutoff (gestational age in weeks plus chronologic age in weeks). We prefer to err on the side of caution because studies to date do not allow a sufficiently accurate prediction of risk.

## TIMING OF SURGERY

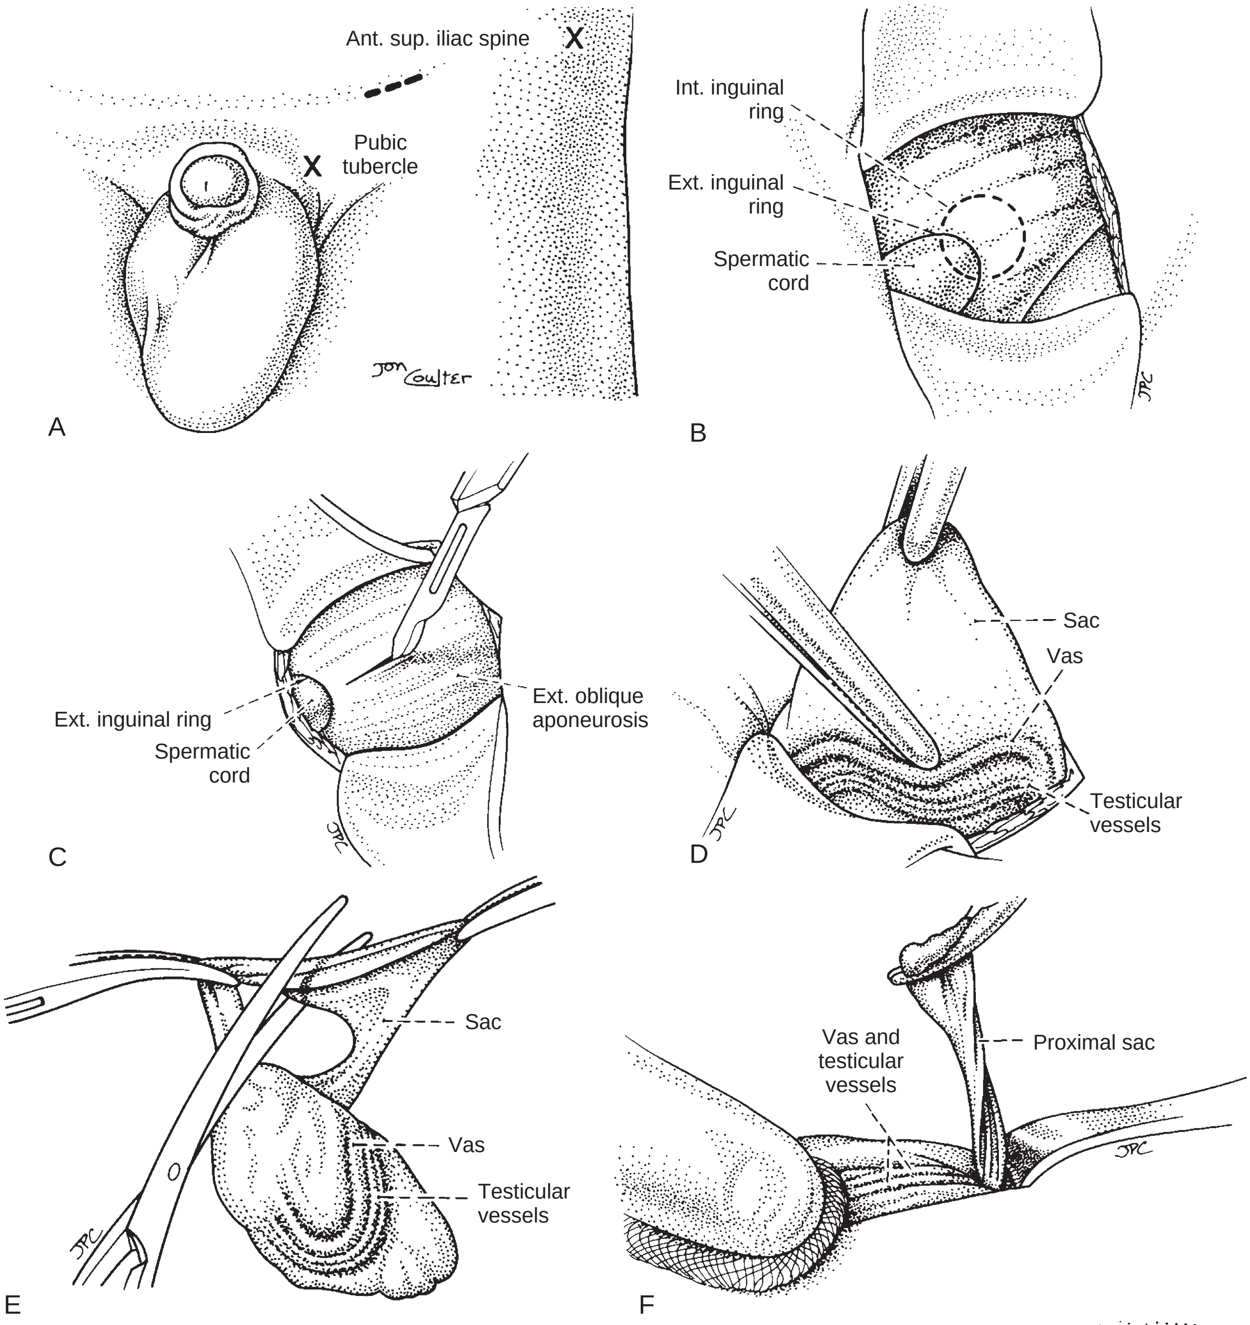
Most surgeons currently recommend repair of the hernia soon after diagnosis.[38] This practice can result in a significant reduction of complications from the hernia and is practicable because of the safety of modern anesthesia. Regarding premature infants, most surgeons recommend repair before discharge after the child has attained a weight of about 2 kg.[38] This is in contradistinction to surgical practice up to 1996, in which only 33% of surgeons polled would operate on a premature infant.[30] Langer and colleagues reviewed a series of infants and young children undergoing inguinal hernia repair. In infants younger than 1 year of age, the risk of incarceration doubled with surgical wait times of more than 30 days compared with fewer than 14.

## TECHNIQUE

The fundamental principle guiding pediatric inguinal hernia repair is high ligation of the hernia sac. A modified Ferguson repair was the procedure of choice for William Ladd and Robert Gross.[22] They preferred this type of repair to the Mitchell-Bank repair popular in Great Britain, which was a simple high ligation of the sac without opening the external oblique and exposing the internal ring. In Ferguson's repair the external oblique is opened and reconstruction of the inguinal canal is performed without altering the relation between the spermatic cord and the inguinal anatomy. In this text we describe our technique for inguinal hernia repair and highlight significant variations in the technique (Fig. 76-4).

With the patient in the supine position the midline, pubic tubercle, and anterior superior iliac spine are marked out. The pubic tubercle is a particularly important landmark because the external ring lies inferior and lateral to it. An incision is made in a skin line with the medial end of the incision just superior and lateral to the pubic tubercle. As children age, the internal ring becomes more lateral, so in infants the internal ring and external ring overlap, whereas in older children the distance between the two increases, necessitating a more laterally placed incision in the older child. Making the incision too medial in a child of any age runs the risk of dissection injury to the cord structures as they exit the external ring before finding the inguinal ligament.

The incision is carried down through the dermis to expose the subcutaneous fat, the Camper fascia. The Camper fascia is spread with scissors to expose the Scarpa fascia. Care is taken not to injure the inferior epigastric vein, which lies above the Scarpa fascia. The Scarpa fascia is then grasped and cut and then spread with scissors to expose the external oblique muscle. Once the external oblique is identified, the inguinal ligament is cleared from lateral to medial by gentle spreading down to the level of the external ring. Care should be taken to stay above the inguinal ligament to avoid injury to the femoral structures. An incision is made in the external oblique along the line of its fibers and extended by spreading with scissors. Straight snaps can be applied to the cut ends of the external oblique, near the external ring, to assist their subsequent identification and closure. The undersurface of the external oblique, superiorly and inferiorly, is then cleared off with forceps and a wet drawn-out sponge to identify the transversalis fascia, iliofemoral and ilioinguinal, nerves and cremasteric fibers. A small incision is made in the cremasterics and then they are spread apart, revealing the hernia sac. The hernia sac is grasped, taking a large gentle bite of tissue and elevating the cord structures into the wound until a clear inverted V-shaped opening underneath the sac is seen. DeBakey forceps are placed through this opening. The spermatic fascia is then bluntly opened, and the vas deferens and vessels are dissected away from the sac. The sac is then checked for contents, and the vas and vessels are then reidentified. Two clamps are then placed across the sac closely together, and the sac is divided. The proximal sac is then cleaned to the level of the internal ring, twisted on itself, and ligated at the level of the internal ring with monofilament absorbable suture. Ladd and Gross[22] had used silk suture to ligate the sac, but we have seen these silks "spit" out of the wound years after the original repair and have now switched to an absorbable suture to avoid this problem. The distal sac is not dissected because this may result in ischemic orchitis or postoperative hematomas. Noncommunicating hydroceles may be windowed open but should not be completely removed for the same reasons. Inspection of the testicle is also not mandatory. If done, care must be taken not to damage the normal insertion of the gubernaculum onto the Dartos fascia. The testis is then returned to the normal scrotal position by pulling on the scrotal skin and the Dartos fascia. The wound



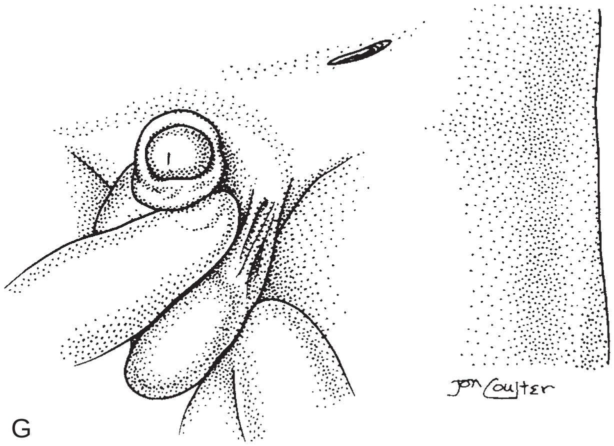


**FIGURE 76-4** Technique of inguinal hernia repair in male children. **A,** The pubic tubercle and anterior superior iliac spine are used as landmarks to place the inguinal incision over the internal ring *(dashes)*. **B,** In infants younger than a year of age the internal and external rings overlap and the inguinal canal is short. Often an incision in the external oblique is not necessary to access the internal ring. **C,** In older children the external oblique aponeurosis is incised lateral to the external ring and over the internal ring. The undersurface of the external oblique is cleared of cremasteric fibers. **D,** The cremasteric muscle is then incised and spread with scissors to expose the spermatic cord, which is then grasped and elevated. The vas and spermatic vessels are then gently separated from the white hernia sac without touching them. **E,** The hernia sac is then inspected for contents. The empty hernia sac is then sharply divided between clamps. The edges of the distal sac are cauterized, and the distal sac is dropped back into the wound. **F,** The proximal sac is then gently dissected to the level of the internal ring where the preperitoneal fat will be seen. The sac is then twisted on itself, taking care not to incorporate the vas deferens and vessels, and doubly ligated. **G,** The testis is then pulled back into position in the scrotum and the spermatid cord is straightened. A standard layered closure is then performed with absorbable suture.

is then closed in layers. The Scarpa fascia is closed with interrupted absorbable suture. We prefer a running subcuticular skin closure, but an interrupted closure is equally effective. Sterile adhesive strips (Steri-Strips, 3M, St. Paul, Minn.) are applied, and an impermeable plastic dressing is placed over the wound to protect it from stool or urine (in children wearing diapers). We have abandoned the use of collodion because of the Occupational and Safety Health Administration's issue with the ether.

## PROCEDURE IN FEMALES

The surgical repair of hernias in females is somewhat simpler than in males because there is no need to identify and preserve a spermatic cord. The surgical approach to the inguinal canal is the same in both males and females. The hernia sac is identified and inspected for contents. Often the ovary, tube, or mesosalpinx is contained within the sac (Fig. 76-5). If the sac is empty, it is divided between clamps. The distal sac is dropped back into the wound after the edges have been cauterized. The proximal sac is dissected out to the level of the internal ring, twisted, and doubly ligated. We then close the internal ring with one or two sutures by approximating the transversalis fascia to the shelving edge of the inguinal ligament and then close in standard fashion.

Before twisting and ligation, we routinely open the sac because up to 40% of indirect inguinal hernias in females have a sliding component. It is not uncommon for the ovary, fallopian tube, and/or uterus to lie within the wall of the sac and not reduce into the abdominal cavity. If the fallopian tube is not readily visibly, some surgeons will place traction on the round ligament in order to identify the fallopian tube before ligation of the sac. We also do not routinely attach the sac and the round ligament to the conjoint tendon in order to reestablish the normal support for the uterus (the Bastianelli maneuver).

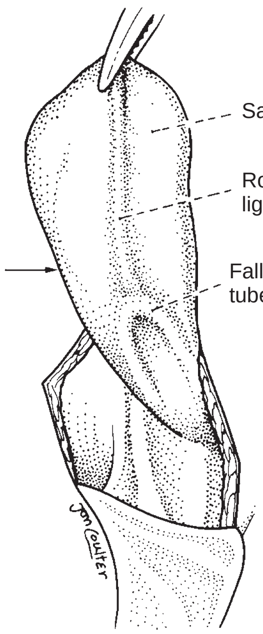

**FIGURE 76-5** Hernia sac in a female. The fallopian tube is often found in the wall of the hernias sac as a sliding hernia and must be identified. If necessary, the hernia sac is opened and the round ligament is followed to the fallopian tube.

If the fallopian tube is identified in the wall of the sac as a sliding hernia, we make no attempt to dissect it off the sac. Rather, we close the sac above the fallopian tube with a purse-string stitch, reduce the sac into the internal ring, and close the internal ring with one or two sutures, known as the Bevan repair.[39]

## LAPAROSCOPIC REPAIR

Laparoscopic repair of inguinal hernias has been fairly commonplace in adults for a number of years. Stated advantages have included less pain, earlier return to work, repair of bilateral hernias though the same ports, and easier repair of recurrent hernias. Disadvantages have included increased cost, longer OR times, and a prolonged learning curve. In addition, multiple techniques have been proposed such as transabdominal repairs and extraperitoneal repairs. For these reasons, most pediatric surgeons have considered laparoscopy for hernia repair unnecessary in children because of the small incisions already used and relative ease of repair compared with adults, as well as the minimal pain patients experience in the postoperative period with the open procedure and rapid return to normal activities. Only recently has laparoscopic repair of inguinal hernias in children become an alternative.

In 1997 El-Gohary reported a series of laparoscopic hernia repairs in 28 females.[40] In his series, the hernia sac was inverted into the abdominal cavity and endoscopic loop tries were placed at the base of the inverted sac. Because this technique does not allow exclusion of the cord structures, the authors recommended this procedure be used only in females. In 1998 Schier reported a series of laparoscopic hernia repairs in 14 females.[41] In his technique 2 to 3 intracorporeally placed Z-stitches were used to close the processus vaginalis.

Montupet and Esposito reported the first successful use of laparoscopic hernia repair in boys.[42] A laparoscopically placed purse-string stitch was placed around the neck of the sac. Care was taken to deliberately exclude the vas deferens and spermatic vessels. There were no surgical complications in 45 males, but there were two early recurrences requiring a second laparoscopic repair. In 2003 Schier[43] updated his series using the Z-stitch and included males. This procedure was performed on 279 patients with 403 hernias. He noted a 2.7% recurrence rate.

Other groups have made use of specially designed devices to pass suture extraperitoneally around the neck of the sac. Lee and Liang[44] reported 450 patients using such a device and found a recurrence rate of 0.88%, which is comparable with open repairs.[44] Prasad and colleagues reported a small series in which a commercially available curved steel awl was used to assist passage of the suture.[45]

More recent variations include the so-called SEAL (subcutaneous endoscopically assisted ligation of the hernia sac) technique in which a percutaneously placed purse-string stitch is placed under laparoscopic guidance to ensure avoidance of the cord structures.[46] In addition, single-site techniques have been used to perform laparoscopic repairs. At present no single technique has been shown to be superior to the others.

The SEAL technique at our center is performed under general anesthesia with the patient supine and a nasogastric tube and Foley catheter (or straight catheterization) in place. A 5-mm trocar

is placed transumbilically and pneumoperitoneum established. A laparoscopic inspection is then performed. Bilaterality, as well as unusual hernias such as femoral and direct hernias, are easily identified. The level of the internal ring on the abdominal wall is then identified with a finder needle. A small nick is made in the skin with a knife, and a 2-0 Ethibond suture is placed through the incision to purse-string the internal ring, taking care to exclude the cord structures. This is done either by skipping over them or dissecting them away from the peritoneum with the needle tip. The dissection of the cord structures from the peritoneum can also be accomplished by hydro-dissection by inserting a hypodermic needle retroperitoneally lateral to the cord and injecting bupivacaine hydrochloride (Marcaine). This elevates the sac completely off the cord. Dissection can also be performed with the tip of the suture needle when passing over the cord. The needle is then brought out to the skin at a separate point and tracked back subcutaneously to the original skin nick. The stitch is then tied down to close the ring. A 3-mm instrument can be placed through a small trocarless incision to assist exclusion of the cord structures if necessary. Published recurrence rates with this technique are between 1.5 and 4%.[47,48]

As mentioned earlier, several alternative techniques are available. One of the most straightforward may be that reported by Prasad and colleagues in 2003.[45] In their technique an umbilical port is placed for the camera and is the only port used. The level of the internal ring on the abdominal wall skin is determined by palpation, and a small skin nick is made with a knife. Under direct laparoscopic guidance a purse-string suture is placed halfway around the internal ring using an extracorporeal needle driver, and the needle is left in the abdomen. A curved, steel awl is used to come around the other half of the ring through the same skin nick, taking care to avoid injury to the cord structures. The awl is used to grasp the needle and pull it back out, completing the purse-string. The knot is tied extracorporeally, and closure of the internal ring is confirmed by the laparoscope.

In one of the largest laparoscopic series, Endo and colleagues[49] in 2009 reported retrospective outcomes on 1257 children using an extroperitoneal technique similar to the awl technique described earlier. Their follow-up ranged from 1 month to 11 years, and recurrence rate was 0.2%. Lower recurrence rates seem to be a consistent feature of extraperitoneal techniques as compared with intraperitoneal ones.

We tend to favor extraperitoneal techniques as described earlier for reasons of cosmesis (no or few port sites needed) and safety (ability to identify and exclude cord structures), as well as possible lower recurrence rates compared with both laparoscopic intraperitoneal approaches and open hernia repair. Moreover, these extraperitoneal techniques are not technically demanding and can be performed by surgeons unaccustomed to laparoscopy. Numerous variations exist and are beyond the scope of this chapter to review. But it appears that the evolution of laparoscopic hernia repair in children is tending toward extraperitoneal repairs and away from intra-abdominal approaches, as well as to fewer and fewer port sites.

Despite the growing number of reported series of laparoscopic repair, there are only two randomized prospective studies comparing laparoscopic repair with open repair, both of which have small patient numbers and limited follow-up. Chan and colleagues[50] randomly assigned 83 patients to open versus laparoscopic repair in 2005. They scored pain and parent assessment of recovery and cosmesis, both of which favored the laparoscopic repair. Their technique uses a transcutaneously placed suture similar to the SEAL technique described earlier. The other study randomized 89 patients to open versus intraperitoneal laparoscopic technique based on the technique of Schier. This study found no significant differences in outcome and recovery or cosmesis. They did not report that the laparoscopic repair was associated with longer operating room times and increased pain.[51]

In females we prefer to use a laparoscopic inversion ligation technique, "LIL repair," because there is no need to be concerned about cord structures. Ports sites are chosen as for males.[52] A bowel grasping or Maryland clamp is placed into the hernia sac, and the apex is grasped and inverted into the abdominal cavity (Fig. 76-6). The sac is twisted on itself, and two ligatures (Endoloops, Ethicon Endo-Surgery, Cincinnati) are placed at the base to ligate the sac. Care needs to be taken when twisting the sac so that adnexal structures are not caught up in the high ligation. We have noted no recurrences in our series, and surgical complications are

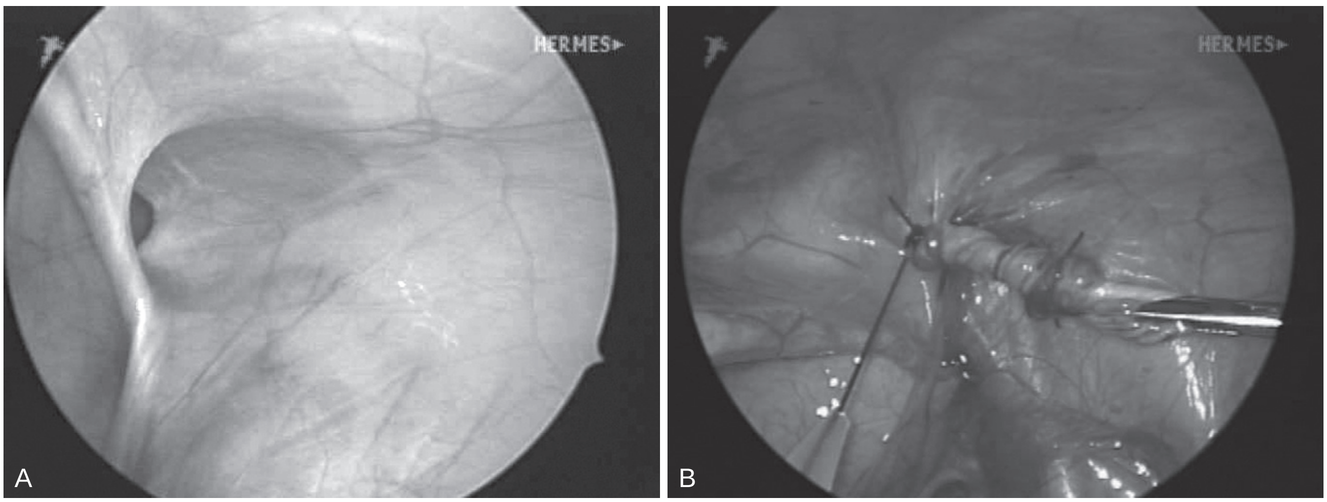

FIGURE 76-6 Laparoscopic view of the processus vaginalis. **A,** Open processus. **B,** Processus inverted into peritoneal cavity and ligated with Endoloops.

quite low. Another simple variation of this involves the use of electrocautery to destroy the inverted sac (personal communication).

## Contralateral Exploration

In 1955 Rothenburg and Barnet[21] reported that 100% of infants younger than 1 year of age and 68.5% of children older than the age of 1 year had bilateral inguinal hernias.[21] Since this report, routine bilateral exploration has been one of the most contentiously debated issues in pediatric hernia surgery. The application of laparoscopy to the diagnosis of bilaterality has recently added to the debate.

Because of the high rate of contralateral hernias, Rothenberg and Barnet recommended routine exploration of the contralateral hernia. What they were seeing, however, was clearly not a contralateral hernia, but rather a patent processus vaginalis. Although many surgeons have supported routine exploration, others have noted that there is a high negative exploration rate because not every patent processus will develop into a clinical hernia. In addition, routine exploration puts both testicles and both vas deferens at risk. Even so, Rowe and Marchildon,[23] in a survey of pediatric surgeons in 1981, found that 80% of surgeons routinely performed contralateral exploration in boys, and 90% did so in females younger than 1 year of age.[23] However, a more recent survey suggests a trend away from routine contralateral exploration. Only 40% of recently surveyed pediatric surgeons routinely explore males younger than 2 years of age and only 13% routinely explore boys between the ages of 2 and 5. Thirty-nine percent routinely explored females, and 51% routinely explored premature infants. This survey also highlighted another trend reporting that 24% of surgeons use laparoscopy to investigate the contralateral side.

We believe that routine exploration of the contralateral side results in a large number of unnecessary procedures, needlessly places the contralateral vas and testicle at risk, and is an unwarranted expense. We base that judgment on the fact that while up to 60% to 80% of infants younger than age 1 and 40% of older children will have a patent processus, only about 20% of patients presenting with a unilateral hernia will develop a clinical hernia on the other side.[6,10,29] Therefore one would need to perform approximately 10 operations to prevent two future hernias. Because of this fact, many surgeons have abandoned routine contralateral exploration on the basis of age of the patient, sex of the patient, or side of the hernia.

### SEX

Historically, many surgeons have performed bilateral exploration on females, primarily on the premise that routine bilateral exploration poses little risk to the patients because of the relative rarity of finding reproductive structures in the sac. In a survey of surgeons in 1981, Rowe and Marchilidon reported that 90% of surgeons routinely explored the contralateral groin in girls younger than 1 year of age.[23] Weiner and colleagues[30] surveyed surgeons in 1996 and found that 84% performed routine exploration in females younger than age 4.[30] It appears that this trend is decreasing because Levitt and colleagues[38] 2002 found that only 39% of surgeons performed bilateral exploration in females younger than age 5. Despite the rare findings of reproductive structures in the hernia sac, damage to the inguinal floor and to the ilioinguinal and iliofemoral nerves still exists and is generally ignored in arguments for contralateral exploration. Because little follow-up data exist in the literature, it is difficult to quantify these risks. It is evident that only about 20% of females with a unilateral hernia will develop a contralateral hernia. Thus a large number of explorations would be necessary to prevent a few hernias from developing. Puri and colleagues recently reviewed 300 females undergoing unilateral hernia repair.[53] In a follow-up ranging from 1 to 4 years, only 8% developed a contralateral hernia and this was not influenced by age at operation of side of initial hernia.

### AGE

On the basis of the findings of Rothenberg and Barnet[21] that 100% of infants younger than 1 year of age will have bilateral patent processus vaginalis, many surgeons routinely perform contralateral exploration in infants. In the most recent survey, 51% of surgeons routinely perform contralateral exploration in premature infants and 40% perform contralateral exploration in boys younger than 2 years of age.[38] This is considerably less than reported from the 1981 survey in which 80% routinely explored the contralateral side in boys.[23] In a large series of 1052 patients followed up to 11 years, contralateral hernias appeared in 13.1% of boys younger than 1 year of age and 13.7% younger than 2 years of age. In females contralateral hernias appeared in 9.6% of patients younger than 1 year of age and 13.9% of patients younger than 5 years of age. Another recent series looked at 181 infants younger than 1 year of age undergoing unilateral repair. Contralateral hernias developed in 7.7% in follow-up ranging from 5 to 10 years. On the basis of these results, it is not completely clear that younger children have a significantly higher chance of developing a contralateral inguinal hernia.

### SIDE AND SIZE

It is speculated that right-sided hernias are more common than left because the right processus vaginalis closes later than the left side. Therefore patients presenting initially with a left-sided hernia would seem to be more likely to have bilateral hernias than those patients initially presenting with a right-sided hernia. As a result, many surgeons recommended routine exploration in patients presenting with left-sided hernias. McGregor and colleagues[12] reviewed a 20-year experience and found that 41% of patients having an initial left inguinal hernia presented with a right hernia, whereas only 14% of patients developed a left inguinal hernia after the right side was repaired.[12] Other series, however, have reported much lower rates of contralateral occurrence after left-sided repair. For example, Kemmotsu and colleagues[54] reviewed 1052 patients who had undergone unilateral repair and found that the side of initial repair did not influence contralateral recurrence.[54] Miltenburg and colleagues[55] found in a meta-analysis that the risk of contralateral hernia repair was 11% (50%) higher than if the initial hernia had been on the right.[55] Overall, it appears that the side of the initial hernia has no bearing on the risk of developing a contralateral hernia.

## LAPAROSCOPY

In an effort to limit the number of negative contralateral explorations, alternative techniques have been used to determine the patency of the contralateral processus. These have included diagnostic pneumoperitoneum (the Goldstein test) in which the abdomen is insufflated via the hernia sac and the contralateral groin is palpated for crepitance, indicating a patent processus vaginalis. A recent study by our group of 62 patients found 11% had a positive study (7 patients).[56] Each underwent exploration and was found to indeed have a contralateral patent processus vaginalis. Of the 55 patients with a negative Goldstein test, only 3 (5%) have subsequently developed a clinical hernia. In our opinion this technique is both safe and reliable. However, others have found that this test is unreliable and often misses patent processes. Bakes dilators have been used to probe the contralateral groin, but this technique is often difficult and unreliable. Herniography has been discussed previously and is rarely used today. Ultrasound has also been discussed previously and found to be fairly sensitive for the presence of patent processes vaginalis when appropriate-size criterion are used.

In the early 1990s laparoscopy was introduced as a means of assessing the contralateral inguinal canal. Laparoscopy has the advantage of being technically easy and allows direct visualization of the contralateral internal ring. And with the increasing popularity of laparoscopy, the equipment is widely available.

Laparoscopy can be performed in a variety of ways. Perhaps the most common technique is to place a port through the ipsilateral hernia sac to insufflate the abdomen and introduce the camera. Evaluation of the contralateral side is made easier by the use of an angled scope (e.g., 70 degrees). Others have introduced the camera via an umbilical port or placed the small cameras through an angiocatheter placed through the abdominal wall to give in-line visualization. Also, both flexible and rigid scopes have been used.[57]

Yerkes and colleagues[58] evaluated 627 patients younger than age 10 with unilateral hernias during a 5-year period for the presence of a contralateral patent processus vaginalis (CPPV) with laparoscopy. Of the patients younger than age 1, 46% were diagnosed with a patent contralateral processus, while 39% older than age 1 had a CPPV. Geisler and colleagues[59] evaluated 358 patients ages 1 month to about 13 years and determined an overall incidence of CPPV of 33%.[58,59] Positive findings were in 50% of patients younger than age 1, 45% younger than age 2, 37% younger than age 5, and 15% older than age 5. Pellegrin and colleagues[60] studied 50 patients and found an overall incidence of CPPV of 31%, while Rescorla and West[61] reported a 48% overall incidence of CPPV. Overall laparoscopy has shown a fairly consistent rate of CPPV, approximately 30% to 45%.

The question becomes, which of these CPPVs will become clinical hernias? The answer, of course, is not known and would most likely require a randomized prospective trial with essentially life-long follow-up, a practical impossibility. However, Kiesewetter and Parenzan[62] performed routine contralateral exploration of 100 infants younger than 2 years and found a 61% incidence of CPPV. Next, they closely followed 231 patients after unilateral repair only and found that 31% went on to develop a hernia, approximately half of what would be expected. On the basis of this information and data from Rowe and Clatworthy, one would expect that laparoscopy would decrease the number of unnecessary procedures from about 1 in 8 to 10 for routine exploration to 1 in 2 for laparoscopic cases, a significant improvement.[63]

Opponents of laparoscopy will point out that at least half the patients will receive a procedure they do not need (not counting any patients with false-negative laparoscopy). Moreover, when factoring in time and equipment, there is a significant increase in cost. With the increasing use of reusable equipment and the decreasing use of disposables, this cost and time factor has been shown, however, not to be as significant as previously thought.

As children age, the rate of CPPV clearly decreases. Is there, then, an age after which laparoscopy is no longer valuable? Bhatia and colleagues[64] studied 101 children between ages 2 and 8 compared with 171 younger than age 2. Thirty-eight percent younger than age 2 had a CPPV, while 20% older than age 2 were positive. In a group of 12 patients older than age 8, only 1 was positive. The authors concluded that laparoscopy is justified in children older than age 2 but could make no conclusion about children older than age 8 because of a small sample size. In the Geisler and colleagues[59] study, CPPV was reported in 15% of patients older than age 5. It seems likely that somewhere in the age 5 to 8 range there will be a significant decrease in return for laparoscopy.

# Nonreducible Hernia

Most inguinal hernias are readily reducible into the abdominal cavity. Those that are difficult to reduce are "incarcerated." A strangulated hernia occurs when there is vascular compromise of the entrapped viscera. This results from constriction by a tight internal or external ring. Most children will progress rapidly to strangulation if the hernia is not reduced. This process can take as little as 2 hours. Initially, constriction by the ring leads to venous and lymphatic obstruction and subsequent swelling of the viscera. Arterial compromise then occurs, and, if the process is unchecked, will lead to gangrene and perforation of the bowel or other viscera. Incarceration and strangulation can also damage the testicle by compromising the blood supply to the testis. Patients with incarcerated hernias are more likely to have testicular atrophy after hernia repair.

Various series have reported the incidence of incarceration to be in the range of 12% to 17% and seem to be similar in boys and girls.[63,65] Incarceration is most likely to occur in the first year of life and then falls off thereafter (Fig. 76-7). Interestingly, the data in premature infants suggest that they are less likely than full-term infants to have an incarceration, even though the incidence of hernia is higher in this subgroup. Full-term infants younger than age 2 to 3 months were found to have a rate of incarceration of 28% to 31%[63,66] and 24% in infants younger than 6 weeks of age.[67] Interestingly, premature infants were found to have a lower incidence of incarceration compared with full-term infants (13% to 18%). This may be a result of larger rings and, therefore, less chance of viscera becoming entrapped. Also, many of these infants are in neonatal intensive care units under constant surveillance; incarcerated hernias may be prevented by early reduction or may simply be underreported as caretakers in the nursery reduce them.

## DIAGNOSIS

If a loop of bowel becomes entrapped in a hernia, the patient often becomes extremely irritable and develops intense pain followed by signs of obstruction (e.g., abdominal distension, vomiting, absence of flatus/stool). A tense, nonfluctuant mass will be found in the groin, possibly extending into the scrotum. As the viscera strangulate, the mass becomes more and more tender. Occasionally the mass will transilluminate and be confused with a hydrocele. Under no circumstances should the mass be aspirated in an attempt to diagnose and treat a supposed hydrocele.

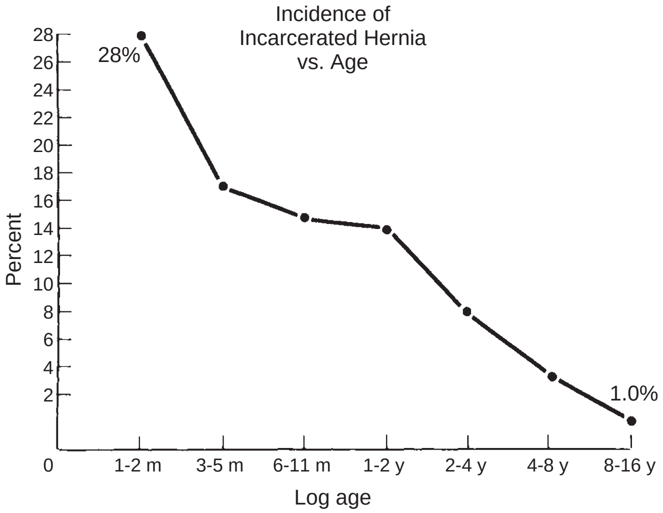

**FIGURE 76-7** Incidence of incarcerated hernias versus age. Incarceration is most common within the first year of life and then drastically decreases.

Late signs of a patient with a strangulated hernia are those of shock, blood in the stool, and peritonitis. The testes are usually palpable, but occasionally they can be large and firm and difficult to distinguish from a testicular torsion. Abdominal radiographs reveal a partial or complete bowel obstruction. Bowel gas may also be seen in the scrotum. In uncertain cases ultrasound can be useful to distinguish bowel from hydrocele fluid or a testicular torsion.

## NONOPERATIVE MANAGEMENT

In patients without obvious signs of shock or peritonitis, nonoperative management is first attempted. We prefer the following technique (Fig. 76-8). Lay the child down and try to calm him or her without feeding with the feet elevated if possible. Standing on the ipsilateral side of the child, or at the feet of an infant, place the left index and middle finger on the ipsilateral anterior superior iliac crest and sweep the fingers down along the inguinal canal toward the ipsilateral scrotum, keeping tension on the testicle in the male child, inguinal mass, or scrotal

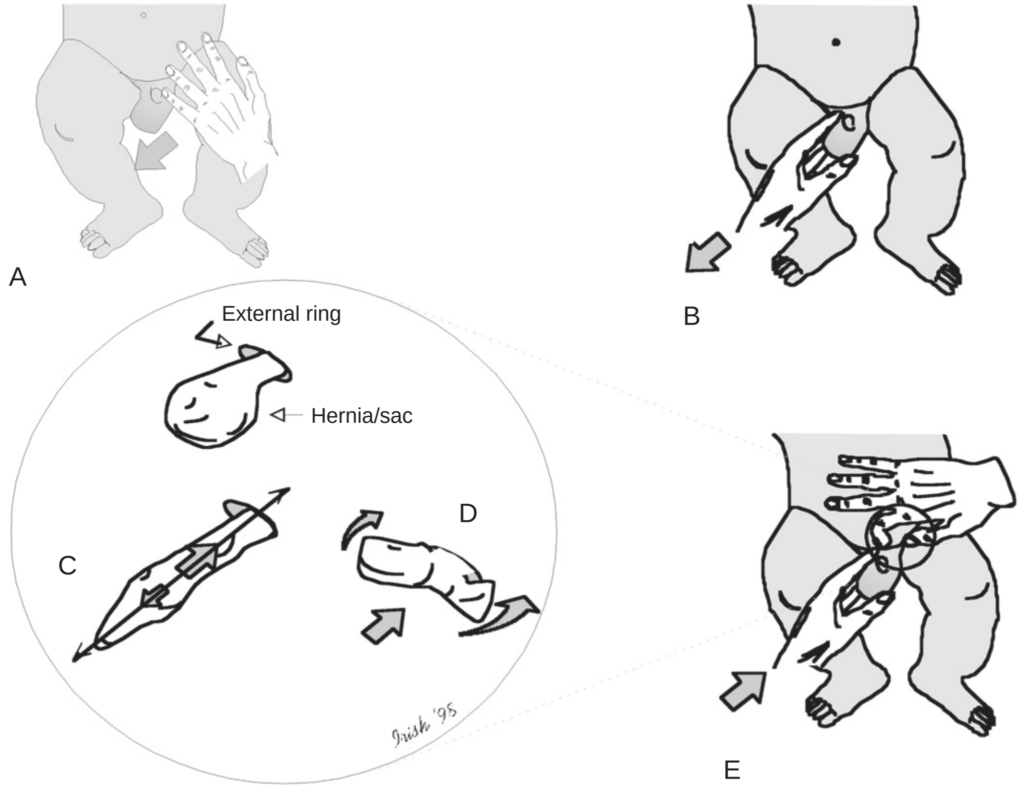

**FIGURE 76-8** Suggested method of reduction of an incarcerated inguinal hernia. **A,** Standing on the ipsilateral side of the child or at the feet of an infant, place the left middle and index finger on the ipsilateral (left in this example) anterior superior iliac spine and sweep your fingers down along the inguinal canal, toward the ipsilateral scrotum. **B,** Keep tension on the testicle, hernia mass, or scrotal skin with the right hand. **C,** Constant, gentle traction on the scrotum helps align the long axis of the hernia with the axis of the inguinal canal. Next, apply pressure with the right index finger and thumb on either side of the hernia neck. **D,** This, along with traction on the scrotum, helps to keep open the external and internal rings and prevents the hernia sac from overlapping or being caught on these potential barriers during reduction. **E,** Finally, with the left hand at the apex of the mass, and with constant pressure on the inguinal canal from your right index finger and thumb, walk your fingers slowly up the groin toward the internal ring, keeping constant pressure on the bottom of the hernia contents.

skin with the left hand. Constant gentle traction on the scrotum or labia majora helps align the long axis of the hernia sac with the axis of the inguinal canal. Next, at the level of the ipsilateral internal ring, apply pressure with the right index finger and thumb on either side of the hernia neck. This, along with traction on the scrotum, helps to align and to keep open the external and internal rings. It also prevents the hernia sac from overlapping or being caught on these potential barriers during reduction. Finally, with the left hand at the apex of the mass, and with constant pressure at the level of the internal ring from the right index finger and thumb, walk your left fingers slowly up the groin toward the internal ring, keeping constant pressure on the bottom of the hernia contents. This may take several minutes. If successful, the hernia contents will gradually disappear into the internal ring. To be certain it is reduced; compare it with the contralateral side. Use a mirror image technique for the right side. If this technique is unsuccessful or the child has a difficult time tolerating it, sedation may be used. We do not recommend reduction of the bowel under general anesthesia because injury to the bowel may occur or gangrenous bowel may be placed back into the peritoneal cavity and be unrecognized. Often sedation alone may be sufficient to promote spontaneous reduction. Reduction of gangrenous bowel has been reported, so we recommend watching the child in the hospital for 24 hours after a difficult reduction.[68] We delay definitive repair of the hernia for at least 24 to 48 hours to let the edema resolve.

## OPERATIVE MANAGEMENT

In those situations where nonoperative management fails or the patient has signs of shock or peritonitis, surgery is indicated. The patient is prepared for surgery in the standard way. Intravenous fluids are initiated, and urine output is monitored. Broad-spectrum antibiotics are given, and if signs of obstruction are present a nasogastric tube is placed. When the patient is adequately resuscitated, the patient is taken to the operating room. If the hernia reduces after the general anesthetic is induced, but before surgery, the operation should still proceed. Several operative approaches have been advocated for incarcerated hernias including inguinal approaches and preperitoneal approaches. The use of laparoscopy can also be valuable in the management of incarcerated hernias.

### Inguinal Approach

The approach is that of a standard inguinal hernia repair, except that the incision is somewhat longer. The external ring is opened, and the hernia sac is identified. If the hernia contents are still present, they are inspected. If viable, the contents are reduced back into the peritoneal cavity and the hernia is repaired in a standard fashion. If the intestine cannot be reduced, then the inferior epigastric vessels are ligated and the floor of the inguinal canal is taken down to enlarge the internal ring. After repairing an indirect inguinal hernia, a formal floor repair will be required in these instances.

If the bowel in the hernia sac is of questionable viability, then it can be covered with a warm moist sponge and reinspected in a few minutes. Again, if the internal ring is constricting, it can be enlarged, taking care not to let the bowel slip back into the peritoneal cavity. If the bowel is determined to be nonviable, it can be resected and primarily reanastamosed through the inguinal incision, through a counter incision through the transversalis fascia (La Roque incision), or through a separate abdominal incision.[69] If the bowel is viable, it is replaced into the peritoneal cavity and the hernia repair proceeds.

Difficulty arises if the hernia contents reduce before they can be inspected. In this instance the hernia sac is inspected and opened. If no evidence of bowel infarction such as bowel contents or foul-smelling or blood-stained fluid is identified, many surgeons proceed with repair. Laparoscopy can be used in these instances to determine bowel viability, with the camera placed either in the umbilical position or through the hernia sac. In fact, a camera can be placed at the beginning of the procedure and the hernia contents reduced under laparoscopic visualization.[70] If the contents are viable, then a standard hernia repair is performed. If the bowel is questionable, it can be laparoscopically reinspected after the hernia repair. If it is clearly nonviable, then the intestine can be brought out through the umbilical port site and resection performed.

### Preperitoneal Approach

Some surgeons prefer a preperitoneal approach to incarcerated hernias. This approach, described for adults by Cheatle in 1921, has been used successfully in children.[71] A recent series of 24 patients described by Kamaladeen and Shanbhogue and another of 12 patients described by Turnock, Jones, and Lloyd found the preperitoneal approach to be easier in terms of reducing the hernia contents and performing the herniotomy.[72,73] If necessary, the peritoneum could be opened to determine bowel viability.

The preperitoneal approach is performed through a skinfold incision at the level of the anterior superior iliac spine, and a standard grid-iron approach is used to reach the preperitoneal plane. The internal ring and hernia sac are identified lateral to the inferior epigastric vessels. The peritoneum is then opened at the base of the hernia sac, and the contents are inspected. Nonviable bowel can be readily dealt with through this incision. Otherwise, the bowel contents are reduced back into the peritoneal cavity and the herniorrhaphy is performed. Should the external ring prevent reduction, one can simply dissect superficially to the external oblique down to the external ring and enlarge it. Once the herniorrhaphy is performed, the wound is closed in the standard fashion. This incision resembles an appendectomy scar on the right side, so the parents should be warned of this.

### Pfannenstiel Approach

Koga and colleagues have recently proposed a Pfannenstiel[74] approach to incarcerated hernias. They perform a Pfannenstiel skin incision followed by a midline fasciotomy. The bowel is reduced and inspected through the fasciotomy, and if resection is necessary, there is excellent exposure through this incision. The hernia sac can also be easily repaired through this incision. The authors also suggest that this approach leaves a cosmetically acceptable scar.

Our preferred approach is to perform laparoscopy through an umbilical port, reduce the hernia contents under laparoscopic visualization, and perform subsequent herniotomy through a standard inguinal incision. There are no reports to date of a complete laparoscopic approach to incarcerated hernias in children.

Special mention must be made of the female patient with an asymptomatic incarcerated ovary in her hernia. Historically

many believed that this incarcerated, mobile, nontender ovary was of long-standing duration and was not at risk for strangulation. Subsequent reports have challenged this idea.[75] The consensus is that these hernias should be done urgently in the next 12 to 24 hours after discovery.[38]

# Postoperative Complications

## SCROTAL SWELLING

After hernia repair and particularly communicating hydrocele repair, fluid may accumulate in the distal sac, forming a noncommunicating hydrocele. Usually this resolves spontaneously: rarely, aspiration or secondary scrotal hydrocele repair may be necessary. Scrotal hematoma may follow excision of the distal sac.

## IATROGENIC UNDESCENDED TESTICLE

Iatrogenic undescended testis after hernia repair is an uncommon but possibly underreported complication. Kiesewetter[76] reported 2 patients with this abnormality in a series of 248 patients, and Hecker and Ring-Mrozik[77] reported 5 patients in a series of 1957 patients, an incidence of 0.2%. Except in the case of congenital undescended testicle, this abnormality results from failure to replace the testis back in the scrotum at the conclusion of the procedure or the testis subsequently trapped in a retracted location. Secondary orchidopexy is required to correct this problem.

## RECURRENCE

It is difficult to determine the precise incidence of recurrence after indirect inguinal hernia repair because factors such as sex and incarceration are not always clearly defined in reported series. In general, the reported recurrence rate for uncomplicated hernia repair is 0% to 0.8%; this rises to about 15% for preemies and about 20% after operation for incarcerated hernias. In many series, patients were not contacted for long-term follow-up; therefore the true incidence is not known and is probably higher than stated. Reports on patients with incarcerated inguinal hernias do not state whether the initial management was operative or nonoperative.

Many factors associated with the development of primary hernias may also predispose to recurrence. For instance, Grosfeld and Cooney, in a series of 25 patients with ventriculoperitoneal shunts, identified three recurrent inguinal hernias (12%).[78] Incarceration is also an important risk factor for recurrence. Steinau and colleagues[79] found that in 24% of 29 patients (25 boys, 4 girls) with a recurrent inguinal hernia, the primary hernia had been incarcerated compared with 7.6% incidence of recurrence in 2754 patients without incarceration. Other risk factors in their study were postoperative complications (9.4% recurrence rate) and concomitant diseases and abnormalities.[80] Interestingly, Harvey, Johnstone, and Fossard found that the level of experience of the surgeon was not a factor, although technical inadequacies contributed to recurrence.[81] Most recurrent inguinal hernias are indirect and probably result from tearing of a friable sac, failure to dissect the complete sac, a slipped ligature at the neck of the sac, or failure to ligate the sac high at the internal ring. Another risk factor for recurrence is prematurity. Several series of inguinal hernia repairs in premature infants have reported increased recurrence rate ranging from 2% to about 15%. Large hernias and inadvertent opening of the hernia sac during surgery have also been noted to increase recurrence.[82] Interestingly, in 2006, Ein and colleagues[83] did not note significantly increased recurrence rates in premature infants, but rather in teenagers.

Less frequently, a "recurrence" presents as a direct inguinal hernia or a femoral hernia missed and not properly diagnosed and repaired at the first operation. Of the 34 recurrences reported by Steinau and colleagues,[80] 4 were direct and one was femoral. In the Fonkalsrud, Delorimier,[84] and Clatworthy series of 14 direct inguinal hernias, 4 (31%) followed repair of an indirect hernia. A direct hernia following repair of an indirect hernia is either a concomitant hernia not recognized at the initial operation or new pathology caused by damage to the posterior wall of the inguinal canal during the initial dissection. A recurrent hernia in the femoral area is also likely to have been a missed hernia rather than a true recurrence.

Several large series now exist of laparoscopic inguinal hernia repair in children. Schier reported 403 inguinal hernia repairs on 279 patients and had a recurrence rate of 2.3%.[85] The technique of laparoscopic inguinal hernia repair varies from surgeon to surgeon and is still in evolution. Moreover, there is likely to be a learning curve with the laparoscopic techniques, such that recurrences are more likely to be higher earlier in one's experience. In our early experience with laparoscopic hernia repair in males, we found recurrences to be quite high and subsequently abandoned the intraperitoneal technique and adopted an extraperitoneal technique. However, in females, using the previously described LIL repair, we have had no recurrences.

## INJURY TO THE VAS DEFERENS

Although vas transection may be obvious interoperatively, accidental operative crush injury to the vas deferens is unlikely to be recognized until adulthood and possibly then only if the injury is bilateral. Vas transections should be immediately repaired with two to three simple monofilament 8-0 absorbable sutures placed with the aid of interoperative magnification. Sparkman[86] reported an incidence of proven injury to the vas deferens of 1.6% on the basis of finding "segments of the vas deferens" in 5 of 313 hernia sacs from children who had undergone hernia repair. Details of the five cases were not published, however, and no histologic or clinical information is available. Walker and Mills found small glandular inclusions in approximately 6% of hernia sacs from prepubertal boys, which they believe to be müllerian duct remnants and not segments of the vas deferens.[87] They emphasized that these structures were of no clinical significance. It is likely that similar structures accounted for some of the findings reported by Sparkman. Perhaps a better estimate is provided by Steigman, Sotel-Avila, and Weber,[88] who reviewed the histology of hernias sacs submitted from 7314 males undergoing hernia repair over a 14.5-year period. Seventeen cases contained vas deferens (0.23%); 22 had epididymis (0.3%), and 30 had embryonal rests (0.4%). Three sacs contained coexisting vas deferens and epididymis. Either vas or epididymis was found in 0.53% of sacs. Also, Patrick and colleagues[89] found a rather low incidence of 0.13% of vas injury in an analysis of

1494 sacs. They also argued that the incidence is so low that routine histologic evaluation of the sac is not warranted.

Shandling and Janick demonstrated the vulnerability of the vas during hernia repair.[90] In their experiments, the vas deferens of rats were exposed and grasped with fingers, nontoothed forceps, bulldog vascular clamps, or mosquito hemostats. Serial studies of the vas were done over 6 months, and damage to the vas was found in all manipulations except digital handling. Ceylan and colleagues[91] demonstrated that stretching of the spermatic cord might also damage the vas and testicle. They applied horizontal stretch force of varying amounts to the spermatic cord of rats. Significant thinning of the smooth muscle layer of the vas was noted with all degrees of stretching, as was testicular atrophy.

The relationship between male fertility and previous inguinal hernia repair is not well defined. Hommonnai and colleagues[92] reported findings on 131 men referred to an infertility clinic who had undergone inguinal hernia repair between the ages of 2 and 35 years. Although 14% of these men had testicular atrophy or abnormal sperm findings that could be related to the hernia operation, clinical details such as the incidence of incarceration and experience of the surgeon were not reported. Yavetz and colleagues reviewed 8500 patients referred to an infertility clinic. Of these, 565 (6.65%) reported inguinal hernia repair with or without testicular atrophy.[93] No correlation was found between age of hernia repair and semen quality following operation.

Operative injury to the vas deferens may result in obstruction of the vas with diversion of spermatozoa to the testicular lymphatics, and this breach of the blood-testis barrier produces an antigenic challenge with formation of spermatic autoagglutinating antibodies. In a review of 76 infertile men with spermatic autoagglutinating antibodies, 12 (16%) had unilateral inguinal hernia repair during childhood.[94] In 10 of these men the site of the inguinal hernia repair was explored, and in 5 patients an obstruction of the vas deferens was identified. The authors concluded that accidental transection or ligation of the vas could and does occur during inguinal hernia repair in a child and may be a reason for infertility in men. Parkhouse and Hendry reported similar findings.[95] Thus although these reports do not indicate the incidence of infertility of men after inguinal hernia repair, they do suggest that an association exists.

## TESTICULAR ATROPHY

The testicular vessels are vulnerable to operative injury, particularly in small infants, but reports of testicular atrophy after routine hernia repair are rare. Fischer and Mumenthaler[97] and Fahlstrom, Holmberg, and Johansson[96] each reported an incidence of testicular atrophy of 1%. In these studies the operative technique varied, and the number of incarcerated hernias was not reported; therefore this may not indicate the true incidence of testicular atrophy when hernia repair is performed by an experienced surgeon using a simple high ligation to obliterate the open sac.

With incarcerated hernia, the blood supply to the testis may be impaired by compression of the testicular vessels by the incarcerated viscus. The incidence of testicular compromise in association with incarcerated inguinal hernia ranges from 2.6% to 5%. The finding of a cyanotic testicle at emergency operation is common, reportedly 11% to 29%. The actual incidence of testicular atrophy as indicated by histologic examination or diminished size at follow-up is much lower, varying from 0% to 19%. Unfortunately, reported series of patients treated with emergency operation consist of small numbers of patients and the length of follow-up and the criteria for evaluation of the testis vary considerably. Puri, Guiney, and O'Donnell,[98] in an analysis of 87 boys with incarcerated hernia treated by nonoperative reduction, found unilateral testicular atrophy in 2 patients or 2.3%. From the available data, we conclude that vascular compromise is common but the risk of actual infarction is low. Therefore unless the testis is frankly necrotic, it should not be removed.

The herniated ovary and fallopian tube are also susceptible to vascular compromise, either as a result of incarceration or, perhaps more likely, torsion of the ovary within the hernia sac. The reported incidence of strangulation of irreducible ovaries is as high as 32%. Boley and colleagues[99] reported a 27% strangulation rate in 15 females presenting with incarceration. In addition, several case reports have demonstrated injury to the fallopian tubes from bilateral hernia repair, resulting in female infertility.

## INTESTINAL INJURY

With incarcerated hernias, the incidence of intestinal infarction is remarkably low. Between 1960 and 1965, the incidence of intestinal resection in the report by Rowe and Clatworthy[63] of 351 patients with incarcerated hernias was 1.4%. A review of three series published since 1978 shows no resections in 221 patients with incarcerated hernia.

## LOSS OF ABDOMINAL DOMAIN

A complication of hernia surgery that is rarely discussed is postoperative respiratory failure as a result of lost abdominal domain. The right of domain is the concept that each organ occupies a space within the body that it has a right to fill. In giant inguinal hernias, particularly bilateral giant hernias, the majority of the intestine can lie within the hernia sac and outside of the peritoneal cavity. If this occurs for some time, the intestine can lose its right of abdominal domain. During repair, the intestine is returned to the abdominal cavity, resulting in increased intra-abdominal pressure and respiratory failure. Bascombe, Caty, and Glick[100] reported an ex-premature infant with large bilateral inguinal hernias who required 41 days of mechanical ventilation after repair.

Respiratory failure after inguinal hernia repair is common, especially in premature infants. Gollin and colleagues[101,102] found 34% of premature infants required mechanical ventilation after herniorrhaphy. It is possible that increased intra-abdominal pressure as a result of loss of domain may be an unrecognized contributor to this problem. As a result of their experience, Glick and colleagues[101] have recommended staged repair of large bilateral hernias in the elective setting, especially because the risk of a second anesthesia is so low using modern technique. In an emergency setting (e.g., repair of giant incarcerated hernias), a silo such as that used for abdominal wall defects may be considered to alleviate abdominal compartment pressures and allow the intestine to be slowly returned to the abdomen.

### CHRONIC PAIN

Chronic pain after adult hernia repair is found in about 10% of patients. This incidence is unknown in patients undergoing hernia repair in childhood. In 2007 Aasvang and Kehlet[103] surveyed adults who had undergone hernia repair younger than the age of 5. Although 13.5% reported some pain from the operated groin (usually associated with physical activity), only 2% reported this pain to be severe.

This issue may be of greater relevance in the older teenager in whom mesh is used. Although mesh repair is not our practice, it is for other surgeons. In fact, there seems to be no general consensus as to the age when mesh repair may be appropriate and the older teenager may receive a different operation if corrected by an adult surgeon versus a pediatric surgeon.

Inguinodynia can be effectively improved in the great majority of patents by combined neurectomy and mesh removal. As noted previously, Ein[83] found in his personal series that teenagers had a significantly higher recurrence rate than other age groups. Interestingly, there are no published studies comparing mesh versus standard repair in adolescents. Clearly, this is an issue that is best addressed with a randomized, prospective trial.

Mesh has also been implicated in male infertility as a result of vasal obstruction. The mechanism appears to be related to the foreign body response to the mesh, leading to dense inflammation and scarring, which can trap or obliterate the vas. This scarring also makes surgical reconstruction of the vas difficult.

## Mortality

Mortality associated with inguinal hernia is related to complications of the hernia or to coexisting risk factors such as prematurity or cardiac disease. In 1938 Thorndike and Ferguson[102] reported an overall mortality of 2.8% for incarcerated hernias treated between 1927 and 1936. In 1954 Clatworthy and Thompson[104] reported one death in 135 patients treated for incarcerated hernia (0.9%), and in a report from the same institution in 1970 of 351 patients treated with incarcerated hernia, there were no deaths.[63] Since then, death from incarcerated hernia has become a rarity. The risk is higher when the hernia is strangulated. In the United Kingdom in 1989, five deaths from infants with strangulated hernia were reported. The risk factors identified include age younger than 6 months and lack of experience in pediatric surgery on the part of the surgeon and the anesthesiologist.

Operative mortality in premature infants is now only rarely seen. In two of the most recently reported series of premature infants undergoing hernia repair, no deaths were reported in a total of 303 patients.[67,105]

## Special Considerations

### PREMATURITY

It is well established that premature infants have a higher incidence of inguinal hernias and are likely to have a bilateral presentation. Moreover, the more premature the infant, the higher is the incidence of inguinal hernia. In a review of 82 infants weighing less than 2000 g, Walsh found a 13% incidence of inguinal hernia. Of 28 infants less than 1500 g, 7 (25%) had an inguinal hernia compared with 4 (7%) infants greater than 1500 g.[5] Rescorla and Grosfeld reviewed 100 infants younger than 2 months of age who required inguinal hernia repair; 30% of these infants were premature and 44% had bilateral hernias.[66] Of 1391 very-low-birth-weight infants (weight $<$ 1500 g) reported by Rajput and colleagues,[4] 222 (16%) developed an inguinal hernia between 28 days and 20 months of corrected age. Peevy, Speed, and Hoff studied 397 newborn infants and found a 9% incidence of inguinal hernias in infants weighing between 1000 g and 1500 g and 30% in those weighing 500 g to 1000 g.[8] In a small series of 37 premature infants weighing less than 1000 g, Harper and colleagues[106] reported that 11 (30%) developed an inguinal hernia. Two of these 11 were incarcerated (18%). Although the incidence of incarceration is increased in infants and may be as high as 28%, it appears to be lower in premature infants, with reported incidences of 13% to 18%, compared with mature infants.

### VENTRICULOPERITONEAL SHUNTS/ PERITONEAL DIALYSIS

A significant factor in the development of an inguinal hernia is excess fluid in the peritoneal cavity, and in patients with a patent processus vaginalis, procedures that introduce fluid into the peritoneal cavity may induce a hernia or hydrocele. Whether hernia is due to the physical presence of the fluid or is secondary to increased intra-abdominal pressure is unknown. Abnormal neuromuscular function may also be a factor. Moazam and colleagues[107] reviewed 134 patients who had ventriculoperitoneal shunt procedures; inguinal hernias developed in 19.5% of patients with meningomyelocele and 47% of those with intraventricular hemorrhage. All of the latter were premature, however. Grosfeld and Cooney[78] found a 14% incidence of inguinal hernia after insertion of ventriculoperitoneal shunts; 20% developed an incarceration and the hernia recurred in 16%. On the basis of this study the authors recommended that (1) after ventriculoperitoneal shunts, infants should be closely watched for the development of a clinical inguinal hernia, (2) operation should be done promptly after diagnosis of a hernia because of the increased risk of incarceration, and (3) in these patients the contralateral side should be explored in the case of a clinical unilateral hernia. Clarnette and colleagues[108] evaluated 430 patients who underwent ventriculoperitoneal shunt placement. In their series, 15% developed an inguinal hernia and a hydrocele developed in another 6% of boys. Hernias were bilateral in 47% of boys and 27% of girls. The incidence of subsequent inguinal hernia development closely paralleled the age at which the shunt was performed. In the last 8 weeks of gestation or in the first few months of life the incidence was 30%, then falling sharply to 10% at age 1 year. They argue that raised intra-abdominal pressure is the likely etiology of these hernias. They also conclude that patency of the processus vaginalis is 30% in the first few months of life and supports the possibility that a patent processus vaginalis can close in the first year of life.

There is a well-established risk of inguinal hernia developing in patients on long-term ambulatory peritoneal dialysis,

ranging from 7% to 15%. In such cases the patent processus vaginalis is likely to develop into a frank hernia. Intraoperative herniography is recommended when the peritoneal dialysis catheter is inserted. Water-soluble contrast is infused through the catheter, and the patient is placed in a head-up position for 15 minutes. If a patent processus vaginalis is identified, repair is in order. Alternatively, direct laparoscopic visualization of the internal ring can be performed at the time of catheter placement, particularly if the catheter placement itself is performed laparoscopically. Repair can then be performed open or laparoscopically.

## SLIDING HERNIA

The fallopian tube or mesosalpinx is frequently found in the wall of the hernia sac in girls and is at risk of injury. The operative management has already been discussed.

The appendix may also be found in the wall of a sliding hernia sac. Appendectomy, if it can be done safely, permits high ligation of the sac in the usual way. Alternatively, the sac is ligated distal to the appendix, and the proximal sac, with the appendix, is reduced into the abdominal cavity, with or without purse-string closure as for a sliding hernia in girls. In the infant, the bladder may lie beneath the internal ring and may be pulled down with the hernia sac during dissection. If this is not recognized, high ligation of the hernia sac may include the bladder wall, leading to hematuria, possible necrosis of the bladder wall, and extravasation of urine. This situation can be avoided by careful inspection of the neck of the sac at the time of transfixion. When there is any question about this possibility, the sac should be opened and the contents inspected. Occasionally, the bladder may extend down the medial wall of the sac as a true sliding hernia. Shaw and Santulli recommend a flap operation, as in the Goldstein-Potts repair in females,[109] but we simply ligate and divide the sac distal to the bladder, invert the stump, and narrow the internal ring (Bevan repair).[39]

## DIRECT INGUINAL HERNIA

A direct inguinal hernia in children had been thought to be extremely rare, but the increasing use of laparoscopy has shown them to be somewhat more common than thought. Previously, the most common presentation was as a recurrence after repair of indirect inguinal hernia repair. This is probably due to the direct hernia being missed at the initial operation or as a result of damage to the floor of the inguinal canal during the first operation. Wright encountered only 19 direct hernias in more than 1600 inguinal hernia operations (1.2%).[110] However, Gorsler and Schier[43] found an incidence of 3.9% direct hernias in 403 inguinal hernias. The diagnosis should be suspected if, when operating on an indirect hernia, a typical sac cannot be found and a fascial defect is found medial to the inferior epigastric vessels. Management is by repair of the transversal fascia such as a Bassini repair or by a Cooper ligament repair when sufficiently developed.

## FEMORAL HERNIAS

Femoral hernias are also rare in children and are often misdiagnosed clinically on examination or at the time of indirect inguinal hernia repair.

Fonkalsrud and colleagues[84] reviewed 5452 patients with inguinal hernias, and Burke[111] reviewed 4567 patients, a total of 10,019 infants and children, and found there were 21 patients with femoral hernia (0.2%). Their ages ranged from 6 weeks to 13 years. There were 18 girls and 10 boys, almost a 2:1 ratio. The correct preoperative diagnosis was made in 8 of 21 patients (38%). Four had bilateral femoral hernias, and in five patients the hernias were incarcerated. De Caluwe and colleagues[112] described 38 patients with femoral hernia over a 20-year period. Four patients had bilateral femoral hernias. Correct preoperative diagnosis was made in 53%. Of the 18 patients with misdiagnosis, seven required a second operation. Whenever intraoperative findings (i.e., failure to find a significant indirect inguinal hernia) do not correlate with the preoperative diagnosis (i.e., indirect inguinal hernia), consideration of a direct inguinal hernia or femoral hernia should be given. Before the availability of pediatric laparoscopy, taking down the inguinal floor and inspecting the inguinal canal were justified in these circumstances. However, with the nearly universal availability of laparoscopic equipment in the pediatric surgical operating room, Lee and Dubois[113] advocate diagnostic laparoscopy as an adjunct to hernia repair particularly in recurrence. They described four patients with presumed recurrence of an indirect inguinal hernia who underwent diagnostic laparoscopy at the second surgery. Three of these patients had femoral hernias. They also identified three contralateral femoral hernias as well. Wright[114] reported 16 patients with femoral hernia and advocated repair through a femoral (infrainguinal) approach, suturing the inguinal ligament to the pectineal ligament and pectineal fascia. Ceran and colleagues[115] have used a mesh-plug successfully in four children, as have Lee and Dubose.[113] We prefer a standard Cooper ligament repair for first-time explorations and find the mesh-plug useful for previously operated groins with ipsilateral femoral hernias. In addition, several different techniques for laparoscopic repair in children have now been reported. Small patient numbers and limited follow-up make conclusions about the effectiveness of these procedures premature.

## INHERITED DISORDERS OF CONNECTIVE TISSUE

Patients with Hunter-Hurler, Ehlers-Danlos, and Marfan syndromes frequently have inguinal hernias and are prone to recurrence unless the floor of the inguinal canal is repaired in addition to the usual high ligation of the sac. Coran and Eraklis[116] found 36% of 50 patients followed with Hunter-Hurler syndrome developed inguinal hernia. The recurrence rate with high ligation alone was 56%, and formal herniorrhaphy was recommended. In adolescents we recommend high ligation of the indirect sac, followed by tensionless floor repair with mesh.

## CYSTIC FIBROSIS

The incidence of inguinal hernia in cystic fibrosis is increased, 6% and 15%.[117] The incidence of absent vas deferens in the general population is 0.5% to 1% on the basis of vasectomy studies.[118,119] In cystic fibrosis, abnormalities of the vas deferens ranging from obstruction to complete absence are invariably present and are usually bilateral. Failure to identify the vas

should, therefore, lead to an evaluation for cystic fibrosis. Agenesis of the vas deferens is found in association with renal dysgenesis in patients who do not have cystic fibrosis, so evaluation of the upper urinary tract is recommended in these situations.

## INTERSEX

Rarely a phenotypic female with a palpable gonad in the labia may be a genetic male with androgen insensitivity syndrome, or a true hermaphrodite. If an ovary is encountered in the hernia sac of a female patient, it should be carefully examined for evidence of testicular tissue ("the ovotestis"). Males with androgen insensitivity syndrome do not have fallopian tubes and a uterus but do have a small testis. Hermaphrodites may have a fallopian tube in the hernia sac, and examination of the gonad reveals an asymmetric ovotestis. In both situations, if an abnormal gonad should be encountered, it should not be removed. Small wedge sections are taken from each pole, the gonad is replaced, and the hernia is repaired. This condition is further discussed in Chapter 123.

## SPLENOGONADAL FUSION

Splenic tissue may be fused to an otherwise normal testis (splenotesticular fusion). Presentation is with a scrotal mass, and the usual preoperative diagnosis is a testicular tumor. Orchidectomy is not necessary; intraoperative frozen section provides the diagnosis and allows preservation of the testis. Spleno-ovarian fusion may also be encountered. Splenogonadal fusion may also present as an undescended testis or intra-abdominal mass. Laparoscopy is useful to both diagnose and treat this condition.

## ADRENAL RESTS

Ectopic adrenal tissue appearing as a small mass of yellowish tissue in the apex of the hernia sac is not rare and has been found in 10 of 385 operations for inguinal hernia (2.6%), an incidental finding in each case.[120] In another series, however, the incidence was 0.2% in 1077 sacs analyzed.[89] The adrenal tissue at this site is likely the result of attachment of developing adrenal cells to the testis before descent from the retroperitoneum to the scrotum during fetal development. Excision of the adrenal tissue is not necessary.

## CONGENITAL HYDROCELE

A hydrocele is a collection of fluid in the space surrounding the testicle between the layers of the tunica vaginalis. Hydroceles may be communicating (patent processus vaginalis with free flow of fluid) or noncommunicating (usually scrotal in males, and may extend to the external inguinal ring). Hydroceles are common in infants and children, and in many cases they are associated with an indirect inguinal hernia. Hydroceles are often bilateral and have a higher rate of occurrence on the right side. If communicating, they can vary in size and will often increase in size during the day while the child is upright and decrease in size overnight when the child is supine and gravity drains the hydrocele. Occasionally, a hydrocele may extend through the inguinal canal into the retroperitoneum as an abdomino-scrotal hydrocele. These are frequently confused with an indirect inguinal hernia. Children may also present with a roundish, tense, but painless mass in the upper scrotum or inguinal canal; this is a hydrocele of the cord. Daily fluctuation in the size, progressive increase in size, or intermittent inguinal bulging is indicative of a communicating hydrocele. An acute hydrocele may be secondary to an acute process within the tunica vaginalis or torsion of the testis, or its appendages. These are associated with considerable pain and tenderness. Alternatively, an acute hydrocele may be seen concurrently with or following an acute upper respiratory infection, or a diarrheal illness when coughing and straining forces fluid into a previously undetected patent processus vaginalis.

Usually a hydrocele can be distinguished from an inguinal hernia on physical examination. Typically a nontender cystic swelling of the scrotum that surrounds the testicle and transilluminates is evident. Simple transillumination does not guarantee the diagnosis of a hydrocele. Incarcerated gas-filled intestine will also transilluminate. Therefore aspiration should never be attempted for diagnosis. It is usually possible to palpate a thin spermatic cord above the hydrocele. However, this may be difficult in a large hydrocele of the cord or an abdomino-scrotal hydrocele.

In the majority of children with congenital hydrocele, the processus vaginalis closes behind the hydrocele (noncommunicating hydrocele) and the hydrocele typically resolves by age 2. Therefore operation is not recommended in the first 2 years of life unless the hydrocele is communicating or a hernia cannot be ruled out. An exception is a large tense hydrocele associated with discomfort. Hydroceles that persist beyond 2 years of age or those that arise in an older child require operation. The operation performed is high ligation of the patent processus vaginalis. The distal hydrocele sac is opened and drained. The open sac is left in place and the edges do not require suturing as in adult hydrocele operations. Reaccumulation of fluid in the sac is uncommon and generally resolves spontaneously.

# Undescended Testis, Torsion, and Varicocele

John M. Hutson

## Undescended Testis

### HISTORY

The importance of a descended testis has been known since ancient times, but the mechanism of descent remained obscure until 1786 when Hunter dissected the human fetus. He found the intra-abdominal testis connected to the inguinal abdominal wall by a ligament called the “gubernaculum testis” because it appeared to guide the testis to the scrotum.

### EMBRYOLOGY

Testicular descent into the low-temperature environment of the scrotum in mammals is a complex multiple-stage process.[1] Up to the time of sexual differentiation in the human fetus at 7 to 8 weeks’ gestation, the fetal testis and ovary occupy similar positions and are held by the cranial suspensory ligament (upper pole) and the gubernaculum (lower pole). The gonadal positions then diverge; the testis remains close to the future inguinal canal, whereas the ovary moves away from the groin.

The cranial suspensory ligament, which persists in girls, regresses in boys while the gubernaculum enlarges, especially at its distal end where it is embedded in the inguinal abdominal wall. The inguinal canal forms by condensation of mesenchyme around the gubernaculum to form the inguinal musculature. The mesenchyme of the gubernaculum persists to form a solid cord, which later becomes hollowed out by a diverticulum of peritoneum, the processus vaginalis.[5] The proximal gubernaculum, which is initially attached to the gonad, becomes expanded by growth of the caudal epididymis. The processus vaginalis grows caudad into the gubernacular mesenchyme, partly hollowing out the gubernaculum. The caudal end of the gubernaculum remains solid, but the proximal part is divided into a central column attached to the epididymis and an annular parietal layer within which the cremaster muscle develops. At the start of the third trimester, the caudal end of the gubernaculum bulges beyond the inguinal abdominal wall (Fig. 77-1) and migrates across the pubic region to the scrotum.[2] The processus vaginalis elongates proportionally inside the gubernaculum so that the testis can leave the peritoneal cavity within it (see Fig. 77-1). Migration of the gubernaculum and the testis to the scrotum is complete by 35 weeks.[2,3] During migration, the gubernaculum is loose within the inguinoscrotal mesenchyme, suggesting enzymatic digestion of the adjacent tissues. After migration is complete, the processus vaginalis becomes secondarily attached to the bottom of the scrotum (see Fig. 77-1).

The different phases of testicular descent are hormonally regulated.[4] The hormones controlling descent and their mechanism of action remain controversial.[3] The early phase of abdominal testicular descent is regulated separately from the migratory inguinoscrotal phase.[5,6] Androgen controls regression of the cranial suspensory ligament of the testis, but regression of this ligament is not essential for testicular descent.[7] Enlargement of the gubernaculum testis is primarily controlled by insulin-like factor 3 (Insl3),[8] which is an analogue of insulin and relaxin produced by Leydig cells.[9,10]

Insl3 is made up of two peptide chains linked by a disulfide bond, with homology to relaxin, and is a member of the insulin family of growth factors.[8] Knockout mice with mutated Insl3 have high intra-abdominal testes and an abnormal gubernaculum, consistent with a role of Insl3 in stimulating the “swelling reaction” of the gubernaculum to initiate transabdominal testicular descent.[11,12] Studies both in vivo and in vitro show a primary role for Insl3 in stimulating early gubernacular growth, with secondary roles for testosterone and müllerian-inhibiting substance.[11,12]

Migration of the testis and gubernaculum from the inguinal region to the scrotum is under androgenic control. In instances of complete androgen resistance or gonadotropin deficiency, inguinoscrotal migration is absent.[13] The mechanism of androgenic control of gubernacular migration is unknown, but there is substantial evidence implicating the genitofemoral nerve. The signals initiating migration of the gubernaculum out from the abdominal wall have many characteristics of an embryonic limb bud.[14] In addition, the mammary line may be important in triggering this dramatic change in the gubernaculum.[15,16] It has been postulated that the sensory branches of the genitofemoral nerve release calcitonin gene-related peptide (CGRP), which may then indirectly control gubernacular migration by stimulation of growth of the gubernacular tip,[17] as well as provide a chemical gradient to allow

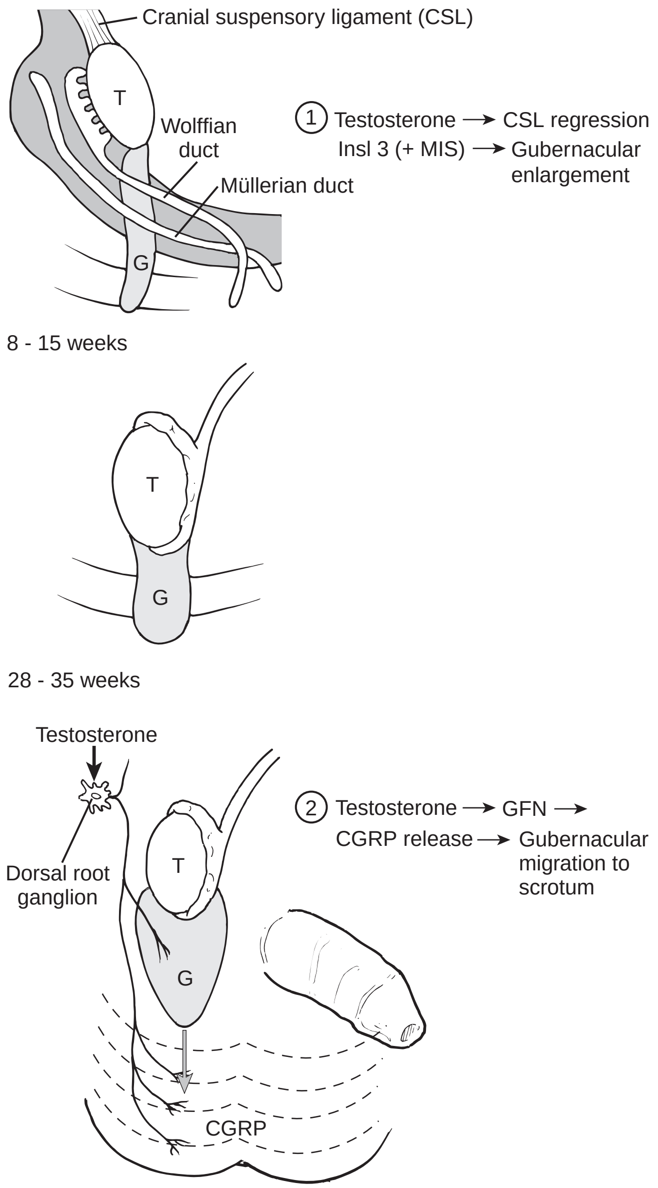

**FIGURE 77-1** Schema showing gubernacular development in the two phases of testicular descent in the human fetus. In the first ("transabdominal") phase at 8 to 15 weeks the testis *(T)* is held near the inguinal abdominal wall during embryonic growth by enlargement of the gubernaculum *(G)*. This relative change in testicular position compared with the ovary is controlled by testicular hormones, with insulin-like factor 3 the primary hormone possibly augmented by müllerian-inhibiting substance *(MIS)*/antimüllerian hormone. The cranial ligament regresses under the action of testosterone. In the second ("inguinoscrotal") phase at 28 to 35 weeks, the gubernaculum migrates by elongation toward the scrotum. This is controlled indirectly by testosterone acting on the genitofemoral nerve *(GFN)* in the dorsal root ganglia to differentiate the sensory fibers to release calcitonin gene-related peptide *(CGRP)*. CGRP controls growth and direction of migration of the rat gubernaculum, and it is hypothesized that it does the same in humans. CSL, cranial suspensory ligament.

migration in the correct direction toward the scrotum. The physical force for migration of the testis is probably provided by intra-abdominal pressure acting through the patent processus vaginalis. Recent work also implicated the propulsive force of the developing cremaster muscle in the wall of the gubernaculum and its sympathetic nerve supply,[18] although this has not been substantiated.[19]

Any anomaly disrupting normal testicular descent leads to cryptorchidism.[20] The complexity of the process suggests that causative factors for nondescent are multifactorial. Most undescended testes are located outside the inguinal canal because the migratory inguinoscrotal phase of testicular descent is deranged more commonly. In contrast, the passive anchoring by the gubernaculum in the transabdominal phase is infrequently disrupted, so the intra-abdominal testes are relatively uncommon, occurring in 5% to 10% of cryptorchid boys.[21] In most cases, the undescended testis is located near the neck of the scrotum, just outside or a little lateral to the external inguinal ring, in the "superficial inguinal pouch," which is the misplaced tunica vaginalis. Abnormalities of gubernacular migration may be related to defects in the migratory mechanism itself or failure of genitofemoral nerve function.[6,22] Defects in the nerve may be caused by deficiency of androgen secretion during the second and third trimester as a result of deficiency of gonadotropin production by the pituitary or the placenta. Recognizable endocrine disorders such as müllerian-inhibiting substance deficiency or decreased testosterone synthesis or receptor function also cause failure of testicular descent but are rare. Since the discovery of Insl3 and its role in transabdominal descent, a search has been made for mutations of the Insl3 gene in undescended testes, but only relatively rare cases have been described.[23–25]

Undescended testes lying well outside the normal line of descent such as in the perineum or femoral region are rare, and their cause is unknown. It has been suggested that this may be the result of an abnormal location of the genitofemoral nerve with consequent abnormal migration of the gubernaculum to the wrong site.[6] The cause of transverse testicular ectopia is also unknown, but in animal models transverse ectopia can be induced readily by cutting the gubernacular attachment to the testes so that the gonad is no longer required to exit the abdominal cavity through the ipsilateral inguinal canal. Increased gonadal mobility may permit accidental descent through the contralateral inguinal canal.[26] The latter also occurs in boys with persisting müllerian duct syndrome, where the elongated gubernacular cord predisposes to accidental descent down the contralateral inguinal canal.

A number of inherited syndromes are associated with undescended testes. The underlying cause is not known, although many are associated with microcephaly, suggesting the possibility of pituitary hormone or gonadotropin deficiency.[27] Some multiple malformation syndromes are also associated with neurogenic and mechanical anomalies, for example, arthrogryposis multiplex congenita.[28] These disorders may cause cryptorchidism either by external compression of the deformed fetus or by intrinsic neurologic anomalies. Experimental inguinoscrotal compression during testicular descent is associated with undescended testes.[29] Intra-abdominal testes are characteristic of the prune-belly syndrome. The cause of the cryptorchidism is controversial, with thoughts ranging from a mesodermal defect to transient prenatal urinary obstruction.[30–33] The absence of a processus vaginalis within the inguinal canal and the position of the testes on the posterior surface of the bladder are consistent with an obstructive cause. Ten percent of infants with posterior urethral valves also have cryptorchidism.[34]

Cryptorchidism is common in infants with abdominal wall defects such as gastroschisis (where the gubernaculum may be ruptured), exomphalos (omphalocele), and exstrophy of the bladder.[35] Undescended testes occur in more than 15% of

infants with gastroschisis and at least a third of children with exomphalos or omphalocele.[27,35] Whether this is caused by decreased abdominal pressure or other mechanical effects is not certain, although a role for abdominal pressure has been determined in experimental animals.[36]

Neural tube defects have a high incidence of undescended testes.[37] When there is a myelomeningocele affecting the upper lumbar spinal cord, the incidence of undescended testes is greater than one third. This could be caused either by abdominal wall paralysis and lower-than-normal abdominal pressure or by dysplasia of the genitofemoral nerve sensory nucleus at the site of the myelomeningocele.[38]

Separation of the body of the epididymis from the undescended testis is frequently observed.[39–41] This is more common in intra-abdominal and high inguinal cryptorchid testis. Whether this is the cause of the cryptorchidism or merely secondary to decreased androgen production in utero occurring simultaneously is not known. Experimental evidence in rodents treated with antiandrogens suggests that in-utero androgen deficiency causes epididymal deficiency.[42] Abnormalities of the vas deferens occur commonly in boys with cryptorchid testes. The impalpable intracanalicular testis may have a vas deferens forming a loop, which protrudes distally through the external inguinal ring. On the basis of an examination of the blood supply of such a long-loop vas, Fowler and Stephens proposed transection of the main testicular vessels to the high undescended testis to permit orchidopexy with testis viability maintained by the redundant vas deferens with its collateral blood supply.[43] Although this operation is less commonly performed as an open one-stage procedure because of the high incidence of atrophy, it is now commonly performed laparoscopically as a one- or two-stage procedure.[44]

## CLASSIFICATION OF UNDESCENDED TESTES

Classification of gonadal position in undescended testes is complicated by the mobility of the testis inside its tunica vaginalis. Undescended testis is best defined as a testis that cannot be manipulated to the bottom of the scrotum without undue tension on the spermatic cord. A normally descended testis resides spontaneously in the lower scrotum even if it was retracted when the patient was first examined. The positions of undescended testes can be divided into those arrested in the line of normal descent and those in truly ectopic positions (Fig. 77-2). The intra-abdominal testis is usually located within a few centimeters of the internal inguinal ring, with the vas deferens and the testicular vessels traveling extraperitoneally and then entering the testis through a short mesorchium. Such intra-abdominal testes were often difficult to find through extraperitoneal exploration through the inguinal canal but are now relatively easy to identify at laparoscopy.

A canalicular testis is one that lies within the inguinal canal but may be difficult or impossible to palpate because of the overlying musculature. Such gonads may be squeezed out of the inguinal canal and become palpable at the external inguinal ring, so-called *emergent testes.*

Undescended testes beyond the external ring may lie near the neck of the scrotum or may be lateral and a little above the external inguinal ring in the superficial inguinal pouch, originally described by Browne (see Fig. 77-2).[45] The latter location is rarely an indication of aberrant gubernacular migration because at surgery the gubernacular attachment is nearly always at or near the neck of the scrotum.[39,46] Essentially, the superficial inguinal pouch is the space created by the tunica vaginalis in the groin and is limited superficially by Scarpa's fascia and its deep attachment to the fascia lata just

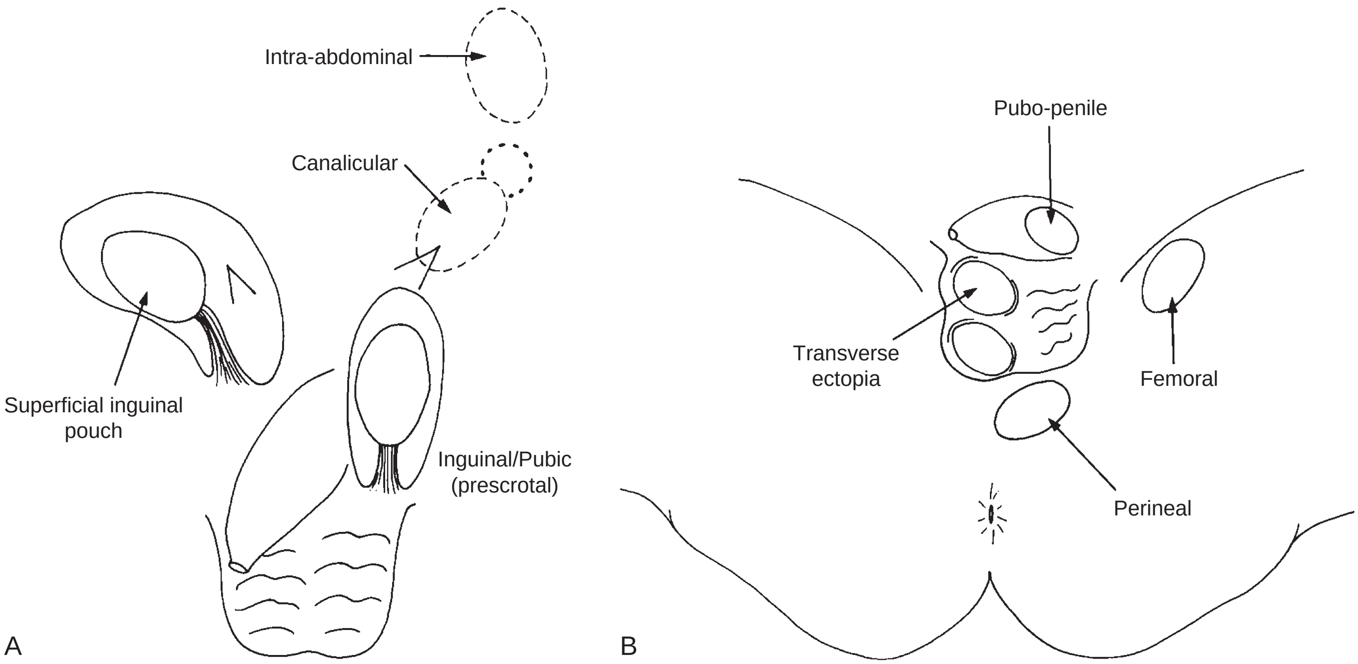

FIGURE 77-2 The range of positions that may be adopted by undescended testes. **A,** In the line of normal descent (including the controversial superficial inguinal pouch, note that the gubernaculum is attached near the neck of the scrotum in most instances). **B,** True ectopic sites, which are rare. (From Hutson JM, Beasley SW: Descent of the Testis. London, Edward Arnold, 1992.)

caudad to the inguinal ligament. Whether testes in the superficial inguinal pouch should be labeled as ectopic is controversial, but because the gubernaculum is attached at or near the neck of the scrotum, they seem to be better classified as testes arrested in the line of normal descent.[47] Truly ectopic testes may be located in the perineum, femoral region, pubopenile region, or contralateral hemiscrotum secondary to transverse ectopia.

## RETRACTILE TESTES

Transient retraction of the testis out of the scrotum is a normal reflex caused by contraction of the cremaster muscle. This muscle functions to regulate the temperature of the testis and to protect it from extrinsic trauma.[48] Retraction occurs as a result of low temperature or stimulation of the cutaneous branch of the genitofemoral nerve (inner thigh).

The normal retractile reflex is weak or absent at birth, and the scrotum is often pendulous. Later in childhood, when androgen levels are low, cremasteric contractility is significantly increased and the cremasteric reflex more pronounced. After 10 years of age, the reflex becomes less pronounced as androgen levels rise with the onset of puberty. The cremasteric reflex and normal retractile testis have been studied by Farrington, who found a high incidence of retractility in the middle of childhood.[49]

At present, there is no consensus about what constitutes a retractile testis.[50] Most clinicians agree that a retractile testis is a descended testis, although careful follow-up is required because it does not always remain descended. The retractile testis probably reflects a normal physiologic response to contraction of the cremaster muscle related to age. Goh and Hutson suggest that so-called retractile testes are, in fact, testes with acquired maldescent.[51] As the distance between the external inguinal ring and the bottom of the scrotum increases with age (from 5 cm in an infant to 10 cm by 10 years of age), it is necessary for the spermatic cord to lengthen for the testis to remain located in the scrotum. Retractile testes may represent acquired maldescent secondary to failure of the spermatic cord to elongate with age, which may be a sequel of excessive contractility of the cremaster muscle in some boys, as in those with cerebral palsy and spastic diplegia.[52]

## ASCENDING TESTES

A newly described variant of the retractile testis is the ascending testis.[50,53,54] In many of these children, long-term follow-up studies have demonstrated that subsequent ascent out of the scrotum later in childhood is often related to delayed descent into the scrotum within the first 3 months after birth. Ascending testes are now being documented by a number of authors.[50,55] The difference between ascending and retractile testes is otherwise not clear, and it may be that they are different names for developing acquired cryptorchidism.

## ACQUIRED UNDESCENDED TESTES

Not all undescended testes are present from birth. Many children with cryptorchidism present later in childhood despite attempts at screening in infancy.[56] In addition, on careful questioning of such families, there is often no history of an anomaly at birth or in early childhood.[57]

Acquired cryptorchidism is caused by failure of the spermatic cord to elongate in proportion to body growth. Such testes appear to ascend out of the scrotum with increasing age, but measurements of the cord length suggest that this ascent is more apparent than real because the scrotum is farther from the groin in older boys. This is certainly true in patients with cerebral palsy, in whom acquired cryptorchidism approaches 50% in postpubertal boys with severe spastic diplegia.[52]

Ascending testes may be caused by persistence of the processus vaginalis either as a patent hernia or an obliterated remnant, which is likely to inhibit elongation of the adjacent vas deferens and testicular vessels.[55,58] In cases in which the testis migrated to the scrotum prenatally and was present within the scrotum in infancy, but the position is too high later in childhood, orchidopexy is often successful through a scrotal approach.[59,60]

## INCIDENCE OF UNDESCENDED TESTES

In 1964 Scorer found the incidence of undescended testes was 4.3% in infants,[61] but by 1 year of age, the incidence had fallen to 0.96%. In 1986 the incidence of cryptorchidism at 1 year of age was 1.58% in British children. The John Radcliffe Hospital Cryptorchidism Study Group found that spontaneous descent occurred postnatally in the first 3 months; beyond that time, it was rare.[53,62] The rate for orchidopexy in England and Wales effectively doubled over several decades.[63] Although this difference between the incidence of cryptorchidism and frequency of orchidopexy suggested that some orchidopexies may be unnecessary, it has been suggested that the apparent doubling of orchidopexy rates may be related to acquired ascending or retractile testes.[50] Because the recommended age for surgery for congenital undescended testes has decreased to 6 months of age, those children with acquired undescended testes are now more readily distinguishable from those children with congenital failure of gubernacular migration.[56]

The frequency of undescended testes is significantly increased in premature infants.[64] When birth weight is less than 1500 g, the incidence of cryptorchidism reaches 60% to 70%.[65] The cause of this high frequency of cryptorchidism is that normal descent is not completed until about 35 weeks' gestation. Most undescended testes in premature infants continue to descend postnatally, so if such children are examined at 12 weeks beyond their expected normal delivery date, the incidence of cryptorchidism has fallen to more normal levels.

## COMPLICATIONS OF CRYPTORCHIDISM

Controversy persists about whether the testis is primarily abnormal, leading to maldescent, or alternatively is undescended, leading to a secondary abnormality. Evidence now suggests that abnormalities seen postnatally in undescended testes are secondary. Occasional primary abnormalities in the hypothalamic-pituitary-gonadal axis, however, lead to inadequate hormone secretion, maldescent, and primary testicular abnormalities.

Species differences have made investigative studies regarding the effects of undescended testes difficult to evaluate. Many studies concerning cryptorchidism have been carried out on rodents, in which the important developmental aspects

of gubernacular migration are complete by the 10th day after birth. The testis, however, does not descend into the scrotum until 2 to 3 weeks in mice or 3 to 4 weeks in rats, at the time of pubertal sexual maturation.[66] Human gubernacular migration and testicular descent occur simultaneously and are normally complete before birth. The effects of undescended testes in the rat, therefore, do not become evident until after puberty.

### Temperature Effects

The scrotal testis resides in a specialized low-temperature environment with the pampiniform plexus, scrotal pigmentation, absence of subcutaneous fat, and regulation by temperature-sensitive muscles such as the cremaster and dartos muscle, all ensuring decreased temperature of the epididymis and gonad. The scrotal testis in the human is maintained at 33°C compared with 34°C to 35°C in the inguinal region and 37°C intra-abdominally (Fig. 77-3).[67,68] The physiology of the testis is well adapted to this lower temperature; therefore in the undescended testis where the ambient temperature is increased, the testis undergoes progressive alteration.[1]

### Endocrine Effects

Steroid pathways in rat testes made cryptorchid by surgical fixation before puberty show no gross abnormalities, indicating that Leydig cells are still functional with cryptorchidism in this model. Measurement of testicular testosterone content in rats made cryptorchid at birth shows no abnormality up to 2 to 3 weeks of age but decreased testosterone production compared with controls after puberty.[69] Gonadotropic regulation of both Leydig and Sertoli cells is abnormal after puberty.[70] The number of Sertoli and Leydig cells, however, remains relatively normal.[71] Functional derangements in Sertoli cells with cryptorchidism have been well documented by de Kretser and Risbridger.[72]

Plasma gonadotropin and testosterone levels have been measured in infants with undescended testes, and the normal postnatal rise in plasma luteinizing hormone (LH) levels and testosterone were found to be significantly lower than normal.[73,74] It is difficult to determine conclusively whether this postnatal androgen deficiency is a primary abnormality or secondary to nondescent.

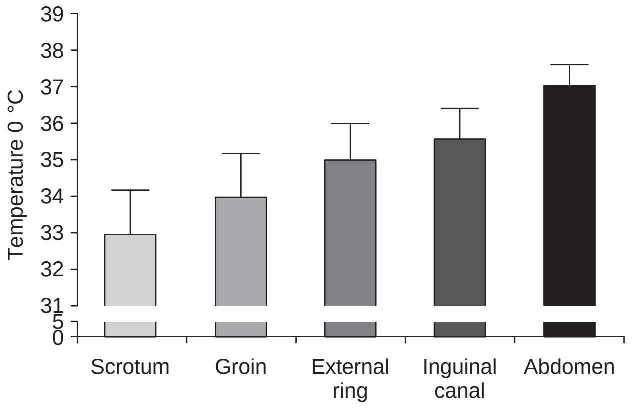

FIGURE 77-3 The temperature (mean ± standard deviation) of the testis at different levels. (From Hutson JM, Beasley SW: Descent of the Testis. London, Edward Arnold, 1992.)

In a study of premature infants born with a mean gestational age of 30 weeks, there was a persistently high incidence (19%) of undescended testes at 18 months despite some testes descending postnatally.[75] The normal rise in testosterone seen in the second and third month postnatally failed to develop in these premature infants with cryptorchidism. The authors concluded that inadequate stimulation of testosterone by human chorionic gonadotropin (hCG) in utero may contribute to the pathogenesis of undescended testes in this special group. Both plasma testosterone and LH levels were decreased in cryptorchid infants between 1 and 4 months of age.[40] Although androgen levels may be deficient, androgen receptor levels in scrotal skin fibroblasts and testicular biopsy specimens taken at orchidopexy are normal in infants with bilateral cryptorchidism.[76] Serum levels of müllerian-inhibiting substance are normally elevated between 4 and 12 months of age, but in children with cryptorchidism this postnatal rise was inhibited.[77]

### Germ Cell Development

Germ cell deficiency in cryptorchidism was previously regarded as congenital.[48] It has been observed, however, that the histology of the testes is initially normal and becomes progressively abnormal with age.[78] Leydig cell development is impaired in undescended testes in the first 2 to 6 months, whereas the Sertoli and germ cells appeared normal.[79,80] By the end of the second year of life, nearly 40% of undescended testes have completely lost their germ cells.[81] It is now well established that the transformation of neonatal gonocytes to type A spermatogonia, an early postnatal step in development of the germ cells, is deficient in infants with cryptorchidism.[82–84]

Moreover, there is now good evidence that type A spermatogonia are the stem cells for subsequent spermatogenesis.[85] Some authors have proposed that these early stages in germ cell development are controlled by androgens and are hence deficient because of postnatal androgen deficiency.[82] There is some contrary evidence to suggest, however, that müllerian-inhibiting substance may be controlling early postnatal germ cell development.[86,87] Certainly, androgen blockade or deficiency does not prevent gonocytes transforming to type A spermatogonia in neonatal rodents.[88]

### Fertility

Fertility is lower in men with a past history of cryptorchidism. In previous generations, it was believed that the undescended testis suffered no adverse changes until after puberty and surgical intervention was not necessary until 12 to 15 years of age.[48] The evidence that germ cell maturation is already abnormal after 6 months of age has led clinicians to appreciate that not only is postnatal degeneration an important issue but also that early intervention may prevent it. In animal studies, it is relatively easy to demonstrate that surgically induced or congenital cryptorchidism causes decreased fertility because of germ cell deficiency after puberty.[89] Paternity rates are not deficient in unilateral cryptorchidism in both animals and humans; but with bilateral cryptorchidism, fertility is significantly impaired.[7,90] Data attempting to correlate fertility rates with timing of surgery are not yet available because there are no long-term studies of children undergoing orchidopexy in the first year of life. Fertility in men with a history of retractile testes remains quite controversial, with some authors describing abnormalities on sperm counts that are not reflected in paternity rates.[91–93] In a recent prospective,

randomized trial, children had orchidopexy at 9 months or 3 years, with follow-up to 4 years of age with testicular ultrasound. Those having earlier surgery had significantly greater testicular volumes at 4 years old, which is promising for improved fertility in the future.[94]

### Malignancy

The risk of a testis tumor occurring in men with a past history of cryptorchidism was at one time believed to be 35 to 50 times greater than normal.[95] By using different methods of calculating the relative risk, Woodhouse[96] suggested the actual risk is 5- to 10-fold. When looking at all men with testis tumors, a relative risk for those with a history of unilateral cryptorchidism is 15-fold or 33-fold for bilateral undescended testes, with the risk of cancer being highest with intra-abdominal testes.[97–99]

The progressive degeneration of germ cells and dysplasia seen in cryptorchid testes is thought to be related to an increased risk of malignancy.[100] Testis tumors are not common in childhood, and they usually occur at the same age as testis tumors in normally descended testes (i.e., 20 to 40 years). Giwercman and colleagues[101] have speculated that testis tumors may be caused by an intrinsic abnormality in the testis rather than secondary dysplasia. They suggest that carcinoma in situ germ cells are the forerunner of invasive tumors and are, in fact, malignant gonocytes. Such germ cells displaying histologic characteristics of carcinoma in situ can be identified in neonates with dysgenetic testes and ambiguous genitalia. Skakkabaek and colleagues[102] have described the histologic features of carcinoma in situ and provided strong evidence that these abnormal cells are a prerequisite to invasive testis tumors. They recommend that young men with a past history of cryptorchidism should be offered testicular biopsy to exclude this condition before malignancy occurs.

### Inguinal Hernia

The processus vaginalis normally obliterates after descent of the testis in the perinatal period. Undescended testes are associated with a higher incidence of patent processus vaginalis and inguinal hernia, in many cases leading to early surgical intervention because of the risk of incarcerated hernia. A clinically evident hernia present with a cryptorchid testis is an indication for immediate intervention. Most surgeons elect to perform a hernia repair and orchidopexy simultaneously.

### Torsion of a Cryptorchid Testis

There is a high incidence of up to 20% for torsion in unoperated undescended testes[48]; however, the trend to early orchidopexy has meant that most pediatric surgeons rarely see torsion in an undescended testis. The mobility of a testis within the tunica vaginalis in the superficial inguinal pouch may predispose to torsion, but the exact frequency is now difficult to determine.[103]

### Trauma

Inguinal testes are at a slightly increased risk of direct trauma, although as with testicular torsion, early surgical intervention has made this a less common problem.[65] The most common clinical cause of trauma in an undescended testis I have seen is in children with cerebral palsy requiring wheelchair restraint. In these children, an inguinal testis may be compressed by the straps of the wheelchair.

### Psychologic Factors

Cryptorchidism is a major psychologic problem because the obvious physical abnormality of the genitalia promotes parental anxiety about subsequent fertility.

### Testicular-Epididymal Fusion Abnormality

Abnormal connection between the testis and the epididymis is common in cryptorchidism.[40,41] The risk of abnormal fusion is greater with testes inside the canal or the abdomen than in inguinal testes or those lying at the neck of the scrotum. These abnormalities may be related to underlying androgen deficiency in utero, and in a percentage of these the abnormality may be sufficient to interfere with fertility.

## DIAGNOSIS

The aim of the clinical examination is to identify the presence or absence of a palpable gonad and to determine the lowest position that it will sit comfortably without undue tension.[104] The lowest limit of testicular position without tension probably corresponds to the caudal limit of the tunica vaginalis. Examination should be conducted in warm surroundings and with the child relaxed. With the child recumbent on the examination table, the genitalia should be inspected for the appearance of the scrotum and any inguinal swelling suggesting a high testis or an associated hernia. It is important to observe the scrotum before palpation because the testis may be seen in the scrotum only to retract briskly into the inguinal space on palpation, which may prove difficult to bring down into the scrotum, confusing the diagnosis. Cranial traction on the suprapubic skin to expose the scrotum often makes testes that are retracted to the upper part of the scrotum conspicuous. The appearance of the scrotum varies dramatically with age, with the neonatal scrotum being thin, pendulous, and flabby compared with the middle of childhood, when the scrotum is small and puckered. If the testis is lying within the scrotum, it is usually visible through the thin scrotal skin. Hypoplasia of the hemiscrotum suggests that the testis has never been within it. A hemiscrotum of normal size is more likely if the testis is retractile or ascending.

The key to locating a suprascrotal testis is to remember that the testis is contained within the tunica vaginalis and is therefore mobile. In addition, the bony landmarks of the inguinal ligament should be identified. It is helpful to begin the examination by blocking the internal inguinal ring with one hand and milk down toward the external ring to prevent the testis from being displaced cephalad into the inguinal canal on palpation. To locate a testis in the superficial inguinal pouch, light palpation with the flat of the hand is most effective. If palpation is too hard, this often displaces the testis from under the fingers, so it may be missed. At least 80% to 90% of testes are palpable in the inguinal region or can be squeezed out of the inguinal canal and felt at the external ring by pressing firmly on the abdominal wall laterally near the anterosuperior iliac spine and pressing downward and medially toward the scrotum. Intra-abdominal or intracanalicular testes that cannot be delivered outside the external ring are uncommon. Once the mobile testis has been identified in the groin, one hand of the examiner attempts to push the testis toward the

scrotum while the other hand attempts to grasp it through the thin scrotal skin. The aim of this maneuver is to determine the lowest level to which the testis can be manipulated without undue tension. A normally retractile testis should be able to be brought right to the bottom of the scrotum and remain there. The position of the testis at physical examination can be documented by measurement from the pubic tubercle as described by Scorer,[61] although this degree of documentation is usually unnecessary.

The most useful clinical observation is whether the testis can reside in the scrotum spontaneously. Examination of the scrotum in the newborn is easy because the testes are readily visible and palpable when in the scrotum. If the testes can be felt above the scrotum, the child should be reexamined at 3 months of age to see whether there has been delayed descent. If the testis remains out of the scrotum at age 3 months, a confident diagnosis of congenital undescended testis can now be made. If the testis has descended within the first 12 weeks, there is a risk that it may reascend out of the scrotum later in childhood, and such children are best kept under close observation.

Determining the exact testicular position may be difficult if there is an associated incarcerated inguinal hernia. Once the hernia has been reduced by manual compression, the position of the testis can usually be identified.

The clinical distinction between a normally retractile testis and an undescended testis can be difficult. Useful criteria for distinguishing normally retractile testes are as follows:

1. The testis can be brought fully to the bottom of the scrotum without difficulty.
2. The testis remains in the scrotum after manipulation without immediate retraction.
3. The testis is normal in size.
4. There is a history that the testis resides spontaneously in the scrotum some of the time.

If the testis cannot be palpated in the usual position in the groin near the external inguinal ring, the sites for an ectopic testis should be examined, such as the femoral region and perineum. Truly impalpable testes are relatively uncommon, being variously reported in 5% to 28% of boys with undescended testes.[105–108] If the testis cannot be palpated, this implies that it is either intra-abdominal (45%) or within the inguinal canal (up to 25%), which is likely if the external ring is palpably open (personal observation). Alternatively, it may be absent (45%). This is known as the vanishing testis and is likely the result of intrauterine torsion of the spermatic cord during migration of the gubernaculum to the scrotum.[84,109,110] This leads to secondary atrophy of the testis, and the contralateral testis is commonly enlarged, which is a useful physical sign.[83,111]

Blind inguinal exploration for the impalpable undescended testis is unlikely to be successful. Numerous imaging techniques have been recommended to identify the position of such a testis.[112] These include abdominal and inguinal ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and spermatic venography and arteriography. Laparoscopy recently has become the most common way to identify the position of an intra-abdominal testis and to exclude the possibility of secondary atrophy.[113–115] Laparoscopy offers the additional benefit of ligation of the testicular vessels should a two-stage Fowler-Stephens operation be contemplated.[113]

## TREATMENT

### Hormone Treatment

Hormone therapy is based on the premise that the undescended testis is caused by deficiency of the hypothalamic-pituitary-gonadal axis and that postnatal treatment can induce the required migration of the gubernaculum.[116] Therapy has been tried with testosterone, hCG, and luteinizing hormone-releasing hormone (LHRH). Direct androgen therapy was abandoned many years ago because excessive doses caused precocious puberty. In the past 10 to 20 years, hCG has been used commonly in Europe but less commonly elsewhere. More recently, LHRH has been tried.

The results of hormone therapy have been mixed and depend on a number of factors. Success rates for treatment range from 10% to 50%.[117–119] Children older than 4 years and those with bilateral undescended testes near the scrotal entrance or retractile testes respond most favorably to hCG. Testes in the superficial inguinal pouch, the most common variant of the anomaly, have a low success rate. It has been suggested that the successful cases are due to the fact that most were retractile testes.[119] In unilateral undescended testis, which is statistically much more likely to be of congenital origin, only 14% of boys have successful hormonal therapy.

In a randomized, double-blind study comparing hCG and LHRH, Rajfer and colleagues found 6% of boys treated with hCG responded with testicular descent compared with a 19% success rate for LHRH.[119] They concluded that neither hCG nor LHRH was effective in promoting descent of truly undescended testes. A double-blind, placebo-controlled study of LHRH nasal spray in boys with cryptorchid testis showed a 9% success rate with LHRH compared with 8% with placebo treatment.[117,120] A second course of LHRH therapy increased the descent rate to 18%. Young children had the lowest response rate, and LHRH was not useful for impalpable testes. There have been recent suggestions that hormone therapy may be useful for germ cell development as an adjunct to surgery,[121] but this remains extremely controversial.[122]

Some clinicians suggest that hormone therapy diagnoses a retractile testis (which has a high success rate) and thereby avoids surgery. Acquired undescended testes with severe retraction or secondary ascent may respond to hCG treatment at levels of 100 IU/kg intramuscularly twice a week for 3 to 4 weeks. Alternatively, LHRH can be given as a nasal spray at 100 mg in each nostril six times a day for 3 to 4 weeks. In my surgical department, hormonal therapy is used rarely, and nearly all children with congenital or acquired cryptorchidism are offered orchidopexy.

### Surgical Treatment

Treatment of cryptorchidism is based on the assumption that early intervention will prevent secondary degeneration of the testes caused by high temperature.[1] The scrotal testis is 3°C to 4°C cooler than the intra-abdominal core temperature, which is essential for normal postnatal testicular development.[67] The timing of surgery remains controversial, with some studies suggesting that delayed orchidopexy late in childhood is associated with good results, whereas others show poor results. Studies showing early degeneration of the germ cells in the first 6 to 12 months through to macroscopic atrophy in school-age children all suggest that undescended testes

undergo progressive degeneration after birth.[82,123] Although the evidence that early surgery prevents this degeneration sequence is not yet available in humans, it is shown in all animal studies.[124]

Orchidopexy is recommended at 6 to 9 months. This is because the first signs of damage to the testes are identified at about 6 months of age.[82] Orchidopexy in such young children, however, can be challenging. In pediatric surgical centers, orchidopexy is safe in the second 6 months of life; however, in centers with less experience in small children, surgery between 12 and 18 months may be safer. When orchidopexy is done in a pediatric surgical center, a younger age does not increase the risk of complications.[125]

Routine examination of all boys should be done at birth with repeat examination at 3 months in those children in whom one or both testes were not descended at birth. If the testis remains undescended at 3 months, the child is best referred for orchidopexy around 6 months of life. When the testis has descended spontaneously in the first 12 weeks, such children are best observed every few years to ensure that they do not develop acquired undescended testes later in childhood. Children presenting with a concomitant inguinal hernia should have the orchidopexy done together with the inguinal herniotomy. This is much safer than delaying the orchidopexy after the herniotomy because reexploration has a higher risk of damage to the vas and vessels. In older boys presenting with acquired maldescent, I recommend surgery once the testis no longer resides spontaneously in the scrotum. This is a controversial recommendation to some.

Orchidopexy is performed as an ambulatory procedure with the child entering the hospital or clinic an hour or so before operation and discharged a few hours later.[126] Topical anesthetic cream is applied to the back of the hand so that induction of anesthesia by injection is not painful. Under general anesthesia, a regional or local anesthetic block is performed to provide pain relief for the first few hours postoperatively.

For inguinal undescended testes, a skin crease incision is made over the external ring and extending a little laterally (Fig. 77-4, *A*). The remaining details are shown in Figure 77-4, *B* to *N*.

A widely patent processus vaginalis is common (up to 70%) and needs to be separated from the vas deferens and the testicular vessels (see Fig. 77-4, *D*). The hernia sac is wrapped around the vessels anteriorly with the vas deferens posteromedial and the vessels posterolateral. In high undescended testes, particularly those found in the inguinal canal, the hernia sac completely envelops the testis so that the vas and vessels are inside the sac within a mesorchium. The method of separation of the hernia sac is that used during routine hernia repair: the sac is stretched over the index finger while round-ended, nontoothed dissecting forceps gently sweep off the other cord structures, taking care not to damage the testicular vessels and vas deferens. En masse separation of the vas deferens and vessels is easier if the sac remains intact. If an opening is made inadvertently, the edges of the peritoneum should be picked up with forceps to maintain extensile exposure. The vas deferens is adherent to the back of the hernia sac, so it must be positively identified before the sac is divided. It is important to remember that the processus vaginalis may encompass the entire spermatic cord because its lateral edges can be fused posteriorly by the external spermatic fascia.

Once the cord structures have been separated from the sac, safely identified, and protected, the sac is divided (see Fig. 77-4, *E*). Dissection is continued proximally up to the internal ring, where external peritoneal fat and divergence of the testicular vessels laterally from the vas medially indicates the retroperitoneum (see Fig. 77-4, *F*). The processus vaginalis is then transfixed and ligated at the internal inguinal ring (see Fig. 77-4, *G*).

Further mobilization of the testicular vessels in the retroperitoneal space may be achieved by dividing small fibrous bands laterally that hold the testicular vessels and prevent them from being gently stretched to allow the testis to reach the scrotum (see Fig. 77-4, *H*). In older children, straightening the curved path taken by the testicular vessels may effectively lengthen the spermatic cord (see Fig. 77-4, *I*), but this advantage is much less evident in small children. Since the advent of laparoscopy, it can be seen that the testicular vessels actually take a straight path from the abdominal aorta toward the internal inguinal ring and that retroperitoneal dissection is more likely to gain length by allowing greater traction and stretching of the testicular artery rather than by straightening the path taken.

The vas deferens usually has sufficient length to reach the scrotum without any special maneuvers. In difficult cases, however, the inferior epigastric vessels can be divided or the posterior wall of the inguinal canal can be opened medial to the inferior epigastric vessels and the testis taken medially to them (Prentiss maneuver). This may give an extra centimeter or so of length to the vas deferens. The method of fixation of the testis in the scrotum is shown in Figure 77-4, *J* to *N*.

An alternative operation, which is particularly suitable for boys with acquired maldescent, is the transscrotal operation described by Bianchi and Squire[59] and Russinko and colleagues.[60] A transverse incision is made at the neck of scrotum, and the tunica vaginalis is exposed, delivered through the wound, and placed under tension. Loose connective tissue attachments to the spermatic cord are divided to expose the spermatic cord itself. Commonly, there is a residual fibrous strand of the processus vaginalis that has not disappeared. Once this fibrous strand has been divided, the vas and vessels stretch out to reach the bottom of the scrotum without difficulty.[58] The testis can be anchored by closing the neck of the scrotum or by suture of the testis to the scrotal septum.

When the testis is located within the inguinal canal or the abdomen, the spermatic cord may have insufficient length to reach the scrotum despite the maneuvers described previously. In this circumstance the surgeon has a number of choices available. If there is necessary expertise and backup support, microvascular anastomosis can be performed, with transection of the testicular vessels and reanastomosis to the inferior epigastric artery and vein.[127] This technique requires a high level of experience and skill with the operating microscope, so it is not often used. More commonly, if the testis has been dissected but does not reach the scrotum, it can be sutured in the groin at the lowermost point where it reaches comfortably as a first-stage procedure, and a second attempt is made 6 to 12 months later. Success rates for this two-stage orchidopexy have been quoted to be 70% to 90%.[128]

An alternative approach is the Fowler-Stephens procedure in which the testicular vessels are ligated intra-abdominally and the testis swung down on a long-loop vas supplied by collateral circulation from the artery to the vas and some

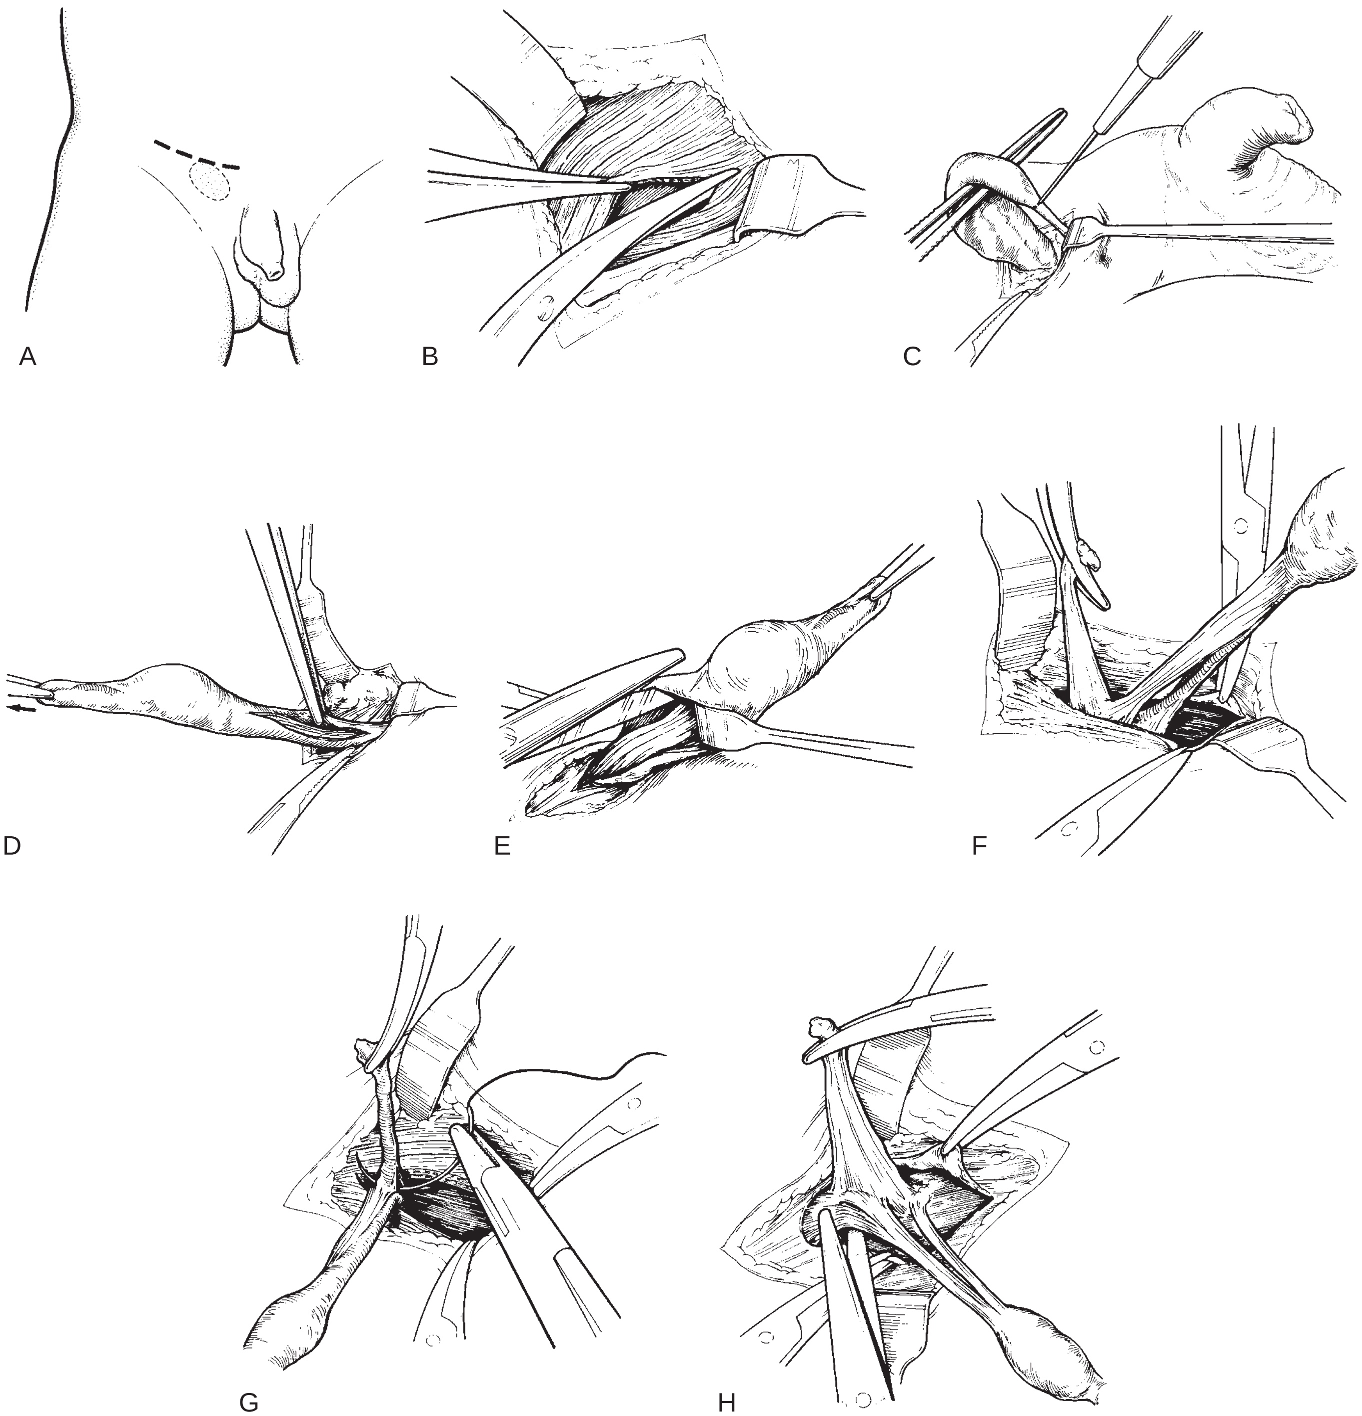

FIGURE 77-4 **A,** Skin crease incision over external ring and extending laterally. **B,** After dividing the Scarpa fascia, the external oblique aponeurosis is exposed and opened with a scalpel and extended medially toward the external inguinal ring with scissors. Application of mosquito forceps to the edges may facilitate subsequent identification and closure. **C,** A testis in the superficial inguinal pouch or pubic region is easily seen at this point, and it can be picked up so that traction on the spermatic cord can permit the distal attachment of the gubernaculum to be identified and divided. In most instances the gubernaculum is attached just lateral or above the neck of the scrotum. **D,** With traction on the tunica vaginalis, the cremaster muscle fibers are stripped off and any residual processus vaginalis is dissected off the vas and vessels, beginning posteriorly where the free edges of the sac are found. **E,** The vas and vessels are identified separate from the hernial sac and are protected by a small retractor while the sac is clamped and divided. **F,** The anteromedial processus vaginalis is dissected from the posterolateral gonadal vessels up to the internal inguinal ring, where the vas deferens diverges medially. **G,** Transfixion and ligation of the processus vaginalis at the internal ring. Twisting the sac first ensures that the needle does not catch any intraperitoneal structures inadvertently. **H,** Extra length may be achieved by freeing up the lateral side of the gonadal vessels in the retroperitoneal space.

*Continued*

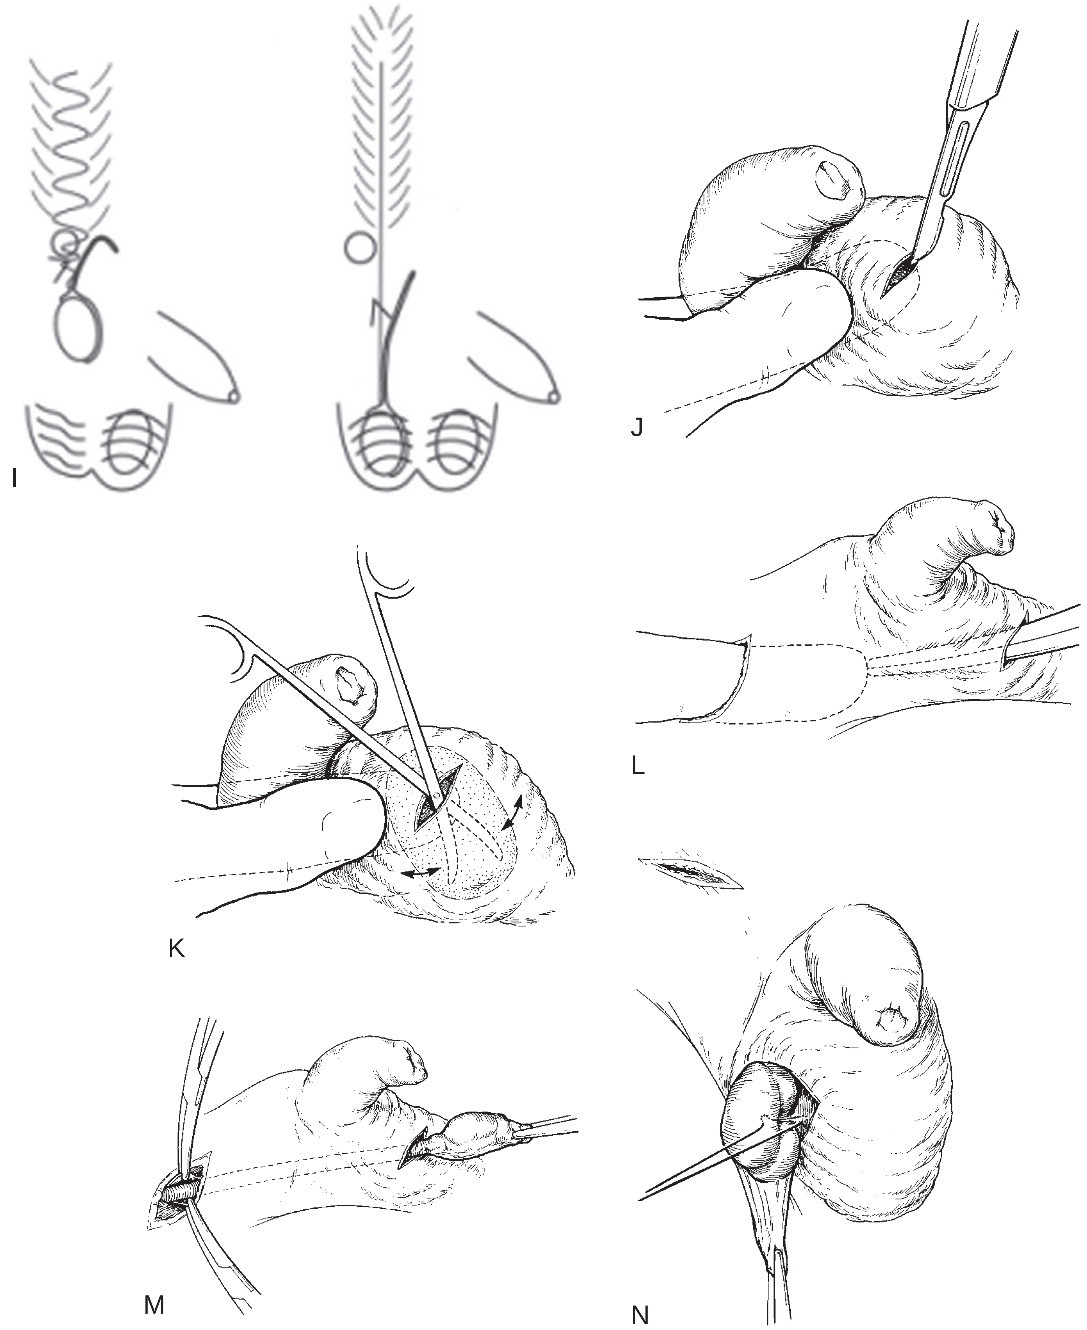

**FIGURE 77-4, CONT'D** **I,** Straightening of the path taken by the gonadal vessels may allow the testis to reach the scrotum. **J,** Incising the scrotal skin after blunt finger dissection has created a path to the scrotum from the inguinal incision. Either midline or transverse incisions may be used to gain entrance to the subdartos space; I prefer the latter because there is less bleeding. **K,** A subcutaneous pouch is made in the scrotum by undermining the incision with scissors or artery forceps. Careful attention must be given to hemostasis to avoid a postoperative hematoma. **L,** A fine artery forceps is pushed through the inguinoscrotal fascia, guided by the retreating finger, to connect the two incisions by a small buttonhole. **M,** The forceps grasps the testis, being careful not to twist the cord structures and pulls the testis down to the scrotal incision through the fascial buttonhole into the subdartos pouch. **N,** There may not be tension on the testis, and anchoring is optional. The testis may be sutured to the scrotal septum by a fine suture through the tunica albuginea, or alternatively the opening in the fascial buttonhole can be narrowed with one or two sutures, particularly if there is any tension on the cord structures, so the testis does not retract upward. The scrotal and inguinal incisions are closed in routine fashion. (From Spitz L, Coran AG: Pediatric surgery. In Rob and Smith's Operative Surgery, 5th ed. London, Chapman & Hall, 1995.)

cremasteric vessels (see Fig. 77-7, *A* and *B*).[43] Radical dissection of the inguinal canal before making the decision to perform a Fowler-Stephens operation may jeopardize its success by damaging the collateral blood supply. This complication can be overcome by performing the Fowler-Stephens operation as a two-stage procedure with initial ligation of the testicular vessels without disturbance to the collateral blood supply; the subsequent second-stage operation then allows the testis to be mobilized on the enlarged collateral vessels from the vas deferens, which then usually reach the

scrotum. In follow-up studies of this two-stage procedure, researchers report 70% to 90% scrotal position without atrophy.[129,130]

Many surgeons now use laparoscopy for impalpable testes in the inguinal canal and abdomen.[106,115] An immediate orchidopexy should be successful if the testis can be pulled to the opposite internal inguinal ring. A staged Fowler-Stephens operation is also relatively straightforward, and results are promising. In the first stage, laparoscopic localization of the testis allows a decision to be made about orchidopexy versus orchidectomy, which should be considered if the testis is small or dysgenetic. If orchidopexy is believed warranted, simple ligation of the testicular vessels above the testes can be performed with an endosurgical tie or a clip.[113] Six months later, the testis can then be mobilized on a flap of peritoneum containing the collateral blood supply and swung down through the medial edge of inguinal canal to reach the scrotum. At present, I perform both stages laparoscopically.[103]

## Complications of Surgery

In the hands of experienced surgeons and particularly with the routine use of magnification, the risk of complications after orchidopexy should be less than 5% (Table 77-1).[20] Damage to the testicular vessels leading to atrophy is the most feared complication, but this is relatively rare. More subtle damage to the vas deferens leading to occlusion of its lumen and subsequent interference with fertility is a theoretic problem, but its exact frequency is difficult to determine. Hemorrhage in the wound secondary to poor hemostasis occurs occasionally.

The most common complication after orchidopexy, particularly now that many are done in infants, is wound infection. Both the inguinal and scrotal incisions are at risk for infection at any age, but, in my experience, scrotal infection is more common in infants. Usually this is of no serious consequence and responds to simple antibiotic treatment or drainage. Secondary ascent of the testis after orchidopexy is an uncommon but important complication caused by inadequate mobilization of the cord or inadequate fixation of the testis within the scrotal pouch. Postoperative lymphedema and vascular congestion of the testis after orchidopexy is a common finding that resolves spontaneously over the first month or two.

After orchidopexy, the child is usually reexamined 1 to 2 weeks later to remove the dressing and assess the short-term outcome. A further follow-up examination is performed 6 to 12 months later to determine whether there has been any significant atrophy or secondary malposition of the testis. The end result and appearance are satisfactory in the majority of instances.

Success rates are higher for those testes that have passed through the external inguinal ring, whereas intracanalicular or abdominal testes have a higher incidence of persisting abnormality after orchidopexy. The intra-abdominal testis may fail to reach the scrotum, at least after a single-stage procedure, or it may be an inadequate gonad subsequently and atrophy. Total infarction of the testis is rare and is reported in 3% of patients with an impalpable testis. A further 15% to 20% have some atrophy after orchidopexy.[131] The risk of atrophy is probably increased if a second operation is required to bring the testis to the scrotum. Exact figures in this subgroup, however, are not available.

The risk of atrophy after orchidopexy is increased if a simultaneous inguinal hernia is performed for incarcerated or strangulated hernia. It is difficult to determine whether the increased rate of atrophy is secondary to compromise of the testicular vessels caused by compression or to the greater dissection required with a large hernia sac. The timing for orchidopexy has therefore been a compromise between the potentially increasing risk of testicular dysplasia with age compared with the potentially increased risk of postoperative atrophy in younger children. Wilson-Storey and colleagues[125] compared 100 infants younger than 2 years of age with 100 toddlers or older children undergoing orchidopexy after age 2 years. They found an incidence of testicular atrophy of 5% in both groups, suggesting that the risk of postoperative atrophy is not directly related to age in pediatric surgical centers.

| Hemorrhage |
| Wound infection |

## Fertility

A significant number of studies have evaluated fertility in men after orchidopexy (Table 77-2).[7,132–137] Testes initially located beyond the inguinal canal have a good prognosis for fertility, although location does not change outcome for unilateral cases.[90] Interpretation of results is difficult, however, because in most current fertility studies of men the operations were

**TABLE 77-2**

**Fertility After Orchidopexy**

between 6 and 13 of years of age, suggesting that this group includes many acquired variants such as ascending and retractile testes. These latter patients are far less likely to have abnormal fertility because early germ cell maturation would have occurred normally when the testis was in the scrotum during infancy. The histology of ascending testis is reported to be similar to congenitally cryptorchid testes, and histopathology correlates with future fertility potential.[138,139]

An extensive review of the literature has failed to demonstrate any significant improvement in fertility with early operation within the range of 4 to 14 years.[137] Although 27 papers were reviewed, only four reports were recently published and we can no longer extrapolate data from operations done on adolescent patients before the 1950s and 1960s. With advances in knowledge and changes in clinical management in the past 25 years (i.e., earlier surgical intervention), it is inappropriate to compare these older historical studies with the results of current treatment. Whether orchidopexy in infancy ultimately achieves a significantly improved rate of fertility remains to be seen, but as described earlier, surgery at 9 months shows early promise for improved testicular volume.[94]

### Malignancy

At present, there are no accurate data available as to whether orchidopexy in early infancy reduces the risk of subsequent testicular cancer. However, Cortes reports that the risk of malignancy for acquired undescended testes is low.[140] There will be a lag time between the current trend of orchidopexy in infancy and convincing evidence that this change in the management alters outcome for congenital undescended testes. At this time, all clinicians can do is define those features that appear to affect prognosis. Good prognostic signs include the testis near the neck of the scrotum, ascending or retractile testes, and possibly operation in early infancy. Poor prognosis is associated with primary dysplasia of the testis or epididymis, intra-abdominal or intracanalicular testes, an associated strangulated inguinal hernia, and possibly operation delayed until late childhood or adolescence.

## Torsion of the testis

Torsion of the testis was first described in 1840 by Delasiauve.[141] The condition was first reported in the newborn by Taylor in 1897,[142] and torsion of a testicular appendage was first described by Colt in 1922.[143] Ombredanne,[144] in 1913, described a lesion that was probably a testicular appendage, although he did not recognize its true nature.

Twisting or torsion of the testis results in occlusion of the gonadal blood supply, which, if unrelieved, leads to necrosis. Although it is not the most common cause of the acute scrotum in childhood, it is certainly the most important (Fig. 77-5). Torsion of the testis is a surgical emergency because of the high incidence of gonadal necrosis.

Intratunical or intravaginal torsion occurs most commonly and is predisposed to by an abnormally high investment of the spermatic cord by the tunica vaginalis. The long narrow mesorchium allows the testis to lie horizontally within its peritoneal sac (tunica vaginalis), the so-called *bell-clapper anomaly*. In the normal testis, the short mesorchium attaches to the full length of the epididymis and allows testicular movement

**FIGURE 77-5** Mechanical causes of the acute scrotum present as pain, swelling, and redness confined to the hemiscrotum, as shown in this 1-year-old infant, because the inflammatory reaction is limited by the ipsilateral tunica vaginalis.

within the tunica vaginalis but prevents complete torsion. The pendulous testis associated with a high investment of the cord has a horizontal lie and allows the testis to be readily twisted by leg movement or cremasteric contractions. A rare variant of intratunical torsion is one in which there is separation between the testis and the epididymis, allowing torsion between these structures. This is likely to be more common in undescended testes.

Extratunical or extravaginal torsion is less common and is confined to the perinatal period. During descent of the gubernaculum and testis into the scrotum, there is a loose areolar plane around these moving structures, which allows the entire tunica vaginalis and spermatic cord to twist.

Beyond the newborn period, testicular torsion is almost always associated with the bell-clapper variant. Trauma and physical activity may be important, as may action of the cremaster muscle.[145] Cremasteric contraction may be either the cause or the effect of torsion. The high incidence of testicular torsion at puberty suggests that recent enlargement of the testis associated with increased serum testosterone levels is a predisposing factor.

Torsion of the testis does not always cause necrosis if the number of twists is small or the testis untwists spontaneously. In an experimental dog model, four complete turns of the spermatic cord caused necrosis within 2 hours, whereas one complete turn produced no ischemia in up to 12 hours.[146] In adolescent boys, necrosis is likely after 24 hours of symptoms but may occur after as little as 2 hours.[147,148]

In 1761 Morgagni described the appendix testis, now known as the hydatid of Morgagni.[104] This is believed to be an embryologic remnant of the cranial end of the müllerian or paramesonephric duct. It is present in more than 90% of males and varies in size from 1 to 10 mm in diameter. It is the most frequently twisted of the four testicular appendages. The others are the appendix epididymis, which is a remnant of

the Wolffian duct, the paradidymis, and the vas aberrans. These vestigial structures have a similar histology, being composed of gelatinous and vascular connective tissue covered with a columnar epithelium. The hydatid of Morgagni is usually pedunculated, which predisposes to torsion. The most frequent time for torsion of the testicular appendix is at about 11 years of age. This peak, just before the onset of puberty, may be related to early pubertal stimulation by estrogens.[149–151]

Inflammatory conditions of the scrotum are often called epididymo-orchitis, even though the epididymis alone is usually affected before puberty. Epididymitis is rare after puberty, whereas epididymo-orchitis is more common after puberty. The mumps virus has a predilection for the postpubertal but not the prepubertal testis. Epididymitis is seen between birth and 6 months, and thereafter is rare until after puberty. It is usually caused by infection reaching the epididymis by retrograde spread along the vas deferens from the urinary tract. *Escherichia coli* is the common organism, and infections are predisposed to by urinary tract abnormalities or urethral instrumentation. The most common group now suffering epididymo-orchitis in childhood are boys with spina bifida having intermittent catheterization. This is occasionally seen in infants with imperforate anus and rectourethral fistula or may be seen in the bladder exstrophy population after closure.

Idiopathic scrotal edema is occasionally confused with torsion of the testis or its appendages. In this condition, there is rapidly developing edema of the scrotum with spread to or from the inguinal region, penis, or perineum. The cause of this edema is not always apparent but may be bacterial cellulitis or a topical allergy.

A rare cause of the acute scrotum, which may be confused with testicular torsion, is fat necrosis. It is characterized by the sudden appearance of tender, often bilateral small lumps within the scrotal skin. The affected boys are often obese, and there may be a history of swimming in cold water.

Henoch Schönlein purpura may present with signs of acute scrotal swelling either before or after other systemic signs and symptoms. It is most commonly bilateral and rarely painful.

## CLINICAL FEATURES

Torsion of the testis is common in adolescence, but before puberty torsion of a testicular appendage is more common (Table 77-3). There are two peaks of incidence for torsion of the testis: in the early neonatal period and in adolescent boys aged 13 to 16. In a review of 771 children up to the age of 16 presenting with acute scrotum, 58% had torsion of the testicular appendage and 29% had torsion of the testes. Epididymitis had been diagnosed in 13%, although a significant number of these subsequently turned out to have torsion of a testicular appendage that had not been recognized.[149]

**TABLE 77-3**
**Causes of Acute Scrotum**

| *Pathology* | *Frequency* | *Age at Presentation* |
|---|---|---|
| Extravaginal torsion of testis | Uncommon | Perinatal |
| Intravaginal torsion of testis | Common | Anytime, peak at 13-16 yr |
| Testicular appendage torsion | Very common | Anytime, peak at 11 yr |
| Epididymitis | Rare | 0-6 mo |
| Mumps orchitis | Uncommon | Only after puberty |
| Idiopathic scrotal edema | Uncommon | 0-5 yr |
| Fat necrosis of scrotum | Rare | 5-15 yr |

Clinical presentation of testicular torsion is usually heralded by the sudden onset of pain in the testis, lower abdomen, or groin, associated with nausea and vomiting. Occasionally the onset is more gradual without severe pain, leading to delayed diagnosis. A previous history of short-lived, similar pains suggests prior incomplete torsion with spontaneous resolution. A horizontal lie of the testis when the boy stands indicates a long mesorchium. Unless the testis and the epididymis are necrotic, local palpation is exquisitely painful. The hemiscrotum rapidly becomes red and edematous, and, if untreated, infarction of the testis may give the hemiscrotum a bluish discoloration. The inflammatory signs usually end abruptly at the edge of the hemiscrotum because this coincides with the limits of the peritoneum, tunica vaginalis. A reactive hydrocele from effusion of edema fluid into the tunica may make the physical signs more difficult to interpret (see Fig. 77-5).

Torsion of a testicular appendage presents with an almost similar history, although often the degree of pain is less severe. A bluish black spot (blue-dot) may be seen through the skin at the upper pole of the testis, but this may not be apparent for 24 to 48 hours after the development of symptoms, and palpation of this area causes extreme pain but usually in point tenderness fashion, whereas palpation of the testis itself causes little discomfort. The degree of inflammation of the epididymis is variable with testicular appendage torsion. Once secondary inflammation and edema of the scrotum occur, it may be impossible to distinguish between testicular torsion and torsion of a testicular appendage.

Investigations such as radioisotope scans and Doppler ultrasound have been used to determine whether there is blood flow to the testes in acute scrotum.[152,153] In adolescents beyond pubertal age, such tests may be more useful because the volume of the testis is large enough to allow a reasonably high level of accuracy. Before puberty, however, when the testis is less than 1 or 2 mL in volume, such tests are of lower accuracy and have limited clinical usefulness. I do not usually perform these studies but immediately explore the scrotum through a small midline scrotal incision.

## TREATMENT

Treatment of the acute scrotum and possible torsion of the testis is immediate operative exploration of the scrotum. A midline incision is made in the scrotum, and the hemiscrotum is opened with diathermy. The edema in the scrotal wall may make identification of the tunica vaginalis difficult. It is easy to recognize once this has been opened by the efflux of hydrocele fluid. The testis is delivered through the incision if there is evidence of torsion of the gonad itself. Where the testis appears normally viable, its upper pole is manipulated into the wound and the twisted hydatid is delivered through the incision and excised. Usually this is a black pea after hemorrhagic infarction. A significant number of hydatids, however, undergo torsion without secondary hemorrhage and appear pale at surgery. These should always be excised and sent for pathologic confirmation of necrosis.

If the testis is twisted, this is untwisted and the viability assessed. In a prepubertal child, this maneuver is usually relatively easy and circulation returns within a few minutes. In the postpubertal testis, particularly when there has been some secondary hemorrhage, viability may be difficult to determine. In this circumstance, it may be better to observe the testis for several minutes while exploring the contralateral scrotum. The use of a Doppler probe may be helpful to determine if there is testicular blood flow.

The contralateral hemiscrotum should always be explored when torsion of the testis has been found because the anomaly is usually bilateral. It is not sufficient to place a few absorbable sutures between the testis and the scrotal wall. The best technique is to create a window of tunica vaginalis by excising a segment of the tunica and suturing the edges of the defect to the tunica albuginea with nonabsorbable sutures.[154] This creates permanent fusion of the testicular surface with the connective tissues of the scrotum and creates a second, anterior mesorchium. Inadequate fixation with absorbable sutures may result in recurrent torsion.[155,156]

It is controversial whether testes of doubtful viability should be excised or left in situ to see whether they will recover any hormonal function. There is now good evidence that testicular ischemia damages the blood-testis barrier and exposes the child older than 10 years of age to the potential risk of autoimmunization against his own spermatogonia.[136] This potentially serious complication has been recognized because spermatogenesis later in life is poor in men who underwent fixation of ischemic testes in adolescence. The risk of autoimmunization related to ischemia is low in children younger than age 10 because there is no blood-testis barrier before spermatogenesis commences.[157,158] It is my practice, therefore, to leave doubtful testes in situ in children younger than 10. In children older than 10 with an ischemic gonad, I recommend orchidectomy.

Another controversial issue is whether neonates presenting with a dead testis, apparently caused by perinatal torsion, should have the contralateral testis fixed.[159,160] As mentioned previously, perinatal torsion is usually caused by torsion of the spermatic cord during testicular descent. A significant percentage of such children, however, also have an unfixed or bell-clapper testis and are therefore at risk of having contralateral torsion. A firm recommendation is difficult to give on this issue, but a strong case can be made for exploration of the contralateral testis and fixation as described for adolescent torsion, especially in an infant younger than a few weeks old. After 3 months of age, secondary adherence of the gubernaculum to the scrotum should have occurred and exploration is less useful.

In adolescents presenting with intermittent recurrent testicular pain, bilateral orchidopexy may be justified, especially if there is a horizontal lie of the testes on clinical examination. Almost one third of adolescents who undergo acute torsion have a history of previous intermittent pain.

# Varicocele

Dilation of the testicular veins in the pampiniform venous plexus causes a varicocele.[161] The countercurrent heat exchange mechanism in the spermatic cord vessels is disrupted, which leads to an increased temperature of the testis and scrotum. The abnormally high temperature can be detected by thermography and causes progressive dysfunction of the testis and epididymis.[1,162] This may lead to subsequent testicular atrophy and infertility, as first proposed by Tulloch.[163] Testicular atrophy may be significant in adult life but may become evident quite early in adolescence.[164] The incidence of varicocele is 15% among men in general and rises to 20% to 40% in men presenting to infertility clinics. In children younger than age 10 years, varicocele is rare, but by the end of adolescence the incidence has risen to that seen in the adult population.[165] Varicocele may occur in small children with Wilms tumor, neuroblastoma, or hydronephrotic kidney that causes obstruction of venous return from the testis. Although most cases of varicocele occur on the left, varicocele on the right side is suggestive of a retroperitoneal tumor.

## CLINICAL PRESENTATION

Varicocele presents as a soft, distensible mass in the upper part of the scrotum (Fig. 77-6). In 80% to 90% of cases they present on the left side, with bilateral lesions reported as occurring between 2% and 20% and right-sided lesions between 1% and 7%.[166] In the supine position, a redundant left hemiscrotum and horizontal lie of the left testis may be noted.[167] On standing, the varicocele fills with blood to produce the typical "bag of worms" appearance. The lesion is not usually painful; however, the boy may complain of a dragging sensation.

Varicoceles may be classified by size into grades I to III or small, medium, and large. Small varicocele (grade I) may be evident only during Valsalva maneuver.[168,169] Medium-size

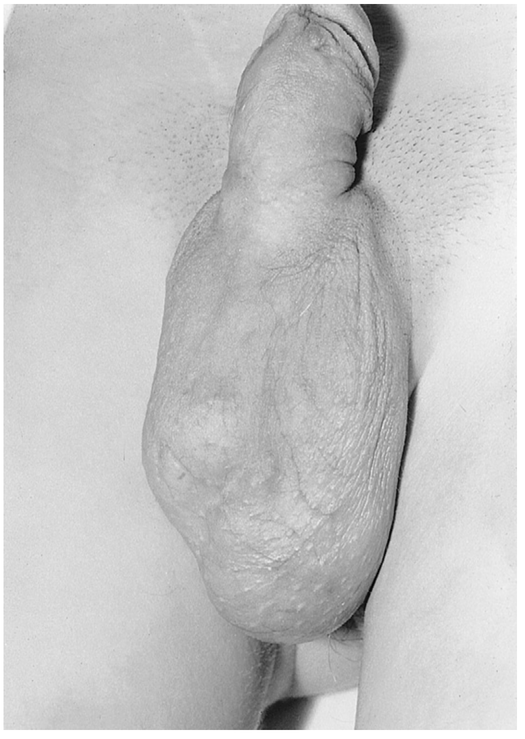

FIGURE 77-6 A grade III varicocele in a 14-year-old boy is visible as a space-occupying lesion of the left hemiscrotum even in the supine position before surgery. On standing, the dilated vessels fill to produce a "bag of worms."

varicoceles (grade II) are palpable without Valsalva maneuver, and large varicoceles are visible as a scrotal space-occupying lesion.[170]

## ETIOLOGY

Lack of valves in the left testicular vein is one of the primary factors in the etiology of varicocele. In postmortem examinations, the left testicular vein contains no valves in 40% of specimens compared with absence of valves in only 23% of right spermatic veins, and the right-angle entry of the left spermatic vein into the high-pressure venous system of the left renal vein may predispose to varicocele.[171] When upright, the long pressure column generated in the pampiniform plexus results in poor venous return and varicose distention of the veins. There are a number of other etiologic theories including disruption of the venous pump created by the coverings of the spermatic cord, compression of the left renal vein between the superior mesenteric artery and the aorta, extrinsic pressure on the left testicular vein by a full sigmoid colon, and vascular spasm at the origin of the left testicular vein caused by adrenaline coming from the left adrenal gland. In a series of 659 patients undergoing spermatic venography, absence of the valves in the left testicular veins was documented in 484 patients.[172] In addition, a further 172 patients with varicocele had valves intact but had reflux of blood into the testicular vein through collaterals draining the left kidney. Renal vein stenosis was identified in 103 patients. The external spermatic vein (cremasteric vein) has also been implicated because it may be dilated in up to 50% of varicoceles.[173]

Because the testis is supplied by three separate arteries, so is the venous drainage formed by more than one set of veins. Blood reaches the testis via the testicular (or internal spermatic) artery from the abdominal aorta, the deferential artery supplying the vas deferens, and the cremasteric (or external spermatic) artery arising from the external iliac artery and inferior epigastric vessels (Fig. 77-7, *A*). These three vessels form an anastomosis around the caudal epididymis. Blood drains from the testis and epididymis into the pampiniform plexus accompanying the testicular artery. Above the internal inguinal ring, the number of venous channels decreases to one or two and finally coalesces into a single testicular vein entering either the inferior vena cava on the right or the left renal vein; the latter join at a right angle. Retrograde flow in the veins is prevented by the presence of valves. Anastomoses with subsidiary veins occur along the vas deferens to the base of the bladder through the cremasteric and scrotal veins to the saphenous vein (see Fig. 77-7, *B*).

## EFFECTS OF VARICOCELE

Varicocele leads to testicular atrophy and subsequent infertility in adult life, probably secondary to abnormally high temperature.[174] How the excessive temperature actually produces testicular dysfunction, however, is not so clear. A number of abnormalities have been documented in hormonal function and other physiologic parameters of the testis, but whether these are primary or secondary abnormalities is uncertain. This is particularly true for a proposed defect in the hypothalamic-pituitary-gonadal axis. Serum testosterone levels are usually normal, although a subclinical defect in the androgen axis is possible.[175] Leydig cell hypoplasia with high serum follicle-stimulating hormone levels has mostly been reported in adults with established testicular atrophy. Inhibited testicular development during puberty is seen in association with histologic changes that are similar to those seen in adults with infertility caused by varicocele.[135,176,177] Where testicular atrophy is recognizable, an abnormal production of pituitary hormones occurs in response to a gonadotropin-releasing hormone stimulation test.

## INDICATIONS FOR TREATMENT

The criteria for treatment are controversial, with common indications including symptoms such as chronic pain or discomfort, demonstrable atrophy of the testis in adolescence, and subfertility in adults. When there is greater than a 10% difference in gonadal volume on orchidometry, Parrott and

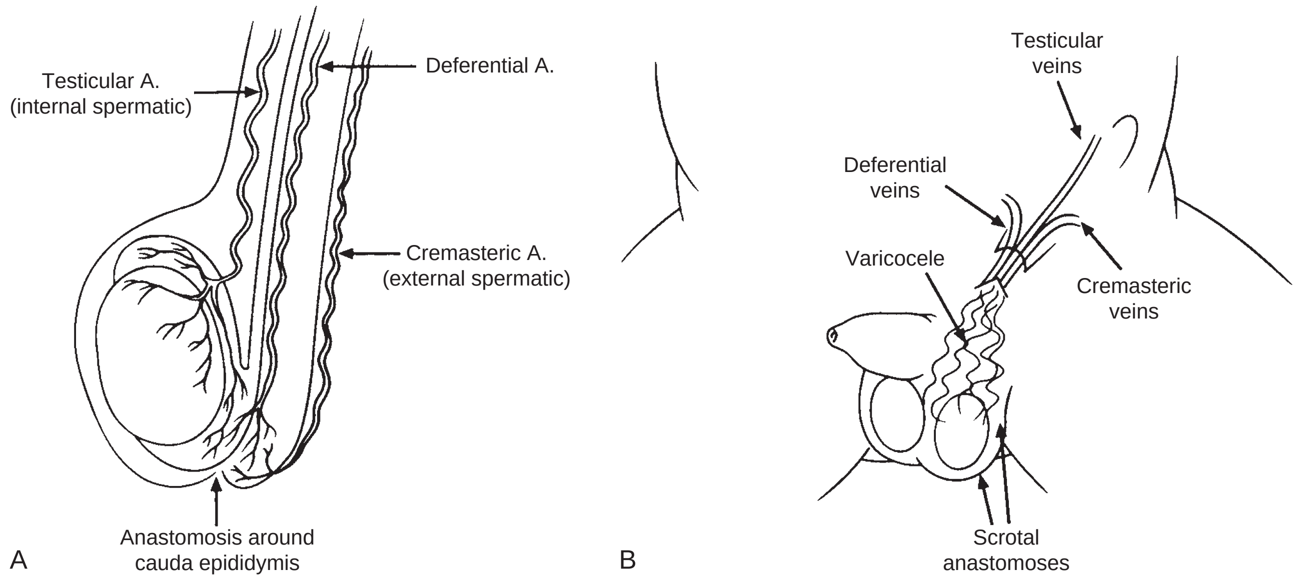

**FIGURE 77-7** **A,** Arterial supply to the testis, epididymis, and vas deferens, with anastomoses around the cauda epididymis. **B,** Venous drainage of the testis, showing the anastomoses with the varicocele. (From Hutson JM: Varicocele and its treatment. Pediatr Surg Int 1995;10:509.)

Hewatt[178] advocate operation. Nagar and Levran[168] have recommended screening of school boys by physical examination to identify varicoceles at any early stage of development and found varicoceles were present but asymptomatic in 10% of nearly 800 boys examined. They propose that screening enabled the diagnosis to be made at an earlier age and a lower stage of disease. They speculated that this should produce improved future fertility in adults, but this will not be proven for some time. Doppler ultrasound is currently a popular test used in adult infertility clinics to identify subclinical varicoceles.[179] In early adolescence, however, when the testicular volume and blood flow is much less than in adults, the role of Doppler ultrasound is less reliable. Diagnostic or therapeutic testicular venography is currently popular for men with a varicocele.[180,181] In young adolescents, general anesthesia is usually required for such a procedure, although a study using therapeutic testicular venography with insertion of spring coils has been described using only local anesthesia.

## OPERATION

The multiple theories of etiology of varicocele have led to a wide range of surgical options (Fig. 77-8). Inguinal exploration has been a standard procedure for many years, with careful ligation of all the venous channels as described by Ivanissevich[182] and by Sayfan and colleagues.[181] Historically, this technique has been associated with a high incidence of secondary hydrocele, accidental ligation of the testicular artery leading to testicular atrophy, and recurrence of the varicocele.[183,184] Poor results in some hands have led to a search for alternative approaches including microsurgical dissection of the testicular veins, preserving the testicular artery and lymphatics within the spermatic cord. Some authors have suggested identifying the artery or veins intraoperatively so that the artery can be preserved. For this purpose, both Doppler ultrasonography and venography have been used, but the role of these intraoperative investigations remains uncertain.[184–186] Antegrade sclerotherapy is also being used in some units.[187]

Shafik and colleagues[188] have suggested plication of the external spermatic fascia to cause external compression of the pampiniform vessels. This is a simple procedure but does not address the persisting problem of retrograde flow of blood within the testicular veins. One might predict a high frequency of recurrence, although this is not currently known.

Laparoscopic ligation of the testicular vein proximal to the internal ring has gained popularity.[115] Some authors have recommended selective ligation of the venous channels preserving the artery, whereas others have recommended mass ligation of the artery and the veins. Many publications attest to the feasibility of laparoscopic ligation, but long-term follow-up is not available.[183,189]

Palomo first proposed mass ligation of the testicular vessels including both artery and veins in the retroperitoneum above the internal inguinal ring.[190] The technique has a high success rate with a surprisingly low risk of testicular atrophy as long as the collateral vessels have been preserved.[178,189,191,192] The operation has been available for a long time but has only recently gained popularity. Fear of devascularizing the testis has made many surgeons cautious. As stated in Palomo's publication, however, the blood supply of the testis should be maintained if any two of the three vessels are preserved. Because the cremasteric and deferential vessels are preserved, the collateral arterial supply of the testis should be intact and no venous channels are accidentally excluded by being mistaken for the testicular artery itself.

Laparoscopic mass ligation as described by Palomo is my personal choice, although I offer the family the option of having the procedure done laparoscopically or by a small open retroperitoneal approach. The laparoscopic method is similar to that described elsewhere in this book, with a 5-mm telescope port through the umbilicus and two 4-mm ports, one in the left abdomen level with the umbilicus and the other in the hypogastrium. With the surgeon standing on the right side of the operating table and the assistant on the left, the video screen is placed near the left foot. The colon can be displaced readily by tilting the patient. The peritoneum is opened several centimeters away from the internal inguinal ring, and the entire vascular pedicle including artery and all venous channels is ligated in continuity with a 3-0 absorbable suture. Lymphatic channels may be preserved if identified.

The open procedure is also straightforward and may be done on an ambulatory basis. Under a short general anesthetic, an incision is made in the left iliac fossa medial and just a little below the left anterosuperior iliac spine. This is usually several centimeters away from the internal inguinal ring. The oblique muscles are divided along the line of their fibers just lateral to the rectus abdominis muscle. Once the peritoneum is visualized, it is mobilized medially by pledget and blunt dissection. Using this site of access, the peritoneal cavity is shallow and medial displacement of the peritoneum immediately exposes the testicular pedicle well below the level of the ureter entering the pelvis. The vascular pedicle is isolated from the overlying peritoneum with a right-angle forceps, and two 3-0 absorbable ligatures are placed in continuity around the pedicle. It is not necessary to divide the testicular pedicle, although this is an option. On removal of the retractors, the peritoneum immediately resumes its normal position and a few tacking sutures can be placed in the muscle layers and the skin closed with subcuticular sutures in the normal manner. Because the Palomo operation does not disturb all the lymphatic drainage of the inguinoscrotal region and leaves collaterals to the cremasteric and deferential vessels intact, the postoperative risk of an acute hydrocele is lower than with other procedures.

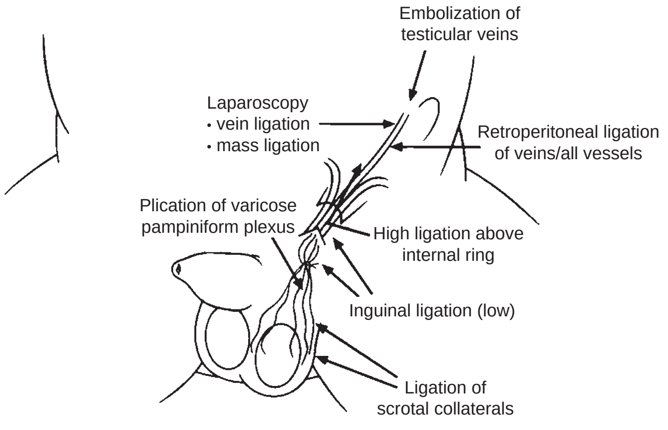

FIGURE 77-8 The large range of approaches to correction of a varicocele. (From Hutson JM: Varicocele and its treatment. Pediatr Surg Int 1995;10:509.)

## RESULTS

The recognized complications of varicocele repair are shown in Table 77-4. The risk of recurrence or persistence of the varicocele is quoted as 5% to 45%.[184] Risk of reactive hydrocele varies between 7% and 39%. The incidence of testicular atrophy, which is one of the most important outcome measures related to this surgery, is rarely reported, so accurate figures are unknown.

**TABLE 77-4**
**Complications of Varicocele Repair**

| | |
|---|---|
| Recurrence/persistence | 5%-45% |
| Reactive hydrocele | 7%-39% |
| Testicular atrophy | Not known |
| Ilioinguinal nerve injury | Not known |
| Injury to vas deferens | Not known |

Ilioinguinal nerve damage has been reported after inguinal approaches, and genitofemoral nerve injuries have been reported after laparoscopy and injury to the vas. Ligation of the veins within the inguinal canal using a modified Ivanissevich procedure has a 16% recurrence, compared with high retroperitoneal selective vein ligation, which has a reported recurrence rate of 11%. In a study of 32 boys treated with mass ligation through the Palomo procedure, no failures and no testicular atrophy were found after any of the operations. I concur from my own experience that the Palomo operation is the preferred technique. The surgical management of varicocele continues to evolve, but at present the laparoscopic Palomo operation holds reasonable promise as having higher success and lower complication rates than previous procedures.

CHAPTER 78

# Hypertrophic Pyloric Stenosis

Marshall Z. Schwartz

## History

The history of what we now refer to as *infantile hypertrophic pyloric stenosis* dates back to the early 1700s. Blair[1] described an infant with postmortem findings consistent with hypertrophic pyloric stenosis in 1717. Hirschsprung, in 1888,[2] provided the first complete description of hypertrophic pyloric stenosis. He believed that this entity was congenital and represented failure of involution of the fetal pylorus and named it *angeborener pylorusstenose* (congenital pyloric stenosis). In a landmark paper in 1908, Dufour and Fredet[3] suggested that surgical correction could be accomplished by splitting the hypertrophied pyloric muscle to the submucosa and closing the muscle transversely. However, in 1912, Ramstedt[4] suggested that closure of the muscle was not necessary, and the current standard operation was established.

Infantile hypertrophic pyloric stenosis (IHPS) is the most common cause of gastric outlet obstruction in infants. The prevalence of IHPS ranges from 1.5 to 4.0 per 1000 live births in Caucasian infants but is less prevalent in African-American and Asian children.[5] Reports have suggested that the incidence is increasing.[6,7] It is well known that it is more common in boys than girls, with a ratio of approximately 2:1 to 5:1.[5] The occurrence of IHPS has been associated with several variables including both environmental and familial factors. IHPS is now thought to be caused by a mechanism other than a developmental defect. Based on considerable evidence, including a study by Wallgren,[8] in which 1000 male infants had a barium swallow immediately after birth, there were no anatomic abnormalities of the pylorus identified. Thus it is generally agreed that IHPS is not a congenital abnormality. Of interest is that subsequently, IHPS developed in five of these infants. In a similar but more recent study, 1400 consecutive newborn infants underwent ultrasound (US) measurements of the pylorus, with no abnormalities seen.[9] In nine of these infants, however, IHPS subsequently developed.

## Anatomy and Histology

The gross appearance of the pylorus in IHPS is that of an enlarged, pale muscle mass usually measuring 2 to 2.5 cm in length and 1 to 1.5 cm in diameter (Fig. 78-1). Histologically, there is marked muscle hypertrophy and hyperplasia[10] primarily involving the circular layer and hypertrophy of the underlying mucosa.[11] Immunohistochemical analysis of the hypertrophic muscle reveals an increase in fibroblasts, fibronectin, proteoglycan chondroitin sulfate,[12] desmin,[13] elastin,[14] and collagen.[15] Confocal microscopy identifies abnormally contorted and thickened nerve fibers.[16] The result of these gross and microscopic changes is either partial or complete obstruction of the pyloric channel.

## Etiology

The etiology of IHPS has eluded investigators for several decades. Despite considerable research attempting to elucidate the etiology of IHPS, no definitive causative factors have been identified. Both genetic and environmental factors seem to play a role in the pathophysiology. Evidence for a genetic predisposition includes variability among races, a clear male preponderance, an increased risk to first-born infants with a positive family history, and certain ABO blood types. Mitchell and Risch studied the familial occurrence patterns of IHPS and noted that it was compatible with either multifactorial threshold inheritance or the effects of multiple interacting loci.[5] Although pyloric stenosis is more common in boys, the risk for IHPS in the offspring of mothers who had pyloric stenosis as infants is greater than if the father had IHPS. Environmental factors associated with IHPS include the method of feeding (breast-feeding versus formula feeding), seasonal variability, erythromycin exposure, and transpyloric feeding of premature infants.[5,17–19]

Another focus has been on alterations in relaxation of the pyloric muscle. One study noted a decrease in ganglion cells in the circular muscle of the pylorus,[20] but a subsequent study found that the ganglion cells were normal in number but appeared to be immature.[21] Zuelzer[22] and Jona[23] did not find any change in number or ultrastructural appearance of the ganglion cells. As new technology and concepts have evolved, additional associations that involve IHPS and gastrointestinal peptides, growth factors, neurotrophins, changes in neural development, and nitric oxide have been described.

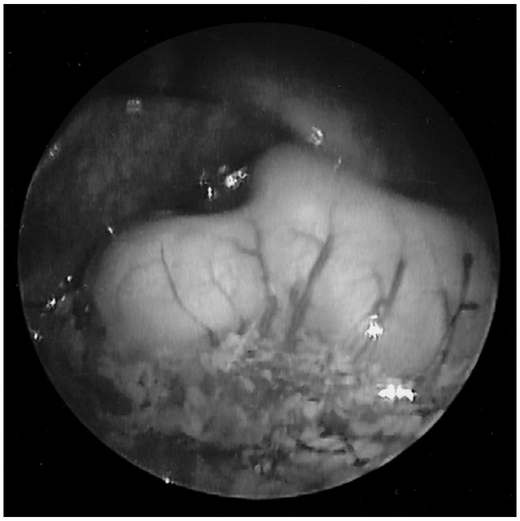

FIGURE 78-1 Laparoscopic view of a hypertrophied pylorus.

## GROWTH FACTORS AND GASTROINTESTINAL PEPTIDES

Over the past several decades numerous gastrointestinal peptides or growth factors have been implicated by direct or indirect methodologies as having a causal relationship including gastrin, substance P, epidermal growth factor (EGF), transforming growth factor-$\alpha$ (TGF-$\alpha$), insulin-like growth factor-I, somatostatin, secretin, enteroglucagon, and neurotensin.[24,25] Other peptides have been evaluated for their potential relationship to IHPS. Substance P, a neurotransmitter responsible for enteric muscle contraction, could produce chronic pylorospasm leading to muscle hypertrophy.[26] This peptide is present in higher concentration in the pyloric muscle of patients with IHPS. Shima and colleagues[27–29] found an increase in the gene expression of EGF, TGF-$\alpha$, and insulin-like growth factor-I and an increase in immunostaining for EGF and TGF-$\alpha$. Somatostatin, secretin, enteroglucagon, and neurotensin have also been implicated.[24,30,31] However, their role has not been substantiated, and no clear etiologic relationship has been identified.

### Neurotrophins, Neural Development, and Nerve Function

Neurotrophins, which are important for nerve differentiation and survival, have been noted to be decreased in IHPS. Further studies have shown that one of the specific receptors for these neurotrophins, the tyrosine kinase A receptor c-kit, is not present in IHPS tissue.[32–34] Investigators also identified that the pylorus in IHPS is deficient in glial-derived growth factors, which may be indicative of immature development of the enteric nervous system.[35]

Other techniques have been applied to the evaluation of pyloric innervation. Okazaki and colleagues[36] used monoclonal antibodies targeted to nerve terminals and neurofilaments. They found a reduced density of both neural elements in patients with IHPS. Kobayashi and colleagues[37] demonstrated a decrease in nerve-supporting cells in both the circular and longitudinal muscle layers in infants with IHPS. Piotrowska and colleagues[38] found that muscle biopsy specimens from IHPS patients have decreased numbers of interstitial cells of Cajal, the pacemaker cells for the gastrointestinal tract, and a lack of heme oxygenase-2, which may play a role in communicating between the interstitial cells of Cajal and smooth muscle cells.

### Nitric Oxide

Nitric oxide can induce smooth muscle relaxation in the esophagus, stomach, and intestine. It was reasoned that a deficiency of nitric oxide in the pyloric muscle might result in failure of relaxation.[39–41] Nicotinamide-adenine dinucleotide phosphate (NADPH) diaphorase (essentially identical to nitric oxide synthase) was measured in biopsy specimens of hypertrophied pyloric muscle wall from IHPS patients. The hypertrophied circular muscle did not demonstrate any NADPH diaphorase activity, but the activity in the longitudinal muscle was normal. The authors concluded that the lack of nitric oxide synthase in pyloric tissue might be responsible for pylorospasm and lead to IHPS.[42]

Thus at present no definitive cause of IHPS has been elucidated. Whatever the mechanism, it must take into account that the process of IHPS generally occurs several weeks after birth and the circular muscle hypertrophy is transient even without myotomy. It is also apparent that whatever triggers IHPS causes a dramatic change in cellular architecture and function through what may be a broad array of pathways.

# Clinical Features and Differential Diagnosis

The typical clinical finding in an infant with IHPS is the onset of nonbilious vomiting at 2 to 8 weeks of age with a peak occurrence at 3 to 5 weeks. Two reports are at variance with traditional concepts: IHPS has been diagnosed at birth[43] and even in utero.[44] Initially, the emesis may not be frequent or forceful, but over a period of several days it progresses to nearly every feeding and becomes forceful (projectile). On occasion, there may be blood in the emesis that gives it a brownish discoloration or a coffee-ground appearance as a result of gastritis or esophagitis. Infants with IHPS remain hungry after emesis and are otherwise not ill appearing or febrile. A significant delay in diagnosis leading to severe dehydration, however, results in a lethargic infant. Some infants have diarrhea (starvation stools) and are thought to have gastroenteritis. Approximately 2% to 5% of infants have jaundice from indirect hyperbilirubinemia, which can reach levels as high as 15 to 20 mg/dL. This is believed to be secondary to glucuronyl transferase deficiency.[45] In premature infants, IHPS is generally diagnosed 2 weeks later than in term infants.[19] The emesis may not be projectile and evolves more slowly, which frequently leads to a delay in diagnosis.

Pylorospasm and gastroesophageal reflux may be difficult to differentiate from IHPS without further imaging evaluation. Other medical causes of nonbilious vomiting include gastroenteritis, increased intracranial pressure, and metabolic disorders. Other surgical causes of nonbilious emesis include antral webs, pyloric atresia, duplication cyst of the antropyloric region, and ectopic pancreatic tissue within the pyloric muscle, all far less common than IHPS.

## Diagnosis

Nonbilious projectile vomiting, visible peristaltic waves in the left upper part of the abdomen, and hypochloremic, hypokalemic metabolic alkalosis are cardinal features of IHPS. A definitive diagnosis can be made in 75% of infants with IHPS by careful physical examination of the upper part of the abdomen. Unfortunately, this is becoming a lost skill. Frequently, imaging procedures are requested by primary care physicians in lieu of a careful physical examination. To be successful in palpating an enlarged pylorus, the infant must be calm, warm, and cooperative. The use of a pacifier or a small feeding (5% dextrose in water) may be helpful. If the stomach is distended, aspiration with a nasogastric tube assists successful palpation of an enlarged pylorus, often referred to as "the olive." With the infant supine and the legs bent to relax the abdominal muscles, the examining hand should be placed on the epigastrium. After the edge of the liver has been identified with the fingertips, gentle pressure deep to the liver and progressing caudally in the midline a third of the distance between the umbilicus and xiphoid should reveal a palpable pylorus if IHPS is present. The examiner should be willing to commit 5 to 15 minutes of uninterrupted time if necessary to obtain an adequate examination. One should be able to roll the hypertrophied pylorus under the fingertips to be convinced of the diagnosis. Failure to palpate the pylorus requires further workup to clarify the cause of vomiting. The differential diagnosis includes gastroenteritis, food allergy, gastroesophageal reflux, pylorospasm, antral web, pyloric duplication, ectopic pancreatic tissue in the wall of the pylorus, and vomiting occasionally accompanying adrenogenital syndrome, metabolic disorders, and increased intracranial pressure.

US has become not only the most common initial imaging technique for the diagnosis of IHPS but also the standard for diagnosing IHPS. Under optimal circumstances, this technique is reliable. However, it is dependent on the level of experience and expertise of the ultrasonographer. The generally accepted criteria for a positive US study are a pyloric muscle thickness of 3.5 (in premature infants) to 4 mm or more and a pyloric channel length of 16 mm or greater (Fig. 78-2).[19] Some centers also determine pyloric diameter and consider more than 14 mm to be abnormal.[46] Lamki and colleagues[47] reviewed their experience with US and concluded that a muscle thickness of 3 mm should be considered a positive finding for IHPS in infants younger than 30 days. US also obviates the need for radiographic contrast studies and the associated radiation exposure.

If US is not available or diagnostic, an upper gastrointestinal (UGI) contrast examination is highly effective in making the diagnosis of IHPS. Barium is generally preferred compared with water-soluble contrast to avoid the chemical pneumonitis should aspiration occur. This study should demonstrate an elongated pyloric channel and indentation on the antral outline, which are indirect findings of pyloric muscle enlargement (Fig. 78-3). If barium does not leave the stomach, it is not possible to confirm the diagnosis of IHPS because pylorospasm can also produce transient complete gastric outlet obstruction. However, if sufficient time is taken with intermittent fluoroscopy, it should be possible to differentiate between the two entities. It is advisable for the radiologist to aspirate the residual barium from the stomach after termination of the radiographic procedure to avoid perioperative aspiration.

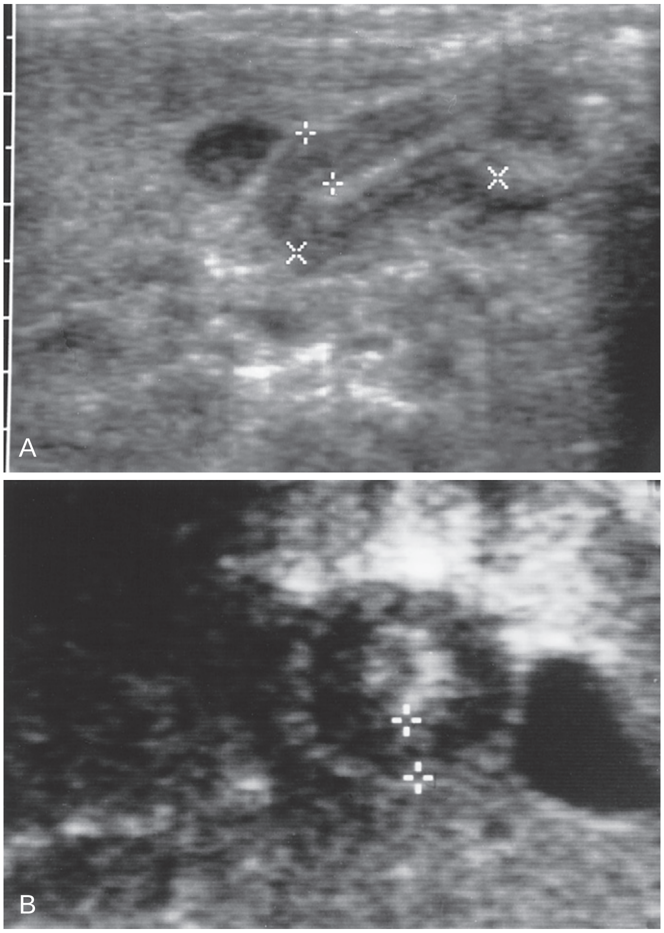

**FIGURE 78-2** Ultrasound images of the hypertrophied pylorus in a 5-week-old infant. **A,** A longitudinal view is shown with pyloric length (X-X) measuring 18 mm and pyloric muscle thickness (+-+) measuring 5.2 mm. **B,** Transverse view illustrating muscle thickness (+-+). (**A,** Courtesy of Dorothy Bulas, MD.)

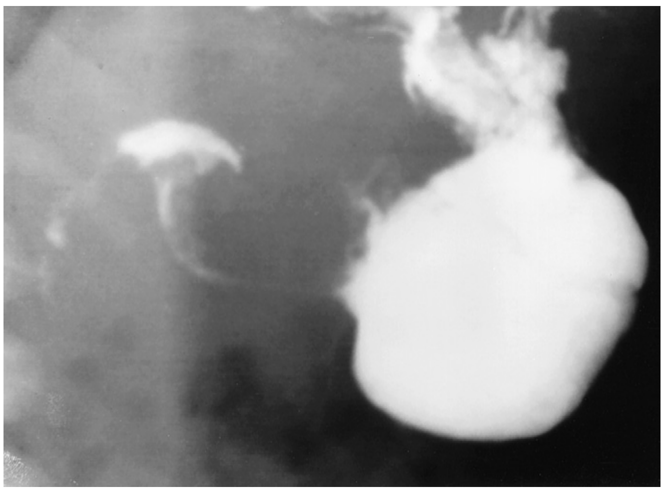

**FIGURE 78-3** Upper gastrointestinal study illustrating an elongated pyloric channel with shoulders proximally as indirect evidence of pyloric muscle hypertrophy. Note the small amount of contrast in the duodenal bulb defining the length of the hypertrophied pylorus.

In 1998 our group conducted a survey of practice patterns for the diagnosis of IHPS among pediatric surgeons in community, university, and children's hospitals.[48] The questionnaire was distributed to 487 board-certified pediatric surgeons, with a 69% response rate. Ninety-one percent of the respondents stated that they would not request a further diagnostic test if a pyloric olive was palpable. US was identified as the diagnostic study of choice for an inconclusive physical examination (86% of the time). Finally, 82% of pediatric surgeons would proceed with an operation with a positive US study even if the results of physical examination under anesthesia were negative. The response to this question indicates that US has essentially supplanted physical examination as the diagnostic test of choice for IHPS.[48]

# Treatment

## PREOPERATIVE PREPARATION

It is most important to prepare the infant adequately for anesthesia and surgical correction of IHPS. The length of preparation depends on the severity of the fluid and electrolyte abnormalities. Benson and Alpern[49] defined three levels of severity primarily on the basis of the serum carbon dioxide content (slight, <25 mEq/L; moderate, 26 to 35 mEq/L; and severe, >35 mEq/L). In addition to the elevated bicarbonate, hypokalemia, hypochloremia, dehydration, and possibly malnutrition may be present.

Most infants with IHPS do not have complete gastric outlet obstruction and can therefore tolerate their gastric secretions. Oral feedings should be discontinued. A nasogastric tube should not be placed routinely because it removes additional fluid and hydrochloric acid from the stomach, which perpetuates the electrolyte and acid-base imbalance.

Fluid resuscitation should be based on the degree of dehydration and the extent of electrolyte abnormalities. Most infants with IHPS should be able to be resuscitated within a 24-hour period. With severe metabolic and fluid abnormalities, however, aggressive resuscitation should be avoided because it can produce rapid fluid and electrolyte shifts, possibly leading to seizures and other complications. Intravenous administration of 5% dextrose in 0.45 normal saline containing 20 mEq/L of potassium chloride is the optimal resuscitation regimen for fluid and electrolyte replacement. Under circumstances of extreme hypokalemia, the concentration of potassium chloride can be increased to 30 mEq/L, but because the intravenous fluid rate likely will be above maintenance rates, the serum potassium level should be carefully monitored. Withholding potassium chloride in the intravenous fluid while awaiting urine output only delays appropriate replacement. The exception (rare) is knowledge of preexisting renal impairment or evidence of acute renal compromise. Hyponatremia is rarely a problem. Nonetheless, it is common to see normal saline given as an initial bolus. However, there is little rationale for the use of normal saline because it enhances the hypokalemia by dilution and provides an excess amount of sodium. Intravenous therapy should be correlated with the level of dehydration. An initial rate for fluid resuscitation is 1.25 to 2 times the normal maintenance rate until adequate fluid resuscitation and urine output are achieved. The concentration of potassium chloride in the intravenous fluid should be based on the level of hypokalemia and the rate of infusion while keeping in mind that a potassium chloride concentration exceeding 30 mEq/L is rarely indicated.

It is necessary to monitor urine output and serum electrolytes. Normalizing the serum bicarbonate level (with the goal of decreasing the level below 30 mEq/dL) usually lags behind normalization of fluid volume and serum potassium and chloride. Administration of ammonium chloride or dilute hydrochloric acid is rarely necessary. As noted previously, indirect hyperbilirubinemia with clinical signs of jaundice occurs in a small percentage of infants with IHPS. It is not usually necessary to evaluate the hyperbilirubinemia further. The hyperbilirubinemia invariably resolves postoperatively.

## OPERATIVE PROCEDURE

Again, it is important to emphasize that fluid and electrolyte abnormalities must be corrected preoperatively including having a serum bicarbonate below 30 mEq/L to avoid respiratory depression and prolonged postoperative intubation.

In the operating room, before the induction of anesthesia, it is important to aspirate the stomach. If a barium UGI study has been performed, it is advisable to remove the residual contrast material by gastric irrigation and suctioning to avoid the risk for perioperative aspiration.

The operative procedure of choice remains the Ramstedt pyloromyotomy. This procedure has stood the test of time because it is straightforward, curative, and associated with remarkably low morbidity. Regardless of abdominal access techniques, the myotomy created is identical.

### Minimal Laparotomy ("Open") Technique

The standard open approach is a right upper quadrant transverse incision of approximately 2.5 to 3 cm made either over or lateral to the right rectus muscle and just superior to the edge of the liver. The fascial layers are divided transversely over the rectus muscle, and it can be either retracted laterally or split longitudinally in the middle. Several other incisions have been described.[3] A commonly used alternative is a supraumbilical curved skin incision followed by division of the midline fascia superiorly for 1 to 2 cm. The edge of the liver is retracted superiorly to expose the greater curvature of the stomach (near the pylorus), which is grasped with a noncrushing forceps or clamp and brought out through the incision. A damp gauze sponge can then be used to grasp the stomach, and with traction inferiorly and laterally to the patient's left, the pylorus can be delivered through the incision. Grasping the duodenum or pylorus directly with forceps can result in injury or perforation of these structures and should therefore be avoided. The pylorus can be stabilized by the index finger of the operating surgeon standing to the right of the patient. The serosa on the anterior wall of the hypertrophied pylorus is incised with a scalpel from the area just proximal to the hypertrophied muscle extending just proximal to the pyloric vein (Fig. 78-4). I and many others prefer to use the back of a scalpel handle to complete the myotomy by bluntly splitting the hypertrophied muscle down to the submucosa (see Fig. 78-4). Other surgeons prefer the use of a pyloric spreading clamp such as that described by Benson.[50] It is appropriate to leave a few pyloric muscle fibers intact at the duodenal end to reduce the risk for duodenal

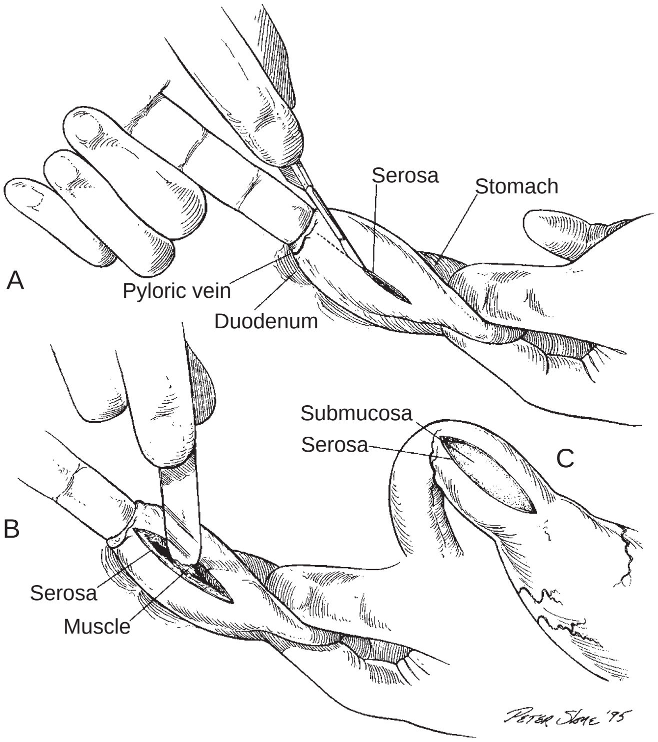

**FIGURE 78-4** Pyloric stenosis, operative technique. **A,** Pylorus delivered from the peritoneal cavity and stabilized between the surgeon's index finger at the duodenal end with the stomach grasped proximally by the assistant. The serosal incision is outlined and begun. **B,** Back of a scalpel handle being used to split the hypertrophied muscle down to the submucosa. **C,** Completed myotomy showing submucosa bulging through the divided muscle.

perforation. Most incomplete myotomies are a result of failure to extend it far enough proximally onto the antrum. A careful check for a leak from the stomach or duodenum should be made before returning the pylorus to the peritoneal cavity. Bleeding from the pyloric muscle edges or submucosal surface is generally venous and almost always stops after returning the stomach and pylorus to the peritoneal cavity.

Entrance into the lumen during pyloromyotomy should be a rare event. If it occurs, the submucosa should be approximated with interrupted fine absorbable suture and a portion of omentum placed over this site. An infrequently needed alternative is to reapproximate the myotomy site, rotate the pylorus 180 degrees, and perform a myotomy on the posterior wall of the pylorus. The fascial layers of the abdominal wall are closed with running absorbable suture. The skin is closed with subcuticular suture and Steri-Strips and covered with a dressing.

### Laparoscopic Procedure

The first description of a laparoscopic pyloromyotomy was by Alain and colleagues[51] in 1991. Since that time, numerous publications have supported this approach. As the procedure is currently performed in most centers, the infant is placed supine at the end of the operating table (Fig. 78-5). A 5-mm port is placed through a small vertical incision in the umbilicus, and the abdomen is insufflated with $CO_2$ to a pressure of 6 to 8 cm $H_2O$. Two additional access sites are chosen (under direct vision with the camera) in the left and right upper quadrants—ports are not usually required (Fig. 78-6). After

**FIGURE 78-5** Position of the infant on the operating room table for laparoscopic pyloromyotomy.

infiltration with a local anesthetic, a No. 11 scalpel blade is used to make a small (2- to 3-mm) skin incision and extended through the abdominal wall. Until recently an arthrotomy knife was used to begin the myotomy: This instrument is no longer available. The extended cautery blade has served as an adequate substitute. A grasper is placed directly through the left upper quadrant incision and used to grasp the antrum just proximal to the pylorus. After the right upper quadrant 2- to 3-mm incision is accomplished, the extended cautery blade is passed directly into the peritoneal cavity. The grasper stabilizes the pylorus, and the cautery blade is used to score the serosa of the hypertrophied pylorus with a low electrical current at the site of the myotomy in a fashion similar to what is done during the "open" technique (Fig. 78-7). The cautery blade (without electrical current) is used to initiate splitting of the hypertrophied muscle and removed. A pyloric spreader designed for laparoscopic procedures is placed through the right upper quadrant incision. This instrument is used to complete the myotomy (Fig. 78-8). At the completion of the myotomy, each side of the divided muscle is grasped and moved in opposite directions to ensure that a complete myotomy has been achieved. Air is then insufflated through a nasogastric tube (typically 60 mL) to check for a leak. If none is seen, the instruments are removed, the $CO_2$ is evacuated, and the umbilical port is removed. The umbilical fascial defect is closed, and the skin at all three sites is closed with subcuticular suture.

## COMPARISON OF THE OPEN VERSUS LAPAROSCOPIC APPROACH

Aesthetics were the initial impetus for developing this procedure; however, proponents of laparoscopic pyloromyotomy now cite many other benefits including faster recovery time with quicker return to full feeding, earlier postoperative discharge, a decrease in postoperative emesis, and a decrease in pain.[52] However, advocates of open pyloromyotomy state that recovery time is similar and that the laparoscopic approach has a greater complication rate including perforation,[8,52–55] missed perforation,[54] incomplete myotomy,[54,56] an increase in operative time, and increased expense.[53] All

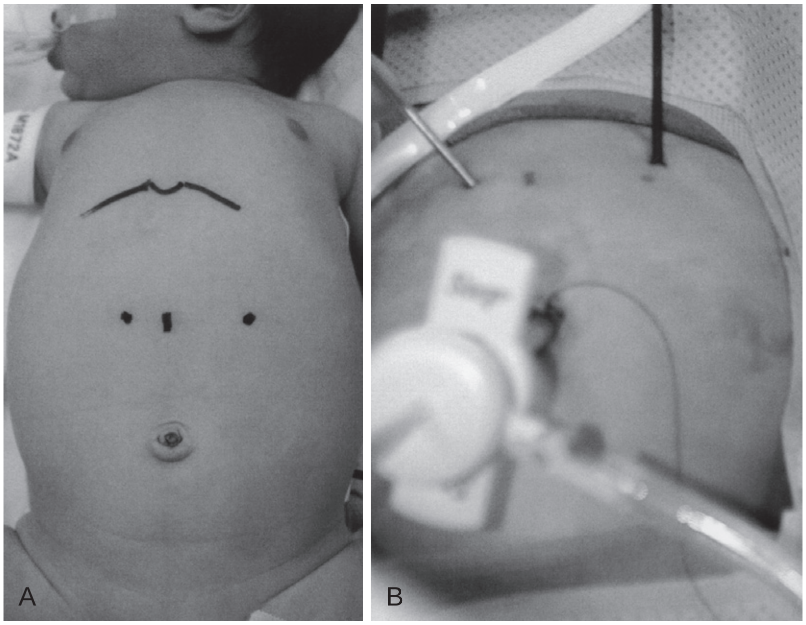

**FIGURE 78-6** Location of "ports" **(A)** and after the instruments and telescope are in place **(B).**

**FIGURE 78-7** View through the laparoscope with the arthrotomy knife being used to incise the serosa over the hypertrophied pylorus.

the published studies to date have been retrospective and demonstrate a marked degree of variability.

The range for the average time to discharge in the published literature for laparoscopy is similar to that for open procedures. Of the four publications that compare time to discharge between the open procedure and laparoscopy, only one group found statistical significance and the difference in discharge time was only 4 hours (Table 78-1).[53,55,57–61]

There is wide variation in the incidence of postoperative emesis. The range for laparoscopy was 1% to 68%, whereas for the open procedure it was 25% to 65%, with no statistical significance observed between the open and laparoscopic groups.[52,53,57,58,62]

The average time to establish full feeding in the laparoscopic group ranged from 16 to 32 hours versus 20 to 61 hours for the open procedure (Table 78-2).[52–54,57,62] The results are no different if the Fujimoto outlier study is eliminated.[52]

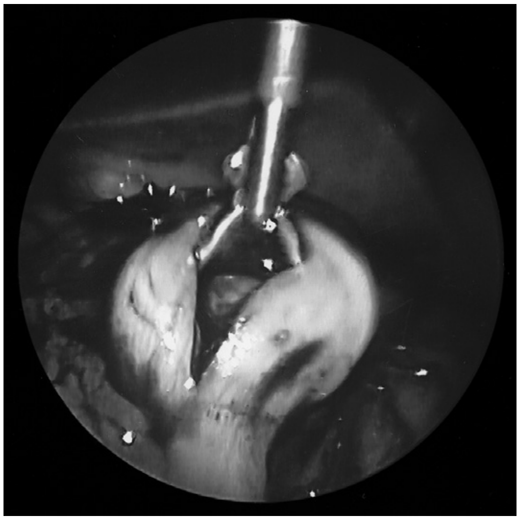

**FIGURE 78-8** Hypertrophied pyloric muscle after being split with the spreader.

Over the past decade, considerable additional experience has occurred and laparoscopic pyloromyotomy has become the standard at the training sites and children's hospitals in the United States with low morbidity and short hospital stays.

The wound infection rate for both groups was similar and ranged from 0% to 6% in the laparoscopic groups and from 0% to 7% in the open groups. None of these studies identified a significant difference between the groups (Table 78-3).[52,54,55,57–59,63]

The operative time was similar for both groups, with laparoscopy taking from 24.3 to 41 minutes and the open procedure taking from 18.9 to 32.5 minutes. Yagmurlu and colleagues[56] (the largest study) showed that laparoscopy was faster by 4.7 minutes on average. Sitsen and colleagues[55] and Scorpio and colleagues[60] found that laparoscopy was slower by 14.3

minutes and 13 minutes, respectively, but in each series the smaller number of patients probably indicates less operative experience at the time of the study. The other five comparative studies failed to reach statistical significance (Table 78-4).[53–62]

The perforation rate, which includes both duodenal and pyloric injuries, had ranges of 0.4% to 10% for laparoscopic pyloromyotomy and 0% to 6% for the open procedure. Four comparative studies found that laparoscopy had a slightly higher perforation rate, but the differences were not statistically significant (Table 78-5).[52–56,58]

Other factors that have been analyzed include the abdominal wall hernia rate, which in some laparoscopic groups ranged from 4% to 7%,[55,60] interleukin-6, and heat loss. Fujimoto and colleagues[52] found that interleukin-6 peak levels were significantly lower in the laparoscopy group 24 hours after surgery. They hypothesized that this could indicate a decreased level of stress on the patient. Holland and colleagues[63] found that laparoscopy tended to decrease the temperature of the infant to a greater degree than the open procedure did, which may have detrimental physiologic effects. These biologic markers indicate subtle differences between the open and laparoscopic procedures, but they may not be clinically significant.

As experience with laparoscopy has increased, the learning curve for the surgeon has become shorter, and technology has continued to improve, application of this technique has become commonplace. The larger laparoscopic studies demonstrate a comparable complication rate, and there may be a decrease in subjective factors such as pain and earlier feeding. Ultimately, the main difference may be the increased cost of laparoscopy. However, for surgeons who have limited exposure or access to laparoscopic techniques and equipment, the "open" Ramstedt pyloromyotomy remains the gold standard with which all other methods should be compared.

## POSTOPERATIVE MANAGEMENT

In the majority of infants, feeding can be started within 4 hours after the surgical procedure. Infants with hematemesis from gastritis may benefit by delaying feeding for an additional

**TABLE 78-6**

| Postpyloromyotomy Feeding Schedule* |
|---|

| Full-strength formula, 75 mL orally every 3 hr × 1 |
| Full-strength formula as desired |

*Begin 4 to 6 hours after surgery. For very small infants, the starting feeding volume may be reduced to 15 mL and the schedule stopped at volumes of 60 to 75 mL, which provide an adequate calorie supply. Breast milk can be substituted for formula if appropriate.

6 to 12 hours after the procedure. A typical feeding schedule is shown in Table 78-6. It is clear that the more aggressive the feeding schedule, the greater the incidence of emesis in the initial postoperative period, but this approach is usually successful and generally allows for earlier hospital discharge.[64] The feeding schedule shown in Table 78-6 is moderately aggressive and allows for hospital discharge approximately 24 hours after the feedings are initiated. In the future, infants may be discharged within 3 or 4 hours after pyloromyotomy, in which case resumption of feeding will be undertaken by the family at home.

### NONOPERATIVE TREATMENT

This approach never gained acceptance in North America but was practiced in the past in some European countries. Although infants with IHPS can be managed with frequent small feedings, this practice necessitates either a prolonged hospital stay or an attentive caregiver at home and may lead to aspiration and malnutrition. It may take months for the hypertrophied muscle to resolve. The occasional mortality and the prolonged interval from diagnosis to resolution led to abandonment of this type of management.

## Complications

Complications after pyloromyotomy should be minimal if performed by experienced surgeons. Vomiting, frequent in the early postoperative period, is thought to be secondary to gastroesophageal reflux, discoordination of gastric peristalsis, or gastric atony and should not be considered a complication. Frequent vomiting persisting beyond 3 to 4 days may suggest an incomplete myotomy or an unsuspected perforation. A postoperative contrast study may demonstrate a leak but is not helpful in evaluating the completeness of the myotomy. It takes several weeks for the radiographic appearance of the pylorus to improve.[65] Persistent and frequent vomiting 1 week beyond the pyloromyotomy may require reexploration.

## Outcome

After pyloromyotomy, mortality should be a rare occurrence and morbidity should be low. In a large series of infants undergoing open pyloromyotomy, the incidence of perforation was 2.3%, wound-related complications occurred in 1%, and there was one death.[50] More recent series have reported even lower morbidity and mortality.[66]

As experience with laparoscopic pyloromyotomy has increased, outcomes have become similar to those after the open approach. With a somewhat aggressive postoperative feeding schedule, infants should be able to be discharged within 24 hours of pyloromyotomy.

The long-term sequelae from pyloromyotomy are minimal. Ludtke and colleagues[67] evaluated the presence of gastrointestinal symptoms, measured scintigraphic gastric emptying, and determined pyloric measurements by US in 36 adults 17 to 27 years after pyloromyotomy. Their results were compared with those of age-matched and gender-matched controls. They identified no differences between the postpyloromyotomy group and the control group for the parameters measured.

CHAPTER 79

# Peptic Ulcer and Other Conditions of the Stomach

L. R. Scherer III

## Acute and Chronic Peptic Ulcer

Reports of peptic ulcer disease in infants and children date back to 1826. A collective literature review on peptic ulcers in 243 children was published by Bird and colleagues in 1941.[1] The series consisted of 119 patients who required surgical treatment for peptic ulcer. Ulcers in infants aged 1 to 15 days of age characteristically presented acutely with hemorrhage or perforation without premonitory signs or symptoms. Preschool-aged children, on the other hand, frequently had a prodromal illness before the onset of hemorrhage or perforation. The heterogeneity of the cause of the ulcers was apparently not recognized, and these differences were ascribed to age.

The theories and etiology of peptic ulcer disease remained consistent for the next 45 years. Careful historical information regarding ulcer-like symptoms in children with no other identified causes and eliciting a family history of peptic ulcer disease were common in instances of primary gastroduodenal ulceration.[2,3] In 1984 Marshall and Warren[4] reported a possible bacteriologic cause for primary ulcers. Secondary ulcers were defined as those caused by severe stress or critical illness. This classification of peptic ulcer is used in this chapter in discussing cause, diagnosis, and treatment (Table 79-1).

## Epidemiology

### PRIMARY PEPTIC ULCER DISEASE

The incidence of peptic ulcer in children is approximately 5.4/100,000 new cases per year.[5] Although the incidence in boys is two to three times higher than that in girls, the sex distribution is equivalent in infants and very young children. Several predisposing factors have been implicated in the development of peptic ulcer disease in patients of all ages. Duodenal and prepyloric ulcers behave similarly and are usually associated with higher levels of hydrochloric acid secretion. The ulcer is usually located in the area of the junction of parietal cell mass and the antral mucosa.[6] The question has been raised as to whether peptic ulcer disease in children is the same condition that presents in adults. A strong familial tendency has been noted. Thirty-three to 56 percent of children with ulcer disease have first- and second-degree relatives with peptic ulcer disease.[7–10] Heritability of peptic ulcer disease has been calculated at 0.91 per first-degree relative for children,[8] a rate considerably higher than the heritability calculation of 0.37 derived for adults. A positive family history for peptic ulcer disease is considered an important characteristic of ulcer disease in children.[2,11] There is a link to primary gastritis and peptic ulceration occurring in children in the presence of *Helicobacter pylori* infection clustering among family members of affected individuals.[12–14] *H. pylori* colonizes the gastric antrum and has satisfied Koch's postulates as a human pathogen causing primary ulceration and chronic-active gastritis in children.[15] The incidence of *H. pylori* infection is estimated to be 0.5% per year in industrialized countries[16,17] and 3% to 10% per year in developing countries.[18] The route of transmission of *H. pylori* is postulated to be fecal-oral or oral-oral.[19,20] Risk factors associated with *H. pylori* infection in children include crowded living conditions, endemic country of origin, poor socioeconomic level, immigrant children, children born of recent immigrants, infected family members, and ethnicity.[21] Pathologic conditions associated with *H. pylori* infection include nodular gastritis, primary duodenal ulcer, gastric ulcers, Barrett esophagus, gastric cancer, and MALT lymphoma.[22–25]

### SECONDARY PEPTIC ULCER DISEASE

Secondary ulcers (stress ulcers) are acute ulcers in children usually associated with major physical or thermal trauma, sepsis, shock, or other critical illness (see Table 79-1). Gastric stress ulcers are usually multiple superficial mucosal erosions found primarily in the fundus of the stomach. The cause of these ulcers has been related to one or a combination of three factors: (1) decreased mucosal blood flow, (2) disruption of the protective mucosal barrier, and (3) intraluminal acidity.[26] Stress ulcers account for 80% of the peptic disease seen during infancy and early childhood.[27] Drug- and chemical-induced ulcers resemble stress ulcers in appearance and distribution. The ulcer that occurs from intracranial disorders, however, is usually a single, deep ulcer and prone to perforation

**TABLE 79-1**
**Classification and Causes of Gastritis and Ulcers in Children**

| *Classification/ Category* | *Etiology* |
|---|---|
| Primary | *Helicobacter pylori* |
| Secondary | |

| | Aspirin |
| | Ethanol (alcohol) |

(Cushing ulcer). Studies in adults indicate that gastric hypersecretion is not associated with stress ulcers or ulcers resulting from drug ingestion.[28,29] Most Cushing ulcers, on the other hand, are associated with an increased acid output.[16,30] Secondary ulcers in older children are frequently single and deep (similar to Cushing ulcer). No detailed studies have been done to determine whether gastric hypersecretion is present in children with stress ulcers.

With the development of pediatric endoscopes, the location of stress ulcers in children was found to be similar to that in adults, mostly occurring in the stomach; other investigators have observed an equal distribution in the stomach and duodenum.[31] Reported series by Williams,[32] Grosfeld,[33] and Deckelbaum[34] of 194, 29, and 25 patients, respectively, found equal distribution of Curling-type single ulcers in the stomach and duodenum. The single gastric ulcers in these studies were usually located in the prepyloric region and behaved similarly to duodenal ulcers. Endoscopy has refined the approach to diagnosis and has led to a better understanding of the presentation and course of ulcer disease in children. Currently, more than two thirds of the patients receiving treatment with corticosteroids or nonsteroidal antiinflammatory drugs (NSAIDs) developed secondary peptic ulcer disease presenting as acute epigastric pain.[35]

## GASTRIC PHYSIOLOGY AND PATHOPHYSIOLOGY

### Aggressive Factors

Acid secretion has been identified in the fetal stomach as early as the nineteenth week of gestation, and pepsin secretion is present by the thirty-fourth week. Term infants can secrete both acid and pepsin.[36] Gastric hyposecretion occurs during the first 5 hours after birth and increases during the next 48 hours when the pH stabilizes to a value of approximately 3.[37] The premature infant can secrete acid and pepsin but in diminished quantities compared with the term infant. Thirty-three percent of premature infants have an alkaline gastric pH, and 20% do not produce acid for 10 days. Many premature infants will maximally produce gastric acid by 4 days. In neonates, the parietal cell mass per unit area is two to three times that found in adults.[38] Infants have a relatively high acid secretion during the first week to 10 days of life (Table 79-2).[37] Maternal gastrin secretion may be responsible for both the increased parietal cell mass and the high acid secretion rate. Acid secretion rapidly decreases after about 10 days of age.[39] During the next 4 months, acid and pepsin secretion increase, paralleling weight instead of age throughout childhood.

**TABLE 79-2**
**Aggressive and Defensive Factors Involved in the Gastroduodenal Mucosal Balance**

| *Aggressive Factors* | *Mucosal Defense Factors* |
|---|---|
| Vascular injury: decreased microcirculation | Mucosal circulation: adequate microcirculation |
| Cancer chemotherapeutic agents | Epithelial cell turnover |
| Aspirin | Increased bicarbonate secretion |
| Nonsteroidal | Inhibit gastric acid secretion antiinflammatory drugs |
| Infectious agents: cytomegalovirus herpesvirus | Preserve vascular cytomegalovirus, flow/microcirculation |
| Systemic stress: increased | Restore epithelial cell surface catecholamines |
| Increased pepsin secretion | Mucous layer: glycoproteins, glycocalyx |
| *Helicobacter pylori* | Bicarbonate layer: pH gradient |
| | Immunoglobulins: IgG, IgA |

Elevated levels of gastric acid secretion have been reported in children with peptic ulcer disease. Similar to adult studies, elevated acid secretion is not necessarily useful in identifying the child with peptic ulcer disease. For example, Ghai[40] used the augmented histamine test to study 18 children with peptic ulcer disease and 16 control children. He found no significant increase in basal acid output in patients with an ulcer. The mean maximal and peak acid output increased, but the two groups overlapped; maximal and peak values increased with the patient's age and weight. Robb[10] noted a similar relationship of age, weight, and acid secretion but did not observe any difference between the acid secretion in 49 children with duodenal ulcers compared with 30 children with dyspepsia and no ulcer. Nagita[41] and colleagues measured the diurnal variation of intragastric pH in children with primary peptic ulcer and healthy children. They found that gastric acidity increased with age and approached adult levels by age 14 years. In children with gastric ulcers, the mean pH for all ages was higher than that for the age-matched controls; in children with duodenal ulcers, the mean time during which the pH was less than 2 was greater than in an age-adjusted comparison group.[41]

In 1984 Marshall and Warren[4] reported the successful culture, under microaerophilic conditions, of a novel gram-negative bacterium *(H. pylori)* from the antral mucosa of humans (see Table 79-2). Recurrent peptic ulcers in adults

may be associated with gastritis that primarily involves the antrum. The accumulation of clinical and laboratory studies provides strong evidence that *H. pylori* fulfills each of Koch's postulates as a cause of chronic active gastritis in humans.[15] The flagella-bearing *H. pylori* organisms require a microaerobic environment for culture, reflecting their environmental niche to navigate through the thick and viscous mucus layer to reach the apical layer of the gastric epithelium.[42] All children infected with *H. pylori* appear to develop chronic-active gastritis. Most have asymptomatic infections that may never lead to clinically evident disease. Theories concerning the mechanism that causes inflammation include the bacterial production of urease and vacuolating cytotoxin. Urease hydrolyzes urea to ammonia and bicarbonate at the gastric mucosal surface. Ammonia can be directly toxic to epithelial cells, and the concomitant increase in the mucosal surface pH may interfere with gastric epithelial function such as production of mucus.[43] This cytotoxin produces vacuoles in the cytoplasm of eukaryotic cells in vitro. The gene *(vacA)* of this cytotoxin has two alleles and is variably expressed among isolates.[44] CagA, a cytotoxic protein, has been isolated in approximately 60% of *H. pylori* isolates, and its presence correlates strongly with the expression of the vacuolating cytotoxin.[45] *H. pylori* that is present in a majority of patients with nodular gastritis, gastric or duodenal ulcer, or in situ expression of cagA is higher in duodenal ulcers ($<0.05$).[46]

Cellular injury in the gastric and duodenal epithelium initiates the inflammatory infiltrate (see Table 79-2) in the gastric mucosa and includes monocytes, macrophages, and polymorphonuclear and plasma cells.[47,48] These inflammatory changes may be due to cagA expression and tumor necrosis factor promoter,[49] which may induce other cytokines including interferon-γ, interleukin-1 (IL-1), IL-2, IL-6, and IL-8.[50]

## Defensive Factors

The presence of hydrochloric acid is required for ulcer formation even though hypersecretion is not usually present (except with Cushing ulcer). Most of the factors contributing to the development of stress ulcers reduce the ability of the stomach mucosa to protect itself against acid injury.[51] Investigators generally agree that mucosal ischemia is also implicated in the pathogenesis of stress ulcers (see Table 79-2).[52] Normally, small amounts of hydrogen ions diffuse into the mucosa but are rapidly cleared or neutralized if mucosal blood flow is adequate. Ischemia reduces production of mucus and the capacity for neutralization of acid entering the tissues, leading to an accumulation of hydrogen ions and subsequent mucosal ulceration. The adverse effect of ischemia on energy metabolism may be an additional factor that reduces the ability of the mucosa to defend itself against injury.[53] Intravenous infusion of sodium bicarbonate administered during the experimental production of mucosal injury by hemorrhagic shock has a protective effect.[54] These findings suggest that ischemia, energy deficits, and systemic acidosis are important factors in the pathogenesis of stress ulcers. In instances of medication-induced ulcers, the drug disrupts the mucosal permeability barrier.[29] A thick mucous gel is secreted from the superficial epithelial cells and mucus cells throughout the stomach. The release of mucus is stimulated by cholinergic agonists, prostaglandins, and inflammatory or immune cytokines. The layer of mucus in the stomach is approximately 20 times the thickness of the surface epithelial cells and is full of charged protein particles. In the normal setting, this mucus provides an effective barrier to the deleterious effects of acid.

Prostaglandins protect against the development of experimentally induced stress ulcers.[55] The mechanism is uncertain but may be related to prostaglandin's stimulation of chloride ion transport out of the cell in exchange for bicarbonate ion, which blocks cyclic adenosine monophosphate (AMP) generation. The available intracellular bicarbonate increases the ability of the cell to buffer acid. Endogenous prostaglandins also have a role in maintaining adequate blood flow to the gastric mucosa and stimulate production of mucus, improving the ability of the mucosa to withstand acid destruction.[56] Corticosteroids and NSAIDs have been implicated as causative agents in peptic ulcer disease. Studies have shown the cytoprotective effect of prostaglandins, the development of ulcers during treatment with NSAIDs and corticosteroids, and a decreased level of prostaglandins in the stomach during treatment.[35,57] Drugs can cause secondary ulcers by damaging the mucosa and thereby allowing acid-peptic digestion. Aspirin is a common agent associated with medication-induced secondary ulcers. In general, drug-induced ulcers should respond to cessation of the medication and conservative supportive treatment, unless complications develop.

## Clinical Presentation

The clinical features of primary peptic ulcer disease in children can easily be confused with those of many other disorders; this similarity may inflate the actual incidence of ulcer disease in children (Table 79-3). Clinical symptoms in the

**TABLE 79-3**
**Clinical Findings in Primary and Secondary Gastritis and Peptic Ulcer Disease**

| *Disease Entity* | *Signs and Symptoms* |
|---|---|
| Primary gastritis | Asymptomatic (most common) |
| | Recurrent abdominal pain (any location) |

infant include refusal of feedings, persistent crying, and vomiting.[6] The risk of a child developing an ulcer may be higher with a positive family history. Several studies present evidence that in an endemic population of infected parents, mothers in particular may play a key role in transmission of *H. pylori* to the child.[11] The diagnosis is often elusive until such complications as perforation or bleeding occur. Vomiting is common in preschool-aged and school-aged children with peptic ulcers. Abdominal pain is recognized with increasing frequency as the child becomes older. The pain is often vague and difficult to describe and may be related to meals or relieved by eating, as is seen in adults.[34,58] In older children and adolescents, the clinical presentation and natural history of peptic ulcers are more comparable with those observed in adults.[59–61] The ulcers present with epigastric and nocturnal abdominal pain in teenagers with a positive family history of peptic ulceration. In this setting, despite healing of the acute ulceration, the natural history of this disease process is for the ulcer to recur. It is now clear that such ulcers are not related to a genetic predisposition to hyperpepsinogenemia but are associated with *H. pylori* infection.[14] Almost all patients with primary peptic ulcer disease present with abdominal pain. Unfortunately, psychogenic, recurrent abdominal pain of childhood, the most common pediatric intestinal disorder, causes nearly identical symptoms.[62] Nocturnal awakening caused by episodes of abdominal pain may differentiate organic from psychogenic origin. Gremse and Shakoor[63] evaluated the predictive values of signs and symptoms of acid-peptic disease in children in whom endoscopy confirmed the diagnosis. Six symptoms correlated significantly with acid-peptic disease: epigastric pain, nocturnal pain, postprandial pain, water brash, weight loss, and a family history of peptic ulcer disease. Only 7% of children with psychogenic recurrent abdominal pain report pain occurring at night compared with 60% of children with peptic ulcer disease. In a study of 110 children with duodenal ulcers, the mean age at diagnosis was 11.3 years; in 46% of children, some symptom of peptic ulcer disease manifested before 10 years of age.[2]

Secondary ulcers are acute. Although the age of patients with secondary ulcers ranges from 1 day to 18 years, most patients are younger than 6 years of age. Secondary peptic ulcers are usually due to noxious agents (e.g., corticosteroids and NSAIDs) or after major stresses (e.g., burns, head injury, systemic illness).[21] In these settings, upper gastrointestinal tract hemorrhage, vomiting, and perforation are frequent presenting features. Diagnosis is therefore more difficult and usually made when a catastrophic event such as hemorrhage or perforation occurs. Gastrointestinal bleeding, the predominant presenting symptom of secondary ulcers, occurs in 92% of patients younger than 6 years of age.[64] The ulcers tend not to recur after healing if either the offending agent or underlying disease predisposing to mucosal ulceration is successfully treated.

## Diagnosis

Endoscopic diagnosis followed by treatment with histamine-2 ($H_2$)-receptor antagonists has changed the presentation and course of acute ulcer disease in children. Before the use of endoscopy in children, patients with peptic ulcer disease frequently presented with an acute surgical abdomen, massive hemorrhage, or perforation; the diagnosis was made at the time of operation or autopsy. The present indications for the early diagnosis of acid-peptic disease are gastrointestinal bleeding, dysphagia, persistent vomiting, and the abdominal pain characterized earlier.[65] Gastric analysis is not a useful diagnostic test. Secondary ulcer was previously diagnosed by contrast radiologic studies, angiography, laparotomy, and autopsy. The known occurrence of secondary ulcers in association with physiologic stress should lead to the diagnosis before signs and symptoms become catastrophic. Radiologic diagnosis can be difficult in the presence of hemorrhage because blood clots can mask the ulcer; therefore endoscopy has become the standard for the diagnosis of the acute bleeding ulcer. In one report, endoscopy provided a diagnosis in 85% of children with upper gastrointestinal bleeding compared with 62% using radiologic studies.[66] Angiography can be useful in locating a bleeding ulcer if the rate of bleeding is at least 0.5 mL/min.[67,68]

***H. pylori*** *Invasive Methods:* Endoscopy is the method of choice to accurately diagnose peptic ulceration in children. Nodularity in the antrum of the stomach is a specific (but not sensitive) feature indicative of active *H. pylori* infection in children. Biopsy specimens should be taken from the stomach and tested for the presence of *H. pylori* by a variety of techniques including staining of biopsy sections (silver, Giemsa, Genta, acridine orange) and microscopic evaluation, culture, and testing for the presence of urease activity. In children and teenagers receiving concurrent therapy with a proton pump inhibitor, biopsies should be performed on the body and cardia (and, possibly, transition zones) of the stomach, as well as from the antrum to reduce the chances of false-negative results.[69] Follow-up endoscopy is rarely necessary in pediatric populations, except in the setting of peptic ulceration associated with complications (e.g., massive hemorrhage or perforation).

*Noninvasive Methods:* Infection with *H. pylori* induces a vigorous immune response resulting in the presence of local and systemic antibodies. *H. pylori*-specific IgG antibodies are present in serum, plasma, whole blood, saliva, gastric juice, and urine. The humoral immune response is less vigorous in children. Therefore the cutoff values established for use in adults to determine the presence or absence of *H. pylori* infection are not appropriate in young children. Increasing concerns have been raised about the utility of testing for antibodies in low-prevalence settings, such as is the case for children and adolescents living in developed nations. Although immunoassays are relatively inexpensive and technically easy to perform, those used in children must first be validated in each country or region, using serum samples obtained from relevant populations.[12] Breath testing using the stable isotope $^{13}$C- or radiolabeled $^{14}$C-urea as substrate shows great promise as an alternative approach to noninvasively diagnose *H. pylori* infection in adults. However, $^{14}$C-labeled substrates should not be used in children and women during their reproductive years. Urea breath testing is accurate in children older than 2 years of age.[70,71] A commercially available stool antigen test has been reported to be highly accurate as a diagnostic test in adults. In contrast to serology, in which antibody titers may remain elevated for months after successful eradication of the organism, the stool antigen test is reported to turn negative within a week after elimination of *H. pylori*. The accuracy of the stool antigen test when used in pediatric populations in a variety of clinical settings validates its usefulness.[71,72]

## Treatment

The treatment of peptic ulcer disease in children is similar to that used in adults. Antacids and $H_2$ receptor antagonists (e.g., cimetidine) are the mainstays of medical therapy. Other therapeutic agents include selective anticholinergic agents, proton-pump inhibitors, cytoprotective agents, and anti-infective agents (Table 79-4).

Omeprazole and lansoprazole, proton-pump inhibitors, inhibit the stimulation of gastric acid secretion at the final common pathway (cyclic AMP-adenylate cyclase, $H^+$-$K^+$ adenosine triphosphatase inhibition). Therefore all forms of secretion (histaminergic, gastrinergic, and cholinergic) are blocked. A pediatric dosage of omeprazole, 1 mg/kg/day up to 20 mg/day; or lansoprazole, 0.5 mg/kg/day up to 30 kg and then 30 mg daily in children greater than 30 kg, is effective in 95% of patients within 4 weeks.[21,73] Although omeprazole is well tolerated, side effects include headache, nausea, and abdominal pain.

In children with documented *H. pylori* gastritis or duodenal ulcer, eradication of this microorganism requires the use of standard antimicrobial agents and bismuth preparations (see Table 79-4). The current standard treatment consists of two antibiotics (choosing two of the following): amoxicillin (50 mg/kg/day), clarithromycin (15 mg/kg/day), or metronidazole (20 mg/kg/day) and a proton pump inhibitor. Treatment regimens include twice-daily dosing of antibiotics for 2 weeks and a proton-pump inhibitor for 4 weeks. The use of this triple therapy results in eradication of the infection in more than 80% to 90% of patients.[21,73]

Antacids effectively neutralize acid secretion and heal peptic ulcer disease compared with placebo (75% compared with 40%). Unfortunately, compliance is disappointing, and the complications of the medications including diarrhea and constipation are bothersome. Therapy requires antacid administration (0.5 mL/kg) 1 hour before meals, 3 hours after meals, and at bedtime.

Histamine is a stimulant of gastric secretion. $H_2$ receptors are present on the gastric acid–producing parietal cells of the stomach; $H_2$ receptor antagonists inhibit responses to all secretagogues and thus are effective in suppressing gastric acid secretion. Cimetidine (20 to 40 mg/kg/day) was the first commercially available antagonist. The antiandrogen side effects and the effects on the central nervous system are likely due to the imidazole ring of the compound, which inhibits the cytochrome P450 system of the liver. Ranitidine (6 to 9 mg/kg/day PO or 2 to 4 mg/kg/day IV), an $H_2$ antagonist that lacks an imidazole ring, is six to eight times more potent and is equally effective (85% to 95%) in healing ulcers in 8 weeks. However, a relapse rate of 20% has been reported. Famotidine and nizatidine are other potent antagonists used in adults, but little information regarding their use in children has been reported.

The cytoprotective effect of sucralfate results from a coating action due to the negative charge of the sulfated disaccharide aluminum salt that adheres to the positive protein charge of the injured mucosa. The compound also seems to stimulate mucus production and prostaglandin synthesis, bind bile salts, and neutralize pepsin and acid. The adult dosage is 1 g (1 g/10 mL slurry) four times per day; the childhood dose is 40 to 80 mg/kg/day. Constipation is the only clinically significant side effect.

The E-type prostaglandins including misoprostol, enprostil, and arbaprostil are cytoprotective.[35] The mechanism of action that provides protection to the mucosa is related to blocking production of cyclic AMP, stimulation of $HCO_3^-$, and an increase in mucosal blood flow. The adult dose is 200 μg four times daily, but there is little documented information concerning experience in children.

**TABLE 79-4**
**Three Recommended Combination Eradication Therapies for *Helicobacter pylori*–associated Disease in Children**

| *Duration of Medications* | *Dose* | *Treatment* |
|---|---|---|
| Amoxicillin | 50 mg/kg/day | 14 days bid |
| Clarithromycin | 15 mg/kg/day | 14 days bid |
| Proton pump inhibitor | 1 mg/kg/day | 1 month bid |
| Amoxicillin | 50 mg/kg/day | 14 days bid |
| Metronidazole | 20 mg/kg/day | 14 days bid |
| Proton pump inhibitor | 1 mg/kg/day | 1 month bid |
| Clarithromycin | 15 mg/kg/day | 14 days bid |
| Metronidazole | 20 mg/kg/day | 14 days bid |
| Proton pump inhibitor | 1 mg/kg/day | 1 month bid |

## Surgical Treatment

Historically and presently, surgical management of peptic ulcer disease has been reserved for complications such as perforation, bleeding, obstruction, and intractable pain.[59–61] Follow-up studies of children with primary ulcer disease treated medically revealed a high rate of recurrence after cessation of treatment throughout childhood and into adult life.[2,74] Increasing numbers of these patients eventually required surgical treatment. Because of the prolonged morbidity reported in medically treated patients, earlier surgical intervention had been recommended.[75] Vagotomy and pyloroplasty rather than gastric resection are recommended as effective treatment, with a minimal effect on subsequent growth and development.[76] In the past decade, highly selective or parietal cell vagotomy has been used extensively in several centers to treat adult patients with peptic disease, but no series has been reported in children. The high recurrence rate observed with this approach (10% to 15%) may be an issue; however, some consider this rate to be acceptable in children because it may cause only minimal disturbance of growth and development while providing a reasonably good long-term outcome.[77]

Bleeding or perforated ulcer that occurs in the first 1 to 2 weeks of life (unassociated with other illness or stress) appears to be an acute ulcer resulting from hypersecretion of acid caused by maternal gastrin. These ulcers are usually complicated by bleeding and often respond to orogastric decompression, accompanied by careful saline lavage to keep blood clots evacuated from the stomach and appropriate volume replacement. Perforation requires prompt surgical intervention with the simplest method (i.e., a Graham patch) to safely close the defect.[60] If the operation is performed for hemorrhage, simple suture ligation of the ulcer bed should suffice.[61] No evidence suggests that these ulcers recur. Although the incidence of bleeding and perforation has diminished over the past 2 decades, the complication of chronic obstruction from peptic ulcer disease is unchanged. In a recent 45-year review, Azarow[78] and colleagues described a persistently high incidence of gastric outlet obstruction requiring surgical intervention. Vagotomy and pyloroplasty or gastroenterostomy were used

to relieve the obstructions. Chronic, partial gastric outlet obstruction secondary to a congenital problem such as a duodenal web[79,80] or hypertrophic pyloric stenosis also can result in peptic ulcers in infants and children. It is important to identify the cause in these instances because the ulcer can be completely eradicated by treatment of the distal obstruction.

## ZOLLINGER-ELLISON SYNDROME

The Zollinger-Ellison syndrome is relatively rare in children.[81] The diagnosis may be suggested by the presence of large gastric rugal folds, duodenal dilatation, and edema of the small-bowel mucosa and can be confirmed by an elevated serum gastrin level. The calcium infusion test, reliable in both adults and children, has been used to confirm the diagnosis of hypergastrinemia. Treatment of the Zollinger-Ellison syndrome has traditionally been total gastrectomy unless the primary pancreatic tumor can be completely resected. Some reports suggest that $H_2$ receptor antagonists or proton-pump inhibitors can eliminate the need for gastrectomy in children.[82] The fact that many of these endocrine tumors may be malignant suggests that a careful evaluation of each case to determine its nature and long-term follow-up after treatment with $H_2$ receptor antagonists or proton-pump inhibitors is necessary before reliable conclusions about management can be drawn. In addition, occasionally the gastrin-producing tumors may occur in the wall of the duodenum and require resection. The multiple endocrine neoplasia type 1 syndrome may be present in 25% of the cases. Somatostatin receptor scintigraphy is useful in detecting primary and metastatic gastrinomas.

## STRESS ULCER

Prevention is the preferred treatment goal for stress ulcers. It has been shown experimentally that, under simulated clinical conditions, development of stress ulcers requires a low gastric pH. The use of prophylactic antacids to maintain the gastric intraluminal pH at a value of 6 or greater is effective. Supportive care with improved ventilatory support, maintenance of vascular volume, correction of acid-base imbalance, and nutritional support may also contribute to the ability of the gastric mucosa to withstand acid-peptic injury.

The effectiveness of $H_2$ receptor antagonists and proton-pump inhibitors for the prevention of stress ulcers is extremely effective.[83,84] An $H_2$ receptor antagonist is probably indicated in the prevention and treatment of Cushing ulcers, which are associated with gastric hypersecretion.

When a secondary ulcer presents as bleeding, immediate supportive treatment with balanced salt solution and blood transfusion is frequently adequate. Children who have experienced a major episode of upper gastrointestinal hemorrhage or recurrent bleeding require endoscopy.[85] Endoscopy for bleeding requires greater skill and greater technical demands than do other endoscopic procedures. The endoscopist should have the knowledge and experience not only to identify the source of bleeding but also to control it. Potential interventions include therapeutic injections (of hypertonic NaCl, epinephrine, or absolute ethanol) and cauterization with heater probe, bipolar coagulation, or laser (Nd:YAG or argon). If the endoscopist is not a surgeon, a pediatric surgeon should evaluate the child before emergency endoscopy. The surgeon may then be available to observe the source of hemorrhage and be immediately available for surgical intervention if necessary.

If massive hemorrhage continues or recurs despite drug and endoscopic therapy, surgical control is indicated. Massive hemorrhage has been defined as blood loss in a 24-hour period equal to the total estimated blood volume in infants younger than 2 years of age and as loss equal to half of the estimated blood volume in older children (with 80 mL/kg used as an estimation of total blood volume). This definition correlates with the report of Williams and colleagues,[32] in which no child recovered without surgical management if the rate of blood loss was more than 60% of the estimated total blood volume in 24 hours. The successful use of selective intraarterial vasopressin to manage bleeding stress ulcer in a child has been reported,[86] but others have not found this to be useful.[33,87] Although bleeding often precedes perforation of a secondary ulcer, perforation can be the initial presentation and requires immediate operation.

The surgical procedures used to treat stress ulcers have ranged from simple closure of a perforation to oversewing of the base of a bleeding ulcer to gastrectomy.[88] As a general rule, these ulcers are not associated with an ulcer diathesis and therefore should respond to the simplest procedure that effectively treats the presenting problem. Because stress ulcers are the result of an underlying disease, recurrence of the ulcer is possible if the underlying problem is unresolved; this fact must therefore be considered when the appropriate operation is being selected. The simplest procedure, plication of the site of perforation or oversewing of the bleeding point, is usually effective. On the other hand, when it is apparent that the underlying problem will remain unresolved for an extended period, a more definitive ulcer procedure may be appropriate. Vagotomy and pyloroplasty are recommended most frequently because they rarely interfere with subsequent growth. Vagotomy and antrectomy may occasionally be necessary to control the bleeding ulcer in patients with extensive burns and intracranial problems.[89] Antrectomy also may be necessary for large perforations that cannot be managed by pyloroplasty, although the possibility of serosal patching to close such large defects should be kept in mind. In adults, even total gastrectomy has been infrequently recommended for treating massive hemorrhage from multiple gastric ulcers. Such a procedure is rarely indicated in children. The surgeon who operates on a child for ulcer disease must remember that the patient must continue to grow and develop; therefore the simplest, least disruptive procedure should be selected. Evidence suggests that these children do have problems such as low hemoglobin levels.[90] Experimental evidence comparing the effects of gastrectomy with vagotomy and pyloroplasty on growth and development in miniature swine[91] suggests that vagotomy with pyloroplasty results in less growth disturbance. Follow-up data indicate that vagotomy with pyloroplasty is an effective method of treatment unassociated with substantial long-term problems.[76] In view of the reports of osteoporosis, iron deficiency, and dumping noted in adults who have had various operations for peptic ulcer disease,[92,93] long-term follow-up is essential. There are rare reports of adenocarcinoma occurring in gastric remnants after subtotal gastrectomy.[94] The risk is higher after a Billroth II (gastrojejunostomy) anastomosis. One of our patients developed cancer in the gastric remnant at age 23 years—12 years after a vagotomy and antrectomy for a chronic obstructing duodenal ulcer. Other tumors may arise

in the stomach and present with bleeding due to erosion. These include rare cases of gastric teratoma and instances of leiomyosarcoma and gastrointestinal stromal tumors (GIST).

# Other Conditions of the Stomach

## CONGENITAL GASTRIC OUTLET OBSTRUCTION

### Pyloric Atresia

***History*** Congenital pyloric atresia (CPA) is a rare condition. It constitutes about 1% of all intestinal atresias. In 1749 Calder reported the first case of CPA, and Touroff performed the first successful operation in 1940. CPA typically occurs in isolation, but associated anomalies are also commonly seen in 40% to 50% of the cases and epidermolysis bullosa (EB) is the commonest. The presence of associated anomalies is a contributing factor for the reported high mortality.

***Embryology and Pathology*** The antral and supraampullary parts of the duodenum develop from the caudal end of the foregut. Atresias in this region occur in the form of webs, membranes, or rarely solid cords (Table 79-5). The cause of antral web and atresia has not been fully elucidated. Skandalakis and Gray[95] have postulated that redundancy and slipping of epithelial lining may initiate the formation of an incomplete diaphragm. Sharma and colleagues[96,97] also hypothesize this etiology on a small series of acquired mucosal obstruction of the pylorus. Although these explanations appear to be a possible cause of membranous webs, it still remains speculative and definite confirmatory evidence is not currently available. The similarities of the clinicopathologic features in related patients and their occurrence in siblings and cousins, in the absence of teratogenic factors, point to a genetic etiology that is similar in pathology to the familial genetic etiology of infants with pyloric atresia[98,99] and epidermolysis bullosa.[100,101] One other cause of gastric outlet obstruction with similar embryology is the pyloroduodenal duplication cyst.[102]

***Clinical Presentation and Pathophysiology*** A maternal history of polyhydramnios is often reported. With the frequent use of prenatal ultrasound, polyhydramnios may be observed and the fetal stomach may be distended during the last trimester.[103] The affected infant presents in the first few days of life with nonbilious vomiting and complete gastric outlet obstruction.[104,105] Examination of the abdomen shows epigastric fullness due to the distended stomach. If diagnosis is delayed, excessive distention of the stomach may lead to perforation. Because the obstruction is proximal to the ampulla of Vater, the passage of a meconium stool may mislead the casual observer.

***Diagnosis*** Abdominal radiography confirms the clinical diagnosis (Fig. 79-1). Abdominal radiography performed in various positions may be required to establish the correct diagnosis. A single gastric bubble is observed with no air visible beyond the pylorus. With symptoms of nonbilious vomiting, a distended stomach, and air noted distal to the stomach, dilute barium or soluble contrast is required for the diagnosis of an incomplete pyloric membrane (Fig. 79-2).

**TABLE 79-5**
**Classification of Antral and Supraampullary Atresias**

I. Pyloric
   A. Membrane
   B. Atresia
II. Antral (1 cm or more proximal to pylorus)
   A. Membrane
   B. Atresia

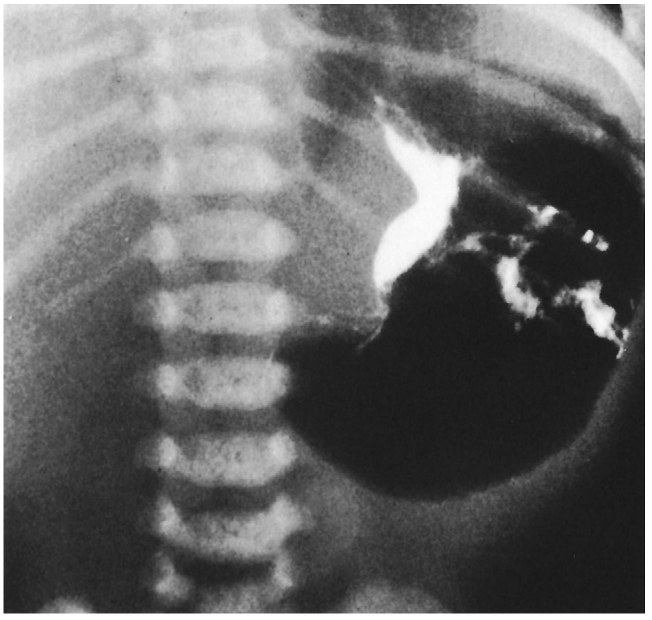

**FIGURE 79-1** Pyloric atresia in a newborn. Air provides excellent contrast. No air extends beyond the pylorus. This child was dehydrated and developed hypochloremic, hypokalemic alkalosis after early postnatal discharge. The anomaly was successfully treated by end-to-end gastroduodenostomy.

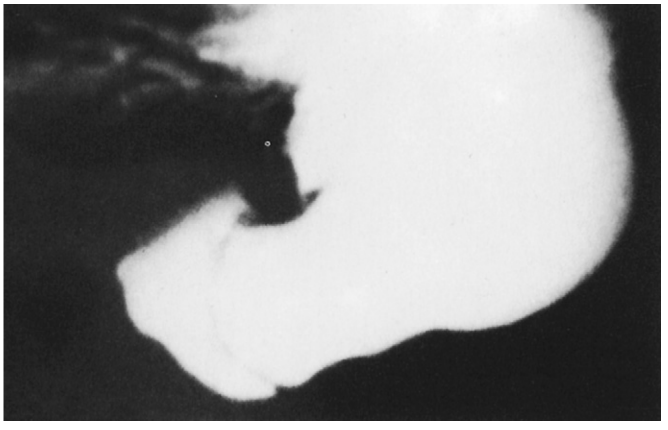

**FIGURE 79-2** Incomplete antral diaphragm in a newborn. This infant had non-bile-stained vomitus shortly after birth. A dilute barium contrast swallow established the diagnosis of an incomplete obstruction. Treatment with a Heineke-Mikulicz pyloroplasty and with excision of the web was successful.

***Treatment*** Pyloric atresia can usually be recognized at the time of operation; a fibrous cord may join two blind ends (Fig. 79-3). Gastrotomy and distal passage of a catheter may be required to detect membranous obstructions (Fig. 79-4). Excision of a complete or partial diaphragm with Heineke-Mikulicz or Finney pyloroplasty is the most straightforward corrective procedure. Haller and Cahill[106] warn against missing a pyloric web in association with a duodenal atresia. They recommend a wide gastrotomy and distal passage of a catheter after excision of the prepyloric diaphragm to identify an associated duodenal diaphragm. In the presence of pyloric atresia with the atretic ends separated by a cordlike or discontinuous segment, gastroduodenostomy is necessary. Dessanti[107] and colleagues described an anatomic pyloric sphincter reconstruction procedure using the atretic cul-de-sac to perform an end-to-end anastomosis. This procedure replaces the resection of the atretic segment and a side-to-side or end-to-oblique anastomosis because of the size disparity between the stomach and duodenum. A temporary decompression gastrostomy and insertion of a transgastric feeding tube may be useful. Recent advances in endoscopy have stimulated development of alternate treatment strategies including balloon dilatation, laser web excision, and laser radial incisions of a type I membrane. The number of these cases is few, and long-term follow-up data are limited.

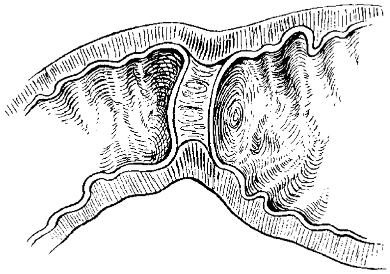

**FIGURE 79-3** Pyloric atresia. The seromuscular layers are uninterrupted. The tissue between the gastric and duodenal mucosa was of two types: fibrous and areolar.

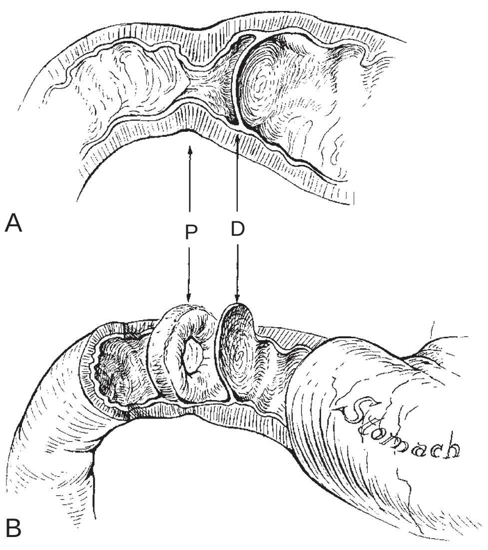

**FIGURE 79-4** Congenital pyloric and prepyloric obstruction. **A,** Prepyloric membrane. **B,** Antral diaphragm. P, Pylorus; D, diaphragm.

***Outcomes*** Survival should be anticipated if diagnosis and surgical intervention occur early and if adequate supportive care is provided. Death has been associated with delayed diagnosis[80,98,108] and associated conditions.[109] Fifty-nine cases of congenital pyloric atresia have been reported. A familial occurrence was described in 13 infants in six families; an unexplained high-mortality rate was seen in this familial group. Some familial cases are associated with epidermolysis bullosa.[98,110] Junctional epidermolysis bullosa/pyloric atresia syndrome is associated with extremely adverse outcomes due to the risk of sepsis, malabsorption, renal disease, and failure to thrive. Of the 70 cases presented in the medical literature, death occurred in 54 patients by 11 months of age. Of the 16 survivors, all are plagued with complications of epidermal disease ranging from 30 days to 16 years.[100] Pyloric atresia associated with junctional epidermolysis bullosa results from mutations in the *PLEC1* gene. The lethal form is associated with intracellular degradation of beta-4 integrin.

### Pyloric Duplication

Duplications of the stomach and pylorus are uncommon, representing less than 3% of alimentary tract duplications. Pyloric duplications are slightly more frequent in girls. They share a common wall with the stomach or pylorus and rarely communicate. Infants present with nonbilious vomiting and weight loss in the first 2 to 3 weeks of life.[111,112] The condition may be mistaken for hypertrophic pyloric stenosis. Occasionally, pyloric duplications present with a palpable mass, further confusing this occurrence with hypertrophic pyloric stenosis. The diagnosis is suggested by ultrasound studies that show a cystic extraluminal mass compressing the gastric outlet.[113] The condition may not be recognized until the time of operation. The procedure of choice is extramucosal excision. Occasionally cyst-gastrostomy may be necessary. Postoperative survival is expected and complications are few. Duplication cysts affecting the stomach usually present later in life. Duplications are covered extensively in Chapter 90.

## VOLVULUS OF THE STOMACH

### History

Gastric volvulus was first reported by Berti in 1886. In 1904 Borchardt described the classic triad of acute or localized distention of the epigastrium associated with pain, inability to pass a nasogastric tube, and nonproductive attempts at vomiting. Gastric volvulus in children is a rare condition; a recent literature review described 581 cases in infants and children.[114] Acute volvulus occurred in 252 children with more than 50% younger than the age of 1 year. Chronic volvulus occurred in 329 children and more than 70% were younger than a year of age. Bautista-Casasnovas[115] and colleagues reported their 25-year experience with children, confirming the early age of diagnosis of acute volvulus in infants.

### Embryology and Classification

Gastric volvulus is rare because the stomach is held securely in place by the gastrophrenic ligaments, esophageal hiatus, retroperitoneal fixation of the duodenum, short gastric vessels, and gastrocolic ligament. Volvulus may occur primarily when these attachments are lax or absent or secondarily when

pathologically associated with eventration of the diaphragm, diaphragmatic hernia, congenital bands, wandering spleen,[116] elongated gastric attachments, or absence of the gastrocolic ligament.[117] They are detailed in Table 79-6. Details of acute volvulus come from case reports. Cribbs[114,118–121] and the largest single-institutional[115] study identify neonates and infants younger than 12 months of age as the most common age group of children with acute volvulus of the stomach. The principal symptoms include cyanosis (11%), acute respiratory distress (10%), abdominal pain (34%), nonbilious emesis (75%), and epigastric distention (47%). In contrast to the acute presentation, 75% of chronic volvulus was of primary etiology. The vast majority of chronic cases are organoaxial (85%). Nonbilious emesis remains the most common symptom. Feeding problems or growth failure (30%) was seen more prominently in chronic cases.

Gastric volvulus is classified according to the plane of rotation (Fig. 79-5). In organoaxial volvulus, the stomach rotates on its long axis; the greater curvature passes anteriorly but may be displaced posteriorly. In the less common mesenteroaxial volvulus, rotation is on an axis from greater to lesser curvature (the pylorus or cardia commonly rotates anteriorly). The opposite rotation may also occur. The torsion may be total, involving the entire stomach, or partial, limited to the pyloric end. The rotating section usually passes anteriorly.

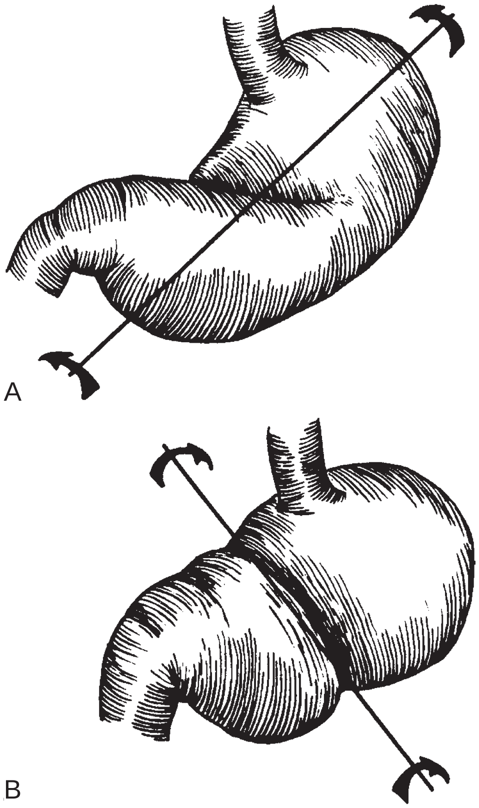

FIGURE 79-5 Gastric volvulus. **A,** Organoaxial. The greater curvature usually passes forward, as depicted, but may rotate posteriorly. **B,** Mesenteroaxial. The pylorus or the cardia commonly rotates anteriorly, but the opposite may occur. (With permission from Cole BC, Dickinson SJ: Acute volvulus of the stomach in infants and children. Surgery 1971;70:707.)

## Radiologic Features

Radiographic examination confirms the diagnosis of gastric volvulus and often identifies underlying associated congenital anomalies or defects. The radiographic features of acute volvulus of the stomach include (1) localized massive distention of the upper abdomen; (2) high greater curvature of the stomach (87%); (3) greater curvature crossing the stomach (83%); (4) fixation of the loop regardless of the position of the patient; (5) delimitation of ingested barium at the tapered extremity of the esophagus, the so-called "bird's beak"; (6) possible evidence of a hiatal sacculation or other diaphragmatic herniation; and (7) deviation of the position of the spleen.

**TABLE 79-6**
**Anatomic Etiology of Gastric Volvulus**

- I. Absence, Failure of Attachment, or Elongation of Gastric Fixation
  - A. Gastrosplenic
  - B. Gastrocolic

  - D. Malrotation and midgut volvulus
  - E. Dislocation or hypoplasia of the left lobe of the liver

## Treatment

Gastric volvulus may present acutely and require acute surgical intervention to prevent or limit vascular compromise. Simple decompression with a nasogastric tube may temporize the situation but is inadequate as a long-term treatment. At operation, gastric decompression facilitates reduction. Once normal anatomic relationships have been restored, the site is carefully inspected to identify possible areas of perforation or gangrene. The remainder of the procedure is focused on preventing a recurrence of volvulus and correcting any diaphragmatic defects (hiatal and Bochdalek hernias). In infants and children, gastrostomy or anterior gastropexy is then performed. Several cases of successful outcomes using each of these techniques by open or endoscopic repair have been reported.[114,115,118,121] Follow-up of these patients ranges from 1 to 10 years without recurrence. Recurrence despite fixation has also been reported.[122] Outside of North America nonoperative treatment strategies are emerging in the management of chronic volvulus. In Africa, Asia, and Europe, 36% to 60% of infants and children are treated successfully

nonoperatively.[114] The management strategy includes positioning the infant on the right side or prone with the head elevated above the torso after feeding. This allowed for the dependent portion of the stomach to remain inferior to the lesser curvature. Such an approach must be tempered by a rapid surgical response to avoid life-threatening complications proven correctable with timely operation.

## GASTRIC PERFORATION IN THE NEWBORN

### History

In 1943 a neonatal gastrointestinal perforation was closed successfully. In 1964 Lloyd and colleagues[123] reported 61 cases of spontaneous perforation of the gastrointestinal tract in the newborn and called attention to the fact that all of these lesions, regardless of location, were the result of ischemic necrosis. The undesirable side effect of an asphyxial defense mechanism, known as selective circulatory ischemia, activated by perinatal stress, hypoxia, or shock, was implicated as the principal factor causing these lesions.[124–126] In 1969 Lloyd[127] reviewed the world literature and found 315 cases of neonatal gastrointestinal perforation qualifying as ischemic lesions. Since then, multiple predisposing factors and causes have been suggested.[128–130]

### Embryology and Pathology

Although ischemia may be the common denominator, a multifactorial cause including congenital muscular defect of the gastric wall,[131] bacterial colonization of the gut with pathogenic organisms,[132] immaturity of the immune system,[133] and endothelial injury related to the use of indomethacin is likely.[130] Gregory[134] and colleagues described the association of perinatal stress in 39 of 42 infants with ischemic necrosis of the gut. The reader is referred to the report of Elsner[125] for details concerning the "diving reflex" theory in mammals and in humans. Asphyxia at birth in infants with low Apgar scores is particularly likely to lead to gastrointestinal perforation. Redistribution of blood flow during hypoxia, hypovolemia, or other stress states[126] with shunting away from mesenteric vascular beds is thought to result in microvascular injury[135,136] and subsequent loss of mucosal integrity.[137] The periods of stress and potential mesenteric ischemia may be temporally remote from the recognition of perforation (intestinal perforation is covered extensively in Chapter 94). Isolated gastric perforation usually occurs along the greater curvature between the smooth muscle layers and, as previously noted, iatrogenic injury due to overzealous resuscitation with an Ambu bag, inadvertent esophageal intubation, or trauma from the passage of an orogastric tube.[133]

### Signs, Symptoms, and Diagnosis

The first indication of spontaneous gastric perforation often occurs at 3 to 5 days of life. Abdominal distention is frequently abrupt and rapidly progressive. Signs of hypovolemia and decreased perfusion are usually present, manifested by tachycardia and lethargy. Respiratory difficulty from massive pneumoperitoneum may be the first sign. Infants born of pregnancies complicated by abruptio placentae, placenta previa, and amnionitis (severe fetal distress) and infants delivered by emergency cesarean section are at increased risk and should be carefully observed.[138] Most infants with gastric perforation have evidence of free air on abdominal radiographs (Fig. 79-6). Further evaluation includes measurement of leukocyte and platelet counts and arterial pH and blood gas analysis.

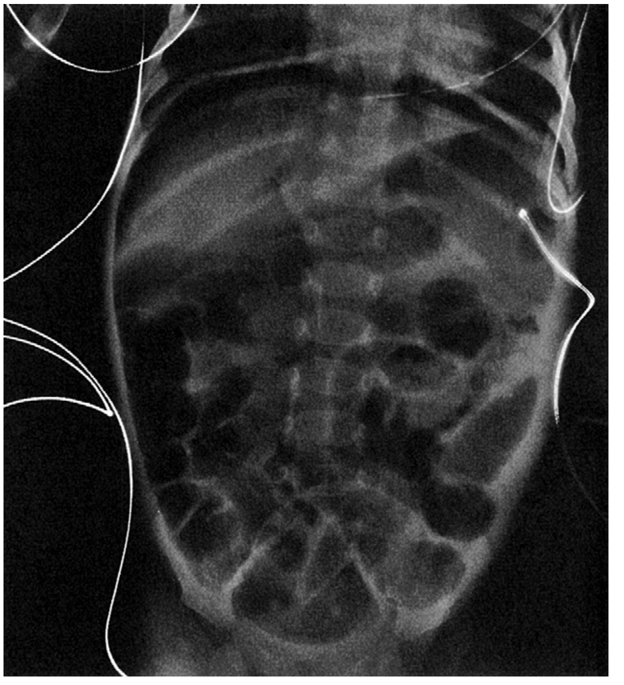

**FIGURE 79-6** Abdominal radiograph in an infant with spontaneous gastric perforation shows free air in the peritoneal cavity.

### Treatment

The condition of an infant with gastric perforation can deteriorate rapidly; therefore early recognition and prompt treatment are essential. This includes rapid fluid resuscitation, blood transfusion, correction of acidosis, administration of antibiotics, orogastric suction, maintenance of body temperature, and performance of only essential diagnostic studies.[139] These infants usually require immediate intubation and ventilatory support. Paracentesis to evacuate the pneumoperitoneum with a blunt needle or plastic catheter may relieve life-threatening respiratory distress due to diaphragmatic elevation during the resuscitation period. Emergency laparotomy through a transverse, supraumbilical abdominal incision is used. The peritoneal contents should be cultured for aerobic and anaerobic bacterial organisms and fungi. Clear gastric contents or slightly bile-tinged fluid often suggests a perforation of the stomach or duodenum. Perforation sites may be occult; after careful examination of the stomach, esophageal hiatus to the lesser omental space may be necessary. Most spontaneous gastric perforations occur along the greater curvature of the stomach distal to the esophagus. Perforation due to a duodenal ulcer in infancy occurs on the anterior wall of the duodenum or near the pyloroduodenal junction, whereas gastric ulcers may perforate along the lesser curvature near the antral-fundic junction. Perforations of the stomach can usually be debrided and closed primarily. If the greater curvature of the stomach is more extensively involved with necrosis, it can be resected. Occasionally when there is extensive necrosis of the gastric antrum, a partial gastrectomy and gastroenterostomy may be required. A Billroth I procedure (gastroduodenostomy) is preferred.

Infants with isolated gastric perforation generally receive antibiotics until the white blood cell count and differential return to normal and there is evidence of bowel function and gastric returns through the orogastric tube are clear and of low volume. Many clinicians obtain a contrast swallow before initiating feedings.

### Outcomes

Current survival for isolated gastric perforation is 75% to 80%: Those infants who succumb often have multiple-organ dysfunction as a result of their initial insult associated with peritonitis, sepsis, and immature immunologic function. Infants with gastric necrosis associated with extensive necrotizing enterocolitis have a high morbidity and mortality.[133,139]

## CONGENITAL MICROGASTRIA

### History

Congenital microgastria is a rare condition first reported in the 1800s.[140] To date, 43 cases have been reported. The malformation has been frequently associated with other congenital anomalies including asplenia, malrotation of the intestines, situs inversus, megaesophagus,[141,142] and upper limb anomalies such as radial, ulnar, and thenar hypoplasia (microgastria-limb reduction association).[140] Increasing regionalization of the care of infants and children in pediatric hospitals has resulted in increased recognition of this condition.[143] Reported therapy for microgastria has ranged from conservative dietary manipulation in patients minimally affected to surgical augmentation of the small stomach.

### Embryology and Pathology

This is a rare congenital anomaly of the caudal part of the embryologic foregut, characterized by a small, tubular stomach, megaesophagus, and incomplete gastric rotation. The esophageal, gastric, small intestinal, and large intestinal mucosae are normal. Many associated conditions of the gastrointestinal tract such as nonrotation of the midgut with duodenal bands and asplenia exist. Situs inversus and asplenia have been reported.[144] Skeletal anomalies including micrognathia, radial and ulnar hypoplasia, vertebral anomalies, oligodactyly, and hypoplastic nails are common. Anophthalmia has also been reported.[145]

Because of the associated anomalies in organogenesis, arrest in development is thought to occur between the fourth and eighth weeks of fetal life. Absence of the gallbladder has also been reported.[146] Massive and persistent reflux into the biliary tract may occur. Patients may have congenital heart disease characterized by a single atrium, a single ventricle, and total anomalous pulmonary venous return into the portal vein.

### Clinical Presentation and Pathophysiology

With the more frequent use of prenatal ultrasound, polyhydramnios and a small stomach may be noted late in a pregnancy. Most patients are beyond the neonatal period at the time of diagnosis, frequently have a dilated esophagus with an ill-defined gastroesophageal junction, and are therefore prone to gastroesophageal reflux. The most frequent presenting signs are vomiting, aspiration and pneumonia, and failure to thrive. Malnutrition and developmental delay may result. Diarrhea is common. An incompetent lower esophageal sphincter has been demonstrated in these cases. When coupled with reduced gastric capacity and a dilated esophagus, vomiting, esophageal erosion, and aspiration are common. Although not well studied, it is postulated that malnutrition and diarrhea may result from a small gastric capacity with rapid emptying of acid content. Bacterial overgrowth and a blind looplike syndrome have been suggested to explain the diarrhea and malnutrition, but results of the Shilling test have been normal.

### Diagnosis

Contrast examination of the upper gastrointestinal tract with barium, usually the first study obtained, demonstrates the features just mentioned. Imaging techniques augment the radiographs.[147] Endoscopy has proved difficult and has yielded confusing results. Appropriate cardiac studies are dictated by the specific findings, and asplenia may be demonstrated by examination of the peripheral erythrocytes for Howell-Jolly bodies and by nuclear imaging. If gastroesophageal reflux disease is a clinical feature, manometry and esophageal pH studies may be appropriate. In patients with diarrhea, malnutrition, or growth retardation, intestinal absorption studies may elucidate the cause.

### Treatment

Medical treatment should be attempted initially. Continuous or nighttime orogastric feedings may allow the patient to grow and the stomach to enlarge so that the patient can then tolerate normal feedings. If gastroesophageal reflux disease develops, prokinetic agents and acid-reducing therapy may improve gastric emptying. Complications of gastroesophageal reflux may require the use of a nasojejunal feeding tube or surgically placed jejunostomy tube. The jejunal feedings supplement the smaller oral feedings, allowing the stomach to enlarge.[148] If the infant's stomach fails to enlarge, several authors have recommended augmenting the stomach capacity by construction of a double-row jejunal reservoir,[149,150] and outcomes from early follow-up are encouraging.

CHAPTER 80

# Bariatric Surgery in Adolescents

Sean Barnett, Victor F. Garcia, and Thomas H. Inge

Obesity is a progressive, chronic, and often fatal disease, refractory to most currently available medical interventions. The definition of overweight and obesity in children is a body mass index (BMI) greater than 85th and 95th percentile (P), respectively, for age and gender. In 2007-2008, 32% of children (2 to 19 years old) were at or above the 85th P, 17% were at or above the 95th P, and 12% were at or above the 97th P of the BMI-for-age. Trend analyses indicated that there was no significant increase in overweight or obesity prevalence between 1999-2000 and 2007-2008. However, prevalence of those at the highest (97th P) levels of obesity among 6- through 19-year-old boys and among non-Hispanic white boys of the same age was increasing. In 2007 the estimated prevalence of extreme pediatric obesity (BMI $>$ 99th P) was 4%.[1] Obesity-related decreases in life expectancy predominantly affect age groups younger than previously thought, especially in young black males.[2]

Childhood and adolescent obesity are independent risk factors for adult morbidity and premature mortality.[3–4] In the extreme form, with BMI for age in the greater than 99th P, obesity is refractory to even the most intensive conventional approaches to weight loss.[5–6] Bariatric surgery is currently the most effective means to achieve durable weight loss and amelioration, if not resolution, of most obesity-related comorbidities in severely obese individuals. It also decreases the long-term mortality of morbidly obese patients.[7–8] The morbidity of surgery varies between 5% and 11%. The mortality was recently estimated by the LABS study group to be 0.3 for gastric bypass procedures[9]; most studies demonstrate even lower mortality risk for adjustable gastric banding (AGB). Experienced centers have shown that weight loss following bariatric surgery in adults can be sustained.[10] Among adults, the nutritional consequences of the most common bariatric surgical procedures are well defined and effectively managed with vitamin and mineral supplementation. Among adolescents, however, it is unknown whether the outcome will be the same as in adults or whether there will be unacceptably high degrees of recidivism and long-term nutritional sequelae related to poor compliance or reduced micronutrient absorption.[11–13] Nonetheless, for the extremely obese adolescent there are currently no effective nonsurgical treatments.[14] As the number of severely obese children increases and the serious health consequences escalate, surgical weight loss is becoming the only effective means to treat severely obese adolescents. On the basis of the best available evidence, this chapter proffers a conceptual framework and clinical guidelines for adolescent bariatric surgery. The approach borrows heavily from the most successful adult bariatric surgical programs and best practice guidelines.

The unique physiologic, cognitive, developmental, and psychosocial needs of the adolescent are best managed with a family-centered, interdisciplinary approach, incorporating behavior modification techniques that have been successful in other chronic health care models. Given the technical difficulty of bariatric surgery, the complexity of the postoperative management of the patient undergoing bariatric surgery, and the extant uncertainty about its long-term outcomes in adolescents, regionalization of care with a focus on prospective clinical data collection will be essential to achieving outcomes commensurate with the best adult series. Further, it will accelerate our understanding of the short- and long-term consequences of bariatric surgery among adolescents.

## History of Bariatric Surgery in Adolescents

The earliest report of pediatric bariatric surgery was Randolph and Weintraub's experience with jejunal ileal bypass.[15] Their reported outcomes were similar to those in adults. More specifically, the weight loss was dramatic and sustained and the improvements in quality of life were viewed as excellent. However, the metabolic complications were significant[15] and considered unacceptable by today's standards. Greenstein[16] reported a largely favorable experience with vertically banded gastroplasty, concluding that adolescents given extensive dietary counseling can experience the same benefits as adults. The subsequent reports of bariatric surgery in pediatrics have consisted of small case series of adolescents largely undergoing open and, more recently, laparoscopic Roux-en-Y gastric bypass surgery (RYGB) or laparoscopic AGB. As summarized in a recent systematic review, the reported outcomes have been good to excellent, with few complications and no procedure-related mortality.[17] As with pediatric laparoscopic cholecystectomy, minimally invasive repair of pectus excavatum, and laparoscopic antireflux procedures, bariatric

operations among adolescents are only now beginning to be studied in a prospective and controlled fashion.[18] None of the adolescents who have undergone AGB have been followed for more than 4 years. The only randomized controlled trial examined AGB compared with lifestyle intervention in a cohort of 50 Australian adolescents. In the gastric banding group ($n = 25$, with 24 completing the 2-year study), a weight loss of 34.6 kg representing a BMI reduction of 28% (excess weight loss of 78.8%) was seen, compared with a 3-kg loss representing a BMI reduction of 3% (excess weight loss of 13.2%) in the lifestyle group. Health and quality of life improvements were also documented.[19] However, eight operations (33%) were required in seven patients for revisional procedures either for proximal pouch dilatation or tubing injury during follow-up. This high rate of surgical complications is of considerable concern and is based primarily on symmetric pouch dilation, a problem infrequently seen in adults. It is likely that maladaptive eating behaviors rather than surgical technique contributed to this problem. Thus programs that focus on banding as a weight loss intervention for adolescents must consider how to best educate patients and families about postoperative dietary behaviors to address preventable complications.

The report with the largest and longest follow-up is that of Sugerman and colleagues.[13] These authors' outcomes reported 33 adolescents (mean preoperative BMI = 52 kg/m$^2$) who underwent various bariatric procedures, primarily gastric bypass. This group had an excess weight loss of 63% (mean BMI = 33 kg/m$^2$) at 5 years and 56% (mean BMI = 34 kg/m$^2$) at 10 years after operation. Only six of nine patients who were 14 years following operation could be found. These six had maintained 33% of their excess weight loss (mean BMI = 38); 15% of the cohort had regained most or all of their overweight, suggesting that recidivism may be just as likely in adolescents as in adults. These data beg several questions—whether adolescents require alternate selection criteria or different postoperative management strategies than adults and whether the long-term nutritional and metabolic outcomes of adolescents will be better or worse than similarly obese adolescents who have undergone bariatric surgery in youth.

In 2001 the first children's hospital–based bariatric surgery program was established at Cincinnati Children's Hospital Medical Center.[18] The bariatric surgery program was integrated into an existing behaviorally based weight management program for children and adolescents. This comprehensive program offers bariatric services to adolescents with intractable clinically severe obesity. Candidates for bariatric surgery are evaluated by pediatric bariatric surgeons, a pediatric psychologist, and other pediatric medical specialists with expertise in pediatric obesity; an advanced practice nurse; dieticians; and an exercise physiologist. Since that time, there have been few dedicated pediatric centers for the treatment of morbid obesity established. The vast majority of these patients are still treated in adult facilities.

Our most recently published data analyzed 61 adolescents with a mean preoperative BMI of 60.2 kg/m$^2$ who underwent laparoscopic Roux-en-Y gastric bypass from August 2002 to January 2007.[20] The mean weight loss for this group was 37.4% one year postoperatively with statistically significant improvements in systolic and diastolic blood pressure, total cholesterol levels, triglyceride levels, and fasting insulin levels.[20] Of the nine patients who were on medications for diabetes preoperatively, only one remained on medication postoperatively.[20]

# Science of Obesity

Obesity research is one of most exciting areas of scientific investigation at the nexus of physiology, genetics, neurobiology, endocrinology, molecular biology, and gastrointestinal surgery. Genes regulate body weight by balancing caloric intake and energy expenditure. Familial aggregation and twin studies have demonstrated that genes contribute to the development of obesity with a heritability index of 0.7 to 0.8, a degree of heritability equivalent to that of height.[21–22] Only about 5% of childhood morbid obesity is a result of a single gene defect, usually in an isoform of the melanocortin receptor, the receptor for melanocyte stimulating hormone.[23] In the remainder of the population, obesity is the result of many genes interacting with environmental factors. Evidence indicates that genes and metabolic processes that predispose to obesity offered our ancestors a survival advantage in times when food was scarce.[24–25] This may explain the highly variable frequency of obesity in different populations (African Americans, Native Americans, and Hispanics) that once lived under adverse conditions.

# Risk Factors for Adolescent Obesity

The risk of obesity accumulates with age and is influenced by genetic, biologic, psychologic, socio-cultural, and environmental factors acting throughout our life span. Recent insights into the fetal, neonatal, and developmental origins of obesity[26] have implications for clinical evaluation of the adolescent candidate for bariatric surgery. There are critical phases in the development of adolescent obesity within the period between preconception and adolescence.[27–31] Epidemiologic evidence has linked birth weight and later body mass index[32] in childhood[33] and adulthood.[34] Lower birth weight elevates the risk for central obesity[33,35] and insulin resistance.[35] Childhood obesity risks are higher for offspring of mothers with diabetes mellitus.[36] Postnatally, longer duration of breastfeeding[37–38] and later onset of adiposity rebound[39] reduce the risk of adolescent overweight. Of all the aforementioned risk factors, low birth weight and high BMI of the adolescent confer the highest risk of chronic obesity.

Obesity in family members is an additional risk factor for adolescent obesity. The odds ratio for persistence of childhood obesity into adulthood is about 3 if one or 10 if two parents are obese.[40] This effect is most pronounced in children younger than 10 years. Puberty is also a critical period for the development of obesity.[41] Earlier menarche is seen in obese children. A BMI greater than the 85th P is associated with a twofold increase in rate of early menarche.[42–43] The risk of obesity persisting into adulthood is far higher among obese adolescents than among overweight younger children.[1,6] Finally, there is a preexisting racial-ethnic disparity in the risk of obesity.[44] Lower socioeconomic groups may be especially vulnerable because of poor diet and limited opportunity for physical activity.[45]

## HEALTH CONSEQUENCES OF ADOLESCENT OBESITY

Adolescent obesity has important health consequences as outlined in Table 80-1. Associated with the rise in the prevalence and severity of pediatric obesity in the United States, there has

**TABLE 80-1**
**Health Consequences of Pediatric Obesity**

| Complications of Adolescent Obesity | |
|---|---|
| Psychosocial | Poor self-esteem[85–87,164] |
| Depression[86–88,165–166] | |
| Eating disorders[167–168] | |
| Attention deficit hyperactivity disorder[169] | |
| Neurologic | Pseudotumor cerebri[170–172] |
| Pulmonary | Sleep apnea[77,173–175] |
| Asthma and exercise intolerance[176–177] | |
| Cardiovascular | Dyslipidemia[61,114,178–179] |
| Hypertension[92,180–182] | |
| Coagulopathy, chronic inflammation[183] | |
| Endothelial dysfunction[184–187] | |
| Gastrointestinal | Gallstones |
| Steatohepatitis[67,72,188] | |
| Gastroesophageal reflux disease[189] | |
| Renal | Glomerulosclerosis[190–191] |
| Endocrine | Type 2 diabetes mellitus,[65,91,192–195] |
| Insulin resistance[33,65,92–93,196–198] | |
| Metabolic syndrome[53,55,93,199–200] | |
| Precocious puberty[50,201] | |
| Polycystic ovary syndrome[95,202] | |
| Musculoskeletal | Slipped capital femoral epiphysis, Blount disease[203] |
| Forearm fractures, flat feet | |

been an emergence of new or newly identifiable health conditions in children[46] with onset at a younger age[47–48] and an increased risk for adult morbidity and mortality.[47] Childhood obesity also has adverse social and economic consequences.[49–50] The persistence of obesity,[51] with approximately 70% to 80% of overweight children becoming obese adults,[1,46] is of particular concern for certain complications. The clustering of hypertension, dyslipidemia, chronic inflammation, hypercoagulability, endothelial dysfunction, and hyperinsulinemia, known as *insulin resistance syndrome* or *metabolic syndrome*,[52] has been identified in children as young as 5 years of age.[53] The Bogalusa Heart Study noted the correlation of cardiovascular disease risk factors with asymptomatic coronary atherosclerosis. The more severely obese individuals had more advanced lesions.[54] The metabolic syndrome is far more common among children and adolescents than previously reported, and its prevalence increases directly with the degree of obesity.[55] Each element of the syndrome worsens with increasing obesity, independent of age, gender, and pubertal status.

A prediabetic state, consisting of glucose intolerance and insulin resistance, is highly prevalent among severely obese children, even before clinical diabetes has been diagnosed.[56] Even though formerly considered an "adult-onset" disease, type 2 diabetes mellitus now accounts for nearly half of all new pediatric diagnoses of diabetes[57–58] and is thought to be largely the result of the pediatric obesity epidemic. Of particular concern are data from the Centers for Disease Control suggesting that 33% of all Americans born in the year 2001 will develop diabetes.[59] For blacks and Hispanics this number rises to nearly 50%.[59] The data suggest that the onset of the beta cell dysfunction associated with diabetes occurs well before the development of hyperglycemia and may commence many years before diagnosis of the disease.[60–63] Other work clearly suggests that type 2 diabetes developing in childhood or early adulthood progresses much more rapidly than in adults[64] and may be more virulent than diabetes that develops later in adulthood. Bariatric surgery in adolescents, particularly gastric bypass, has been shown to completely resolve type 2 diabetes following significant weight loss.[65] Given these findings and the progressive nature of the disease, established type 2 diabetes mellitus is a strong indication for weight loss surgery in adolescents.[66]

Nonalcoholic steatohepatitis is recognized as a common cause of chronic liver disease in children.[67] This condition is frequently associated with obesity, with 25% of overweight children in one report having abnormally elevated liver function tests.[68] It has been suggested that obesity-related pediatric nonalcoholic steatohepatitis[69] may become a major cause of hepatic failure and a leading indication for liver transplantation in decades to come.[67,70–72] Bariatric surgery has been shown to decrease not only the amount of steatosis[73] but also the associated inflammatory markers.[74] Currently weight loss is the only treatment for severe steatosis and is considered a strong indication for bariatric surgery.[66]

Exercise intolerance, sleep-disordered breathing, and asthma are frequent pulmonary complications of adolescent obesity.[75–77] Asthma and exercise intolerance can also limit physical activity and contribute to further increases in weight.[78] Obstructive sleep apnea (OSA), the most severe manifestation of sleep-disordered breathing, can significantly impair the obese adolescent's health-related quality of life,[77,79] result in abnormal left ventricular geometry,[80] and put him or her at increased risk for hyperactivity and learning difficulties.[81] Although up to 20% of adolescents with obesity have moderate to severe OSA, those presenting for bariatric surgery have a prevalence of greater than 50%.[82] Within our institution using polysomnography, OSA significantly improves or resolves completely in adolescents undergoing gastric bypass.[77] Therefore moderate to severe OSA is a strong indication for early bariatric surgery in adolescents.[66]

Pseudotumor cerebri is a process for which the major symptoms include headache, dizziness, nausea, tinnitus, and blurry vision due to increased intracranial pressure caused by morbid obesity. The treatment of choice has long been bariatric surgery,[83] and these symptoms can improve over the course of months following surgery in adolescents.[84]

Arguably the most prevalent and debilitating consequences of adolescent obesity are psychosocial.[85–88] The psychologic stress of social stigmatization imposed on obese children may be as damaging as the medical morbidities.[89] Many obese adolescents have low self-esteem associated with sadness and high-risk behaviors.[85] In a recent inventory of health-related quality of life (QOL) indices, obese adolescents demonstrated significantly lower QOL scores than lean children and scores that were comparable with pediatric cancer patients.[79] Overweight has also been associated with lower levels of socioeconomic attainment. Women who were overweight adolescents

were less likely to marry and had completed fewer years of school.[90] A recent longitudinal prospective study demonstrated a significant improvement in depressive symptoms and quality of life over the first postoperative year following bariatric surgery in adolescents.[87]

The health consequences of childhood obesity are broader in scope, greater in prevalence, and more severe at a given time point in disease progression than previously thought.[91–96] BMI thresholds for obesity do not account for the ethnic disparity of disease burden nor the accelerated progression of disease in certain populations of obese adolescents.[94,97–98] The progressively younger age at which adult diseases are recognized in children;[53,99] the increasing prevalence of impaired glucose tolerance, insulin resistance, metabolic syndrome, and type 2 diabetes mellitus in younger children;[53,56,100–102] and the suggestion that childhood-onset type 2 diabetes mellitus may be more virulent than adult-onset diabetes validates concerns about the clinical relevance of the current definitions of obesity in children and about disease burden over time affecting the ability to control these comorbidities.[103–105] Longitudinal studies performed at our institution assessing the characteristics of 61 adolescents undergoing gastric bypass demonstrated a mean baseline BMI of 60.2 kg/m$^2$. At 1-year follow-up, the cohort had experienced a BMI reduction of 37%, but only 17% achieved a nonobese BMI of less than 30 kg/m$^2$. Of note, those adolescents with a baseline BMI above 65 kg/m$^2$ reached a nadir BMI still in the morbidly obese range (47 kg/m$^2$) at 1 year, suggesting that "late" referral at the highest BMI values all but eliminates the chances of attaining a nonmorbidly obese BMI after the most intensive of treatments.[20] One could argue that earlier referral, with BMI values in the 35 to 50 range should be the goal to optimize treatment outcomes in adolescents.

# Adolescent Cognitive Development: Concepts and Principles Relevant to Adolescent Bariatric Surgery

Cognitive development refers to the development of the ability to think and reason. Around 6 to 12 years of age, children develop the ability to think concretely. Adolescence marks the beginning of more complex thinking. At any given age, adolescents are at varying stages of cognitive and psychosocial development, which more closely correlates with pubertal status than with chronologic age.[106] Additionally, there are gender differences in the attainment of formal operations and identity formation enabling new levels of intellectual functioning, abstract thinking, and cognitive skills, which are critical to providing assent to, and complying with, medical recommendations. Examples of formal operations include thinking about possibilities, hypothetical-deductive reasoning, anticipating events that have not yet happened, thinking about conventional limits, and thinking about thought. Before the attainment of formal operations, the adolescent functions and reasons in concrete operations. At this stage of development, adolescent problem solving is confined to identifiable objects that are either directly perceived or imagined and mental operations are only possible when they are applied to information from the direct experience. In acquiring formal operations, the adolescent has the ability to reason, think abstractly and logically, form hypotheses, and consider various consequences of behavior. The adolescent who has acquired this ability is better able to consider the consequences of taking or not taking nutritional supplements or of following and adhering to the prescribed protein-sparing diet. Adolescence is also generally regarded as a period of social experimentation, limit-testing, risk taking, and egocentrism—all of which predictably add to the challenge of adolescent compliance with desired health behaviors.

The postoperative management of the adolescent bariatric patient requires an assessment of the level of cognitive development and an understanding of the risk-taking propensity of adolescents.[107] It is also important to note that the level of cognitive sophistication differs from adolescent to adolescent and may be independent of chronologic age.[108] The attainment of new mental abilities does not carry with it immediate proficiency in their use, nor does education alone enhance cognitive maturity. Enhanced compliance with a vigorous nutritional and lifestyle regimen requires effective education that applies cognitive development theory and also input from peers and family that helps the adolescent attain a more realistic appreciation of their own vulnerability.

## COMPLIANCE

Long-term therapeutic success with bariatric surgery is dependent on compliance with the prescribed dietary, lifestyle, and nutritional supplement regimen. Adolescence is generally viewed as a time of increased experimentation with a variety of health-related behaviors such as diet and exercise. Expertise with enhancing adherence to preventive health practices and compliance with treatment regimens is critical. Historically, compliance with health recommendations in the adolescent population is disappointingly low, estimated at 40% to 50% for adolescents with chronic medical conditions such as cystic fibrosis, diabetes, and asthma.[109] Rand and McGregor found that after bariatric surgery, less than 20% of adolescents demonstrated perfect compliance with vitamin and mineral supplementation regimens.[11] For adolescents with chronic medical conditions, adherence with rigorous medical and dietary regimens is substantially improved with use of behavioral therapy.[110–115] Unfortunately, there is no clear profile of the psychosocial factors consistently associated with the compliant patient, thus precluding a "cookbook" solution for the prevention and management of poor compliance in the adolescent who has undergone bariatric surgery. To enhance adolescent compliance with a lifelong postoperative dietary and nutritional supplement regimen, an adolescent bariatric surgery program should employ professionals capable of assessing levels of cognitive development, personality characteristics such as self-esteem and locus of control, as well as family variables such as cohesiveness and level of effective communication.[108] Prior knowledge of these factors may enhance the ability of the bariatric team and the primary care physician to offer useful anticipatory guidance postoperatively. For example, it can be useful to know when and with whom most nonnutritive calories are consumed so that the team is aware of the periods/people that may increase the adolescent's vulnerability to maladaptive postoperative eating habits. Adolescent compliance may be enhanced by

**TABLE 80-2**
**Strategies to Improve Postoperative Compliance**

- Dietary regimen rehearsal preoperatively enables problem identification and solving before the surgical intervention.
- Use of actual measuring cups, a food scale, and photographs of specific food items that are recommended enhances the adolescent's ability to follow through with plans.
- Provide the adolescent with a diet diary and exercise diary with form pages for him or her to fill out, and practice this preoperatively.
- Provide a list of acceptable food items for every phase of the postoperative recovery (first week, second through fourth week, second through third month, etc.) including the caloric density and protein, carbohydrate, and fat content of the items to encourage label reading.
- Provide a detailed listing of micronutritional supplements needed postoperatively that includes the reason why the supplement is necessary, as well as the potential consequences of not taking it.

(1) visual aids, (2) focus on immediate benefit from treatment, (3) participation in self-management, (4) self-monitoring, and (5) self-reinforcement.[116] Adolescent self-management and related strategies encourage independence from the family, an important developmental task of adolescence. With the alterations in eating patterns that are required after bariatric surgery, repetitive reinforcement is necessary to facilitate the formation of lifelong health-promoting habits. Patients and their families may require counseling and close follow-up to promote their physical and emotional well-being.

The adolescent bariatric surgery program should build on the best practices of other adolescent disease management programs[111,117–118] and thus be based on the premise that sustained weight control for the adolescent requires structured family involvement and continued support. Specific strategies to increase adolescent compliance include education, treatment regimen modification within the social-cultural context of the patient, and enlisting family and peer support[108] (Table 80-2). Some adolescents respond to formalized modes of reinforcement such as contracting.

# Bariatric Surgery

Bariatric surgery should be viewed as a surgical discipline and not just a technical procedure. Bariatric patients are a distinct and often problematic cohort with serious and often multiple concurrent comorbidities. They have unique postoperative needs and in the event of postoperative complications conventional diagnostic approaches often do not work. They require close long-term follow-up making the transition of the adolescent who undergoes bariatric surgery to adult care an essential component of the clinical care plan.

The majority of bariatric surgery is now performed laparoscopically. Minimally invasive bariatric surgery has significant advantages over open surgery but is one of the most technically difficult operations to perform.[119] The learning curve is steep.[8] Schauer suggests the curve levels off at 100 operations.[120] Laparoscopic skills employed in foregut surgery are not directly transferable to bariatric surgery, and proficiency in minimally invasive surgery may not confer the same level of proficiency in minimally invasive bariatric surgery. Several societies and associations have developed credentialing criteria and guidelines for bariatric surgery, and most recently the American Society for Bariatric Surgery has introduced criteria for Centers of Excellence in Bariatric Surgery. Pediatric surgeons pursuing bariatric surgery should at a minimum take a course in bariatric surgery and have their early experience proctored by an experienced laparoscopic bariatric surgeon. Additionally, they must be cognizant of and take into account, during patient selection, patient characteristics that are recognized as risk factors for perioperative complications and mortality.[121–125] Recent data demonstrate the mean BMI of patients undergoing gastric bypass at our institution is 60.2 kg/m$^2$.[20] Adult studies of patients with BMI greater than 60 kg/m$^2$, coined the super-super obese, have shown longer procedure times and longer hospital stay.[126] The pediatric bariatric surgeon must also be prepared for these more difficult patients early in their learning curve given current referral patterns.

# Surgical Options

There are five bariatric procedures in general use: RYGB; laparoscopic AGB; vertical banded gastroplasty; biliopancreatic diversion (BPD), with or without duodenal switch (DS); and the laparoscopic sleeve gastrectomy. Each has its unique profile of potential complications and nutritional concerns.[127] All of these operations can achieve significant weight loss with improvement or reversal of obesity comorbidities. Each can be performed laparoscopically, which may result in shorter length of hospital stay, shorter convalescence,[122,128–129] and decreased risk of wound complications. Attempts to determine what patient features might predict which particular operation might be best suited to an individual's needs are ongoing, but none have been prospectively evaluated.[130] For the most part, vertical banded gastroplasty is of historical interest and is not addressed further. Table 80-3 outlines the percent of excess weight loss, associated morbidity and mortality, and whether the operations can be revised or reversed.

**TABLE 80-3**
**Comparison of Bariatric Procedures**

| *Procedure* | *Weight Loss % EBW* | *Mortality %* | *Morbidity %* | *Can Be Reversed* | *Can Be Revised* | *Durability of Weight Loss* |
|---|---|---|---|---|---|---|
| RYGBP | 65-70 | 0.5 | 5 | Yes | Yes | ++++ |
| LAGB | 47 | 0.1 | 5 | Yes | Yes | ? |
| LSG | 33-83 | 0.39 | 0-20 | No | Yes | ? |
| BPD ± DS | 70 | 1.5 | 5 | Yes | Yes | ++++ |

BPD ± DS, biliopancreatic diversion with or without duodenal switch; EBW, excess body weight; LAGB, laparoscopic adjustable gastric band; LSG, laparoscopic sleeve gastrectomy; RYGBP, Roux-en-Y gastric bypass.

### Roux-En-Y Gastric Bypass

Gastric bypass is chiefly a restrictive procedure that modifies normal appetite signals and is modestly malabsorptive as well. It is the first of the gastric procedures and the most common bariatric procedure performed in the United States. The restrictive component is a small gastric pouch (15 to 20 mL) with a small gastric outlet (1 to 2 cm) that results in early and sustained satiety. Intestinal continuity is reestablished with a gastrointestinal bypass of varying segments of bowel—standard, 75 cm; long limb, 150 cm; and very long limb or distal gastric bypass, 250 cm.[119] The limb can be positioned retro-colic or ante-colic and the gastrojejunal anastomosis can be fashioned with an end-to-end stapler or linear stapler, or it can be hand sewn.[119] See Figure 80-1. Currently a 25-mm, end-to-end, circularly stapled gastrojejunostomy with an antecolic or retrocolic reconstruction is commonly performed.

In patients with BMI greater than 50 kg/m$^2$ the longer limb bypasses result in weight loss comparable with that of standard gastric bypass in less obese patients. Weight loss (30% to 40% of preoperative weight) occurs over 1 to 2 years, followed by a plateau and then gradual regain of 5% to 10%. Complications include dumping syndrome, gastrojejunal stomal stenosis, marginal ulcers, and internal hernias. This operation has been studied for more than 14 years and results in durable weight loss over this period of time.[10]

## Laparoscopic Adjustable Gastric Banding

The AGB procedure is the least invasive bariatric procedure and the most common procedure performed in Europe, Latin America, and Australia. The U.S. Food and Drug Administration (FDA) approved the Lap Band for use in adults in 2001 and the Realize Band in 2007. Their use and acceptance in this country is increasing. The laparoscopically placed band creates a small pouch and a small stoma high on the stomach. A port for adjustment of the band is placed in the anterior abdominal wall. Periodic adjustments of the band are critical for a successful outcome, requiring from 4 to 10 visits within the first postoperative year. Complications of the Lap Band include gastric prolapse, stomal obstruction, erosion of the band into the stomach, and problems with the access port. The pars flaccida technique has significantly reduced the risk of gastric prolapse.[131] Average weight loss after 3 years is approximately 25% to 30% of the baseline weight.[121] The LAGB is currently being used within the context of an investigational device exemption from the FDA in adolescents younger than 18 years at several U.S. centers. Results of the trial are still pending.

## Biliopancreatic Diversion/ Duodenal Switch

BPD[132] is widely used in Europe. The DS is a modification developed by Hess and colleagues.[133] Both are primarily malabsorptive operations involving the creation of a 100- to 150-mL gastric pouch. By dividing the intestine into a long enteric limb anastomosed to a long biliopancreatic limb, a common channel 50 to 150 cm from the ileocecal valve is created and toxic problems seen with jejuno-ileal bypass are avoided. The weight loss is greater with BPD/DS than with the other weight loss procedures. However, the vitamin, nutrient, and protein deficiencies are more common with these procedures than with the aforementioned bariatric procedures.[134–135] Given the well-described compliance issues among adolescents and the aforementioned protein and vitamin deficiencies, the risks of the surgery outweigh the benefits and are not recommended in adolescents.[66]

### Laparoscopic Sleeve Gastrectomy

Laparoscopic sleeve gastrectomy (LGS) has long been used as part of the larger biliopancreatic diversion/duodenal switch (BPD/DS) or as a bridge to BPD/DS in the super-obese patient. This restrictive procedure involves the longitudinal resection of the stomach along a narrow 32- to 34-Fr bougie, although some have used larger bougie sizes. The resection extends from roughly 6 cm from the pylorus to the angle of His, thus creating a long gastric tube along the lesser curve. The fundus and greater curvature of the stomach are removed. The mechanism of weight loss is not yet understood but may be the result of both restriction and alteration of appetite and satiety signals from the gut to the brain including changes in ghrelin and PYY levels.[136] Excess weight loss ranging from 33% to 83% have been reported with the longest follow-up of only 3 years.[137] Complication rates range from 0% to 24% with an overall reported mortality rate of 0.39%.[137] Long-term data have not been reported for sleeve gastrectomy at this time, and the lack of these data should be discussed with the patient before the operation. Laparoscopic sleeve gastrectomy does involve much less anatomic and physiologic derangement than that of RYGB and is an intriguing alternative in the adolescent patient population. We have currently performed 14 laparoscopic sleeve gastrectomies at our institution and in our early experience have found similar weight loss compared with our patients undergoing RYGB. Long-term data are still necessary to determine whether LGS is a durable alternative or will require conversion to RYGB at a later date in some patients.

## New Procedures

A number of new concepts/procedures are being developed for use in the bariatric arena including the intragastric balloon, vagal and gastric stimulators, greater curve gastric plication, Endosleeve bypass, and new endoscopic techniques.[138] Although none of these is currently FDA approved in the United States, they among others are certainly on the horizon for the surgical treatment of obesity.

## NUTRITIONAL AND METABOLIC CONSEQUENCES

Nutritional and metabolic consequences of bariatric surgery have been well-delineated.[139–144] There is impaired absorption of iron, folate, calcium, and vitamin $B_{12}$ after all procedures that bypass the lower stomach and proximal small intestine. Even with supplementation, iron, vitamin $B_{12}$, folate, and calcium deficiencies may occur. Given the known poor compliance among adolescents,[11] certain factors such as vitamin $B_1$, folate, and calcium warrant special consideration.

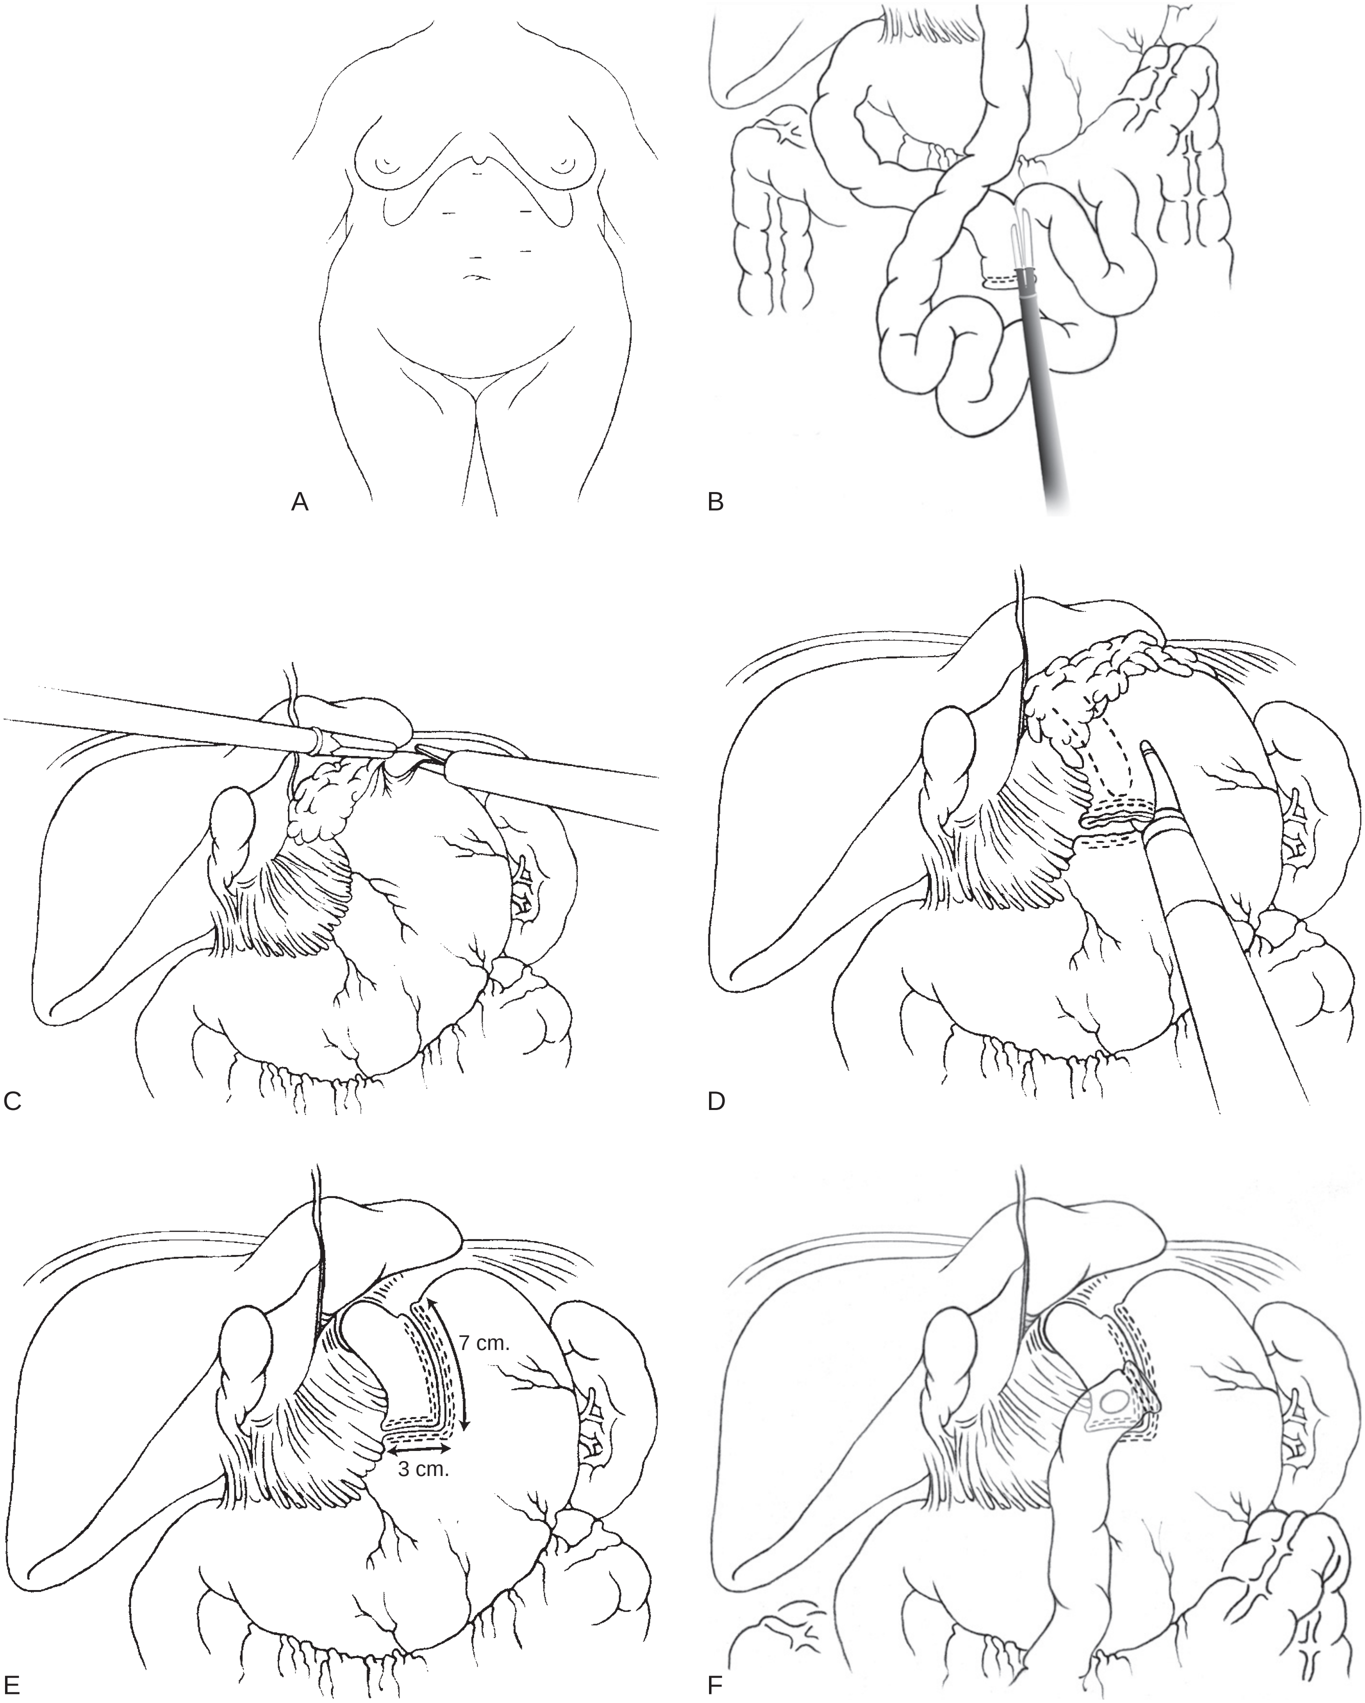

**FIGURE 80-1** Roux-en-Y gastric bypass surgery. **A,** Sites for various laparoscopic ports. **B,** Preparation of the Roux limb. **C,** Mobilization of stomach. **D,** Preparing bypass pouch. **E,** Pouch is 3 cm wide and 7 cm long. **F,** Gastrojejunal anastomosis.

Folate is specifically necessary for the synthesis of DNA and RNA and amino acid interconversion, particularly methylation reactions in the methionine-homocysteine cycle. It is essential for growth, cell differentiation, gene regulation, repair, and host defense.[139,140,145] Folate deficiency is more prevalent in the general population than previously suggested. Adequate maternal periconceptional folic acid consumption during critical periods of organ formation may reduce the likelihood of neural tube defects, conotruncal structural heart defects, obstructive urinary tract abnormalities, limb defects, facial clefts, and congenital hypertrophic pyloric stenosis. Closure of the neural tube occurs between 26 and 28 days after conception (e.g., 1 to 2 weeks after the first missed menstrual period, before pregnancy is recognized). Folic acid supplementation started after this critical period is therefore unlikely to prevent a neural tube defect.

Maternal folic acid deficiency is also associated with perinatal complications such as low birth weight, prematurity, placental abruption, infarction, and the development of neuroectodermal tumors in children. Folic acid deficiency, suggested by elevated plasma homocysteine, is also associated with cardiovascular diseases, increased risk of dysplasias, and the subsequent development of cancer. Given the protean manifestations of folic acid deficiency, the general recommendation is that all women of childbearing age take folic acid supplementation. In the adolescent who undergoes bariatric surgery, folic acid supplemented food items (such as cereals) may be inadequate. Additional supplementation contained in multivitamins is thus critical; measurement of serum folate and homocysteine concentrations may be useful.[142,146–148]

Adolescence is a period of enormous skeletal growth. This period of peak skeletal mineral accretion is a window of opportunity to influence lifelong bone health, both positively and negatively. Variations in calcium nutrition in adolescence may account for as much as 50% of the difference in hip fracture rates in postmenopausal years.[149,150] Though it is generally assumed that the obese adolescent has greater than normal bone mass[151] and is not operating at a disadvantage as it pertains to calcium absorption and risk for fracture or later osteoporosis, some experts disagree.[152] It is not clear whether the decrease in bone density that occurs after surgical weight loss, combined with potential poor compliance with vitamin D and calcium intake, will put the adolescent bariatric patient at greater risk for fractures later in life. Thus we consider it essential to closely monitor bone mineral density of adolescents undergoing bariatric surgery, particularly gastric bypass and biliopancreatic diversion.

## Guidelines for Performing Bariatric Surgery in Adolescence

Severely obese adolescents who have failed nonsurgical attempts at weight loss and have serious comorbidities should be considered candidates for bariatric surgery. Current recommendations for patient selection can be found in Table 80-4. There are others with such extreme obesity that activities of daily living may be severely impaired and in whom the development of health consequences of obesity is inevitable. For adolescents who have failed 6 months of attempts at professionally supervised weight loss, bariatric surgery is a reasonable weight loss option. See Table 80-5. Increasing preoperative weight and male gender are risk factors for procedure-related complications and mortality.[122,153] Given current referral patterns, the mean baseline BMI at our institution is 60.2 kg/m$^2$.[20] It is important for the surgeon to consider the impact of patient size on the potential for increased risks of the procedure. Some authors have suggested that surgeons who are early in the learning curve should avoid these high-risk patients to reduce complications.[153]

Adolescent bariatric surgery should be performed in centers having a multidisciplinary team capable of providing long-term follow-up and managing the unique behavioral challenges posed by the adolescent age group. Consistent with the guidelines established by the American Bariatric Surgical Association and the American College of Surgeons, these teams should include specialists with expertise in adolescent obesity evaluation and management, psychology, nutrition, physical activity instruction, and bariatric surgery. Depending on individual needs, additional expertise in adolescent medicine, endocrinology, pulmonology, gastroenterology, cardiology, orthopedics,

**TABLE 80-5**
**Attributes of Adolescent Bariatric Candidate**

- Patient is motivated and has good insight
- Patient has realistic expectations
- Family support and commitment are present
- Patient is compliant with health care commitments
- Family and patient understand that long-term lifestyle changes are necessary
- Agrees to long-term follow-up
- Decisional capacity is present
- Well-documented weight loss attempts
- No major psychiatric disorders that may complicate postoperative regimen adherence
- No major conduct/behavioral problems
- No substance abuse in preceding year
- No plans for pregnancy in upcoming 2 years

and ethics should be readily available. The team approach should include a review process similar to that used in multidisciplinary pediatric oncology and transplant programs. This review should result in culturally sensitive treatment recommendations tailored for the patient and family.

The optimal timing for weight loss surgery for overweight adolescents is unknown and largely influenced by the pressing health needs of the patient. There are growth and maturation factors that need to be considered. Physiologic maturation is generally complete by sexual maturation (Tanner) stage 3 or 4. Skeletal maturation (adult stature) is normally attained by the age of 13 to 14 in girls and 15 to 16 in boys. Overweight children generally experience accelerated onset of puberty. As a result, they are likely to be taller and have advanced bone age compared with age-matched, nonoverweight children. If there is uncertainty about whether adult stature has been attained, skeletal maturation (bone age) can be objectively assessed with a radiograph of the hand and wrist. If an individual has attained greater than 95% of adult stature, it is unlikely that a bariatric procedure would significantly impair completion of linear growth.

In determining patient suitability, all candidates should undergo a comprehensive psychologic evaluation. Goals of this evaluation are (1) to identify psychologic stressors or conflict within the family; (2) to identify past/present psychiatric, emotional, behavioral, or eating disorders; (3) to define potential supports and barriers to patient adherence, as well as family readiness for surgery and the required lifestyle changes (particularly if one or both parents are obese); (4) to assess whether there are reasonable outcome expectations; and most importantly, (5) to determine the level of cognitive and psychosocial development of the adolescent. With the alterations in eating patterns that are required after bariatric surgery, repetitive reinforcement is necessary to facilitate the formation of lifelong health-promoting habits. Bariatric surgical programs for this age group should be based on the premise that sustained weight control for the adolescent requires intensive and regular postoperative psychologic support. The role of the behavioral therapist depends on the level of intellectual function of the adolescent and includes behavioral rehearsal of regimen components before surgery, the use of behavioral contracts to outline regimen requirements and document the patient's agreement to adhere, a plan for patient and parental monitoring of adherence, and contingency reinforcement for adherence. The therapist plays a central role in developing parent-adolescent communication and conflict resolution skills and empirically based behavioral and family interventions, which facilitate the family's management of the patient's new lifestyle. A stable family environment, with full, unconditional support of all family members, is a desirable prerequisite for bariatric surgery in adolescents.

## Clinical Pathway for the Management of the Adolescent Undergoing Bariatric Surgery

The long-term consequences of bariatric surgery performed on adolescents have not been prospectively evaluated. The goals of adolescent bariatric surgery centers and programs should be to not only achieve dramatic and sustained weight loss but also contribute to the understanding of the most effective operations, risk factors for recidivism, and long-term outcome of adolescents undergoing bariatric surgery. Centers performing adolescent bariatric surgery should pay particular attention to bone mineral density and the ramifications of lifelong decreased vitamin and nutrient absorption on the adolescent and, particularly relevant to reproductive females, their offspring. Progress in this regard will require the implementation of broad-based clinical and basic research programs at these centers. The potential benefits of regionalizing selected, complex surgical procedures such as adolescent bariatric surgery have been well documented.[154–159] To this end, adolescent bariatric surgery should be concentrated in centers willing and able to provide comprehensive and extended preoperative and postoperative investigations including laboratory and diagnostic evaluations. Therefore the clinical pathway developed by the Comprehensive Weight Management Center at Cincinnati Children's Hospital Medical Center is designed to better characterize the prevalence and resolution of obesity-related complications among adolescents who undergo bariatric surgery, as well as provide surveillance for the known and potential consequences of the more popular bariatric surgical procedures performed at a comparatively young age.

Our preoperative panel includes a complete chemistry profile, liver function tests, uric acid, transferrin, iron, folate, lipid profile, urinalysis, electrocardiogram, cell blood count, hemoglobin A1C, fasting blood glucose and fasting insulin levels, thyroid stimulating hormone, and a pregnancy test for females. Nondiabetics receive a 2-hour glucose tolerance test. With the exception of the glucose tolerance test, the aforementioned laboratory and diagnostic panels are repeated at 3, 6, 9, and 12 months postoperatively, then yearly. Body composition is assessed with either bioelectrical impedance, for patients weighing in excess of 300 lb, or dual energy x-ray absorptiometry analysis (DEXA), for patients weighing less than 300 lb preoperatively and annually postoperatively. DEXA not only allows for the measurement of rate and relative amounts of fat and lean body mass loss but also provides a quantitative assessment of changes in bone mineral density. This body composition analysis is used to modify dietary plans intended to preserve lean body mass during the period of dramatic weight loss. Evidence suggesting that even as little as a two-standard-deviation change in bone mineral content of the adolescent can significantly increase the risk of osteoporosis and bone fractures in later life underscores the importance of meticulous and extended monitoring of nutrient, vitamin, and mineral absorption.[160] Because of the increased prevalence of abnormal heart geometry[161–163] and sleep disorders[80] among obese adolescents compared with nonobese adolescents, candidates for bariatric surgery undergo echocardiography and pediatric specific polysomnography.

Adolescent obesity may represent a disease that is more serious[2] and more difficult to manage[11,13] compared with this disease in adults. We currently lack an understanding of the long-term outcomes (both positive and negative) of bariatric procedures in this population. Thus centers offering bariatric care to these patients are obligated to critically evaluate outcomes, both positive and potentially negative, by ensuring that a mechanism is in place to carefully collect detailed data regarding comorbidity change and adverse events on all

adolescents who undergo surgery. This will help us to better define the role of bariatric procedures in the management of these patients. Ongoing longitudinal studies such as Teen-LABS (http://www.teen-labs.org) will provide long-term data to allow us to better understand the impact of bariatric surgery on the adolescent.

## Conclusion

The obesity epidemic in this country has generated a population of adolescents with the premature onset of adult disease. Clinical and epidemiologic studies have elucidated some of the life course risk factors for the development of childhood and adolescent obesity. Currently, bariatric surgery is the most effective treatment that achieves sustained weight loss and resolves or ameliorates the majority of the associated comorbidities. Success in adolescent bariatric surgery should be defined not only in terms of weight loss and morbidity resolution but also in terms of normal progression through adolescence and adulthood. Toward this goal adolescent bariatric surgery programs should have expertise that increases the likelihood of lifelong compliance with complex nutritional and lifestyle regimens (i.e., expertise that enables them to assess and meet the unique medical, cognitive, physiologic, and psychosocial needs of the adolescent). The guidelines for bariatric surgery should be conservative, be sensitive to the potential impact on the growth potential of the adolescent, and offer surgery during the time course of the disease that minimizes the risk of procedure-related complications and ensures the greatest likelihood of treating the comorbidities associated with obesity. Adolescent compliance with the strict nutritional and lifestyle regimens required after bariatric surgery may be best managed with a family-centered team that incorporates behavioral strategies to maximize compliance with postoperative dietary and physical activity instructions. Bariatric surgery is an exceedingly complex and technically difficult operation. The relative effects of hospital volume and surgeon volume in terms of procedure-related mortality and outcomes have direct implications for volume-based referral. Given the existent uncertainty about long-term outcomes of bariatric surgery in adolescents, regionalization of care and a national patient database are essential to achieve outcomes commensurate with the best adult series and to accelerate our understanding of the short- and long-term consequences of bariatric surgery among adolescents.

CHAPTER 81

# Duodenal Atresia and Stenosis—Annular Pancreas

Harry Applebaum and Roman Sydorak

## Short Capsule History

The duodenum is one of the most common sites of neonatal intestinal obstruction.[1] Although duodenal atresia, stenosis, and annular pancreas were recognized as disease entities as early as the eighteenth century, successful treatment of congenital high intestinal obstruction was a rare exception well into the twentieth century. The first reported case of duodenal atresia is attributed to Calder, in 1733.[2] Cordes, in 1901,[3] described the typical clinical findings associated with this congenital defect, while Vidal from France and Ernst from the Netherlands are credited with the first successful surgical repairs, in 1905 and 1914, respectively.[4,5] By 1929, Kaldor was able to identify 250 patients with duodenal atresia reported in the literature, although a review by Webb and Wangensteen, in 1931, revealed only nine survivors.[6,7] In stark contrast, modern surgical management has resulted in greater than 95% survival, with the uncommon mortalities usually related to anomalies of other organ systems.[8]

Historically, when duodenal atresia was encountered in association with trisomy 21 (Down syndrome), a finding in nearly one third of patients, the newborn obstruction was often intentionally left untreated. It was not until the1970s that changing societal and medical ethics led to a universal operative approach for infants born with these paired anomalies.[9–11] A gradual decline in the incidence of newborns with duodenal obstruction can be attributed to the increasing ability of perinatologists to determine an abnormal chromosome association early in gestation, leading to elective termination of many of these pregnancies.[12–15]

## Introductory Issues

The incidence of duodenal atresia has been estimated at 1 in 6,000 to 1 in 10,000 births.[16] A recent large review of 18 congenital anomaly registries across Europe identified 64 cases among 670,093 births, or 1 in 10,500.[17] Although no specific genetic abnormality is known to cause duodenal atresia, the number of reports of the anomaly occurring among siblings and among several generations of a family, as well as its frequent association with trisomy 21, suggests that one may be present.[15,18–25]

## Embryology

During the third week of embryonic development, gastrulation occurs. The cellular surface of the embryo facing the yolk sac becomes the endoderm, the surface facing the amniotic sac becomes the ectoderm, and the middle layer becomes the mesoderm. The endoderm gives rise to the gut tube beginning in the fourth week of development. In the sixth week, the gut epithelium proliferates rapidly, resulting in obliteration of the intestinal lumen. The intestine is then gradually recanalized over the next several weeks of development. Errors in recanalization are thought to be the primary cause of duodenal atresia and stenosis.[26–28] This differs from that of intestinal atresias and stenoses in other parts of the bowel, which are thought to result from vascular accidents during the later phases of gestation.[29]

The pancreas begins to develop from the endodermal lining of the duodenum in the fourth week of gestation. Two pouches are formed, which develop into a larger dorsal and a smaller ventral pancreatic primordium. The ventral bud then rotates dorsally to fuse with the dorsal bud during the eighth week. If the ventral bud fails to rotate completely, it remains anterior to the duodenum, and fusion with the dorsal pancreatic primordium results in a ring of pancreatic tissue encircling the duodenum, creating an annular pancreas with concomitant partial or complete obstruction.[26–28,30,31]

Approximately half of all infants with duodenal atresia or stenosis will also have a congenital anomaly of another organ system.[32–39] Sweed[40] collated statistics for associated anomalies from a dozen large series of duodenal obstructions, and found Down syndrome, annular pancreas, congenital heart disease, and malrotation to be the most common (Table 81-1).

**TABLE 81-1**
**Associated Anomalies (Collected Statistics)—after Sweed[40]**

| *Anomaly* | *Percent* |
|---|---|

*EA/TEF*, Esophageal atresia/tracheal esophageal fistula.

## Spectrum of Disorders Involved

Several varieties of intrinsic and extrinsic congenital lesions can cause complete (81%) or partial (19%) obstruction of the duodenum.[1] The spectrum of abnormalities causing intrinsic obstruction includes imperforate and perforate webs of variable thickness within continuous bowel as well as complete or almost complete bowel discontinuity. Abnormalities causing extrinsic obstruction include annular pancreas, preduodenal portal vein, Ladd bands, and volvulus.[20,41–47]

Gray and Skandalakis[48] have grouped the variations of duodenal atresia into three types:

**Type 1** (92% of cases)[49]: There is an obstructing septum (web) formed from mucosa and submucosa with no defect in the muscularis. The mesentery is intact (Fig. 81-1, *A*). A variant of type 1 duodenal atresia, a "windsock deformity," can occur if the membrane is thin and elongated. The base of the membrane usually lies in the second portion of the duodenum, but balloons out distally, distending the third and fourth portions. Thus, externally the obstruction appears considerably more distal than it actually is.[50]

**Type 2** (1% of cases): A short fibrous cord connects the two blind ends of the duodenum. The mesentery is intact (Fig. 81-1, *B*).

**Type 3** (7% of cases): There is no connection between the two blind ends of the duodenum. There is a V-shaped mesenteric defect (Fig. 81-1, *C*).

In type 1 atresia, the obstructing septum may vary in thickness from one to several millimeters. Imperforate septa cause a complete obstruction, whereas those with central perforations cause incomplete obstruction (Fig. 81-2). With perforate septa, the diameter of the opening directly determines the degree of obstruction, and is therefore inversely related to symptoms.[50]

Although intrinsic blockage may occur in almost any portion of the duodenum, it occurs near the junction of the first and second portions in 85% of cases. The distal portion of the

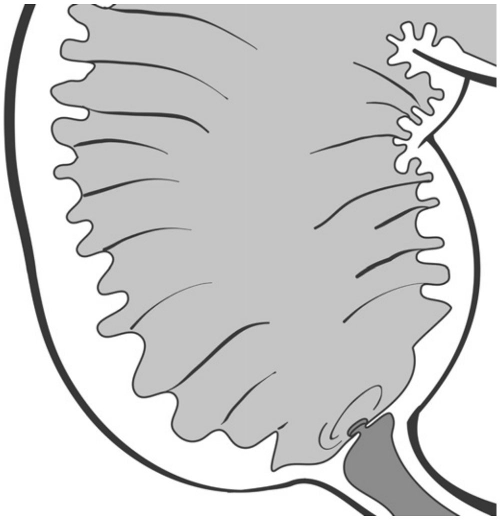

**FIGURE 81-2** Typical duodenal web with central perforation.

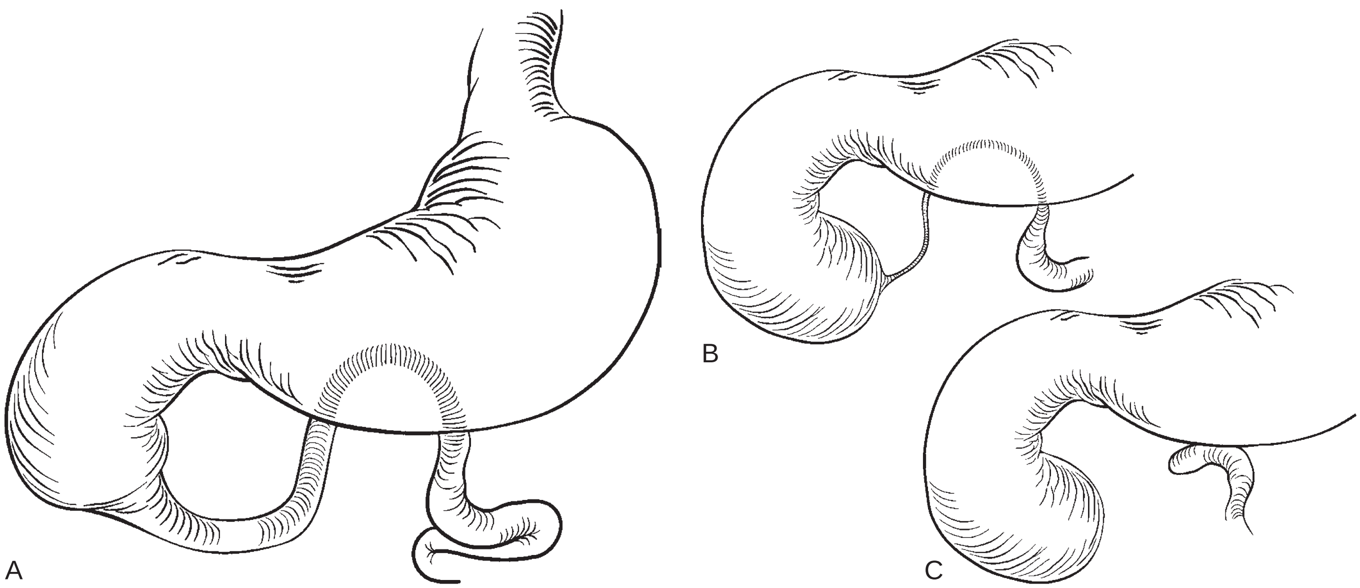

**FIGURE 81-1** **A,** Type I duodenal atresia. **B,** Type II duodenal atresia. **C,** Type III duodenal atresia.

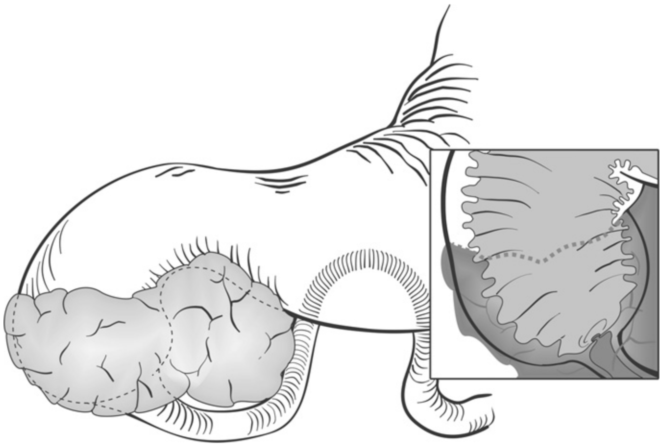

**FIGURE 81-3** Annular pancreas with underlying web causing partial duodenal obstruction.

common bile duct often traverses the medial portion of the septum, with the ampulla commonly located on the proximal surface of the obstruction. In rare instances, the distal portion of the duct is bifid, with proximal and distal openings, giving rise to what at first glance appears to be an impossible situation of air and bile distal to a complete congenital obstruction.[52,53]

With an annular pancreas, the ring of pancreatic tissue encircling the duodenum may itself cause an extrinsic partial obstruction. More often, however, a duodenal atresia or stenotic web underlies the annulus and is the actual cause of blockage (Fig. 81-3).[41,54] A preduodenal portal vein crosses the anterior surface of the second portion of the duodenum, rather than running posterior to it, and may cause incomplete obstruction by compression. This rare cause of extrinsic duodenal compression is usually found in infants with complex congenital heart disease.[8,47] Intestinal malrotation results in Ladd bands that usually give rise to an extrinsic partial obstruction of the second to third portion of the duodenum. Varying degrees of midgut volvulus—acute, intermittent, or chronic—can occur in these infants, also resulting in obstruction.[55]

## Clinical Presentation

Advances in prenatal care have allowed the majority of duodenal obstructions, both complete and incomplete, to be detected before birth.[56] Maternal polyhydramnios, noted in 30% to 65% of cases, is an early clue.[1,46] The classic "double-bubble" obstructive pattern is usually identifiable on fetal ultrasonography (Fig. 81-4). The larger of the twin bubbles juxtaposed in the fetal abdomen is the dilated, fluid-filled stomach, whereas the other is the distended proximal duodenum. An annular pancreas may also be recognizable.[57,58]

Repeated bilious emesis is the characteristic clinical feature of almost all newborns with duodenal obstruction. Because of the proximal level of intestinal blockage, the infant does not appear distended, although a subtle upper abdominal fullness may be noted. In patients with complete or high-grade duodenal obstruction, a plain film of the abdomen will generally confirm the diagnosis, with a finding of the "double-bubble" sign. The lack of more distal intestinal gas is diagnostic of a complete obstruction, whereas the presence of gas indicates

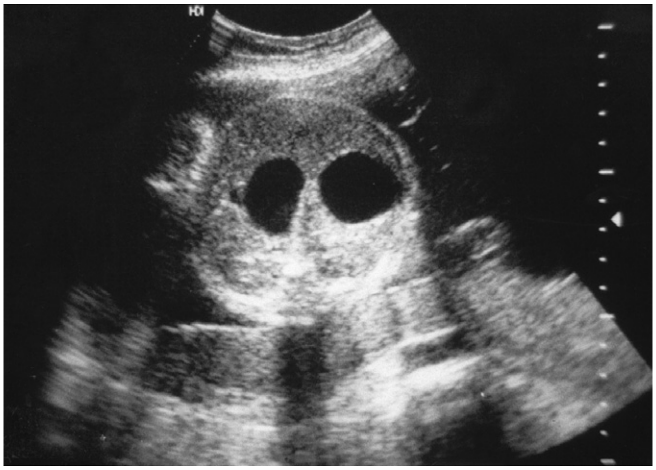

**FIGURE 81-4** Fetal ultrasound with "double-bubble" sign.

a partial obstruction (Fig. 81-5, *A* and *B*). In situations where the diagnosis is suspected but the "double-bubble" sign is not clearly visible, injection of 30 to 60 mL of air through the nasogastric tube may demonstrate this characteristic imaging finding.

The recognition of partial obstructions may be considerably delayed if the obstruction is of a relatively minor degree.[16] In this situation, it is not uncommon for symptoms to first occur when advancing the infant from formula to solid food, or it may only be unmasked much later in infancy, childhood, or, in rare instances, adulthood, when a progressive decrease in

**FIGURE 81-5** Plain abdominal film of newborn with duodenal stenosis (perforated web). Note the small amount of air distal to "double-bubble." The same finding with a lack of distal air would indicate duodenal atresia.

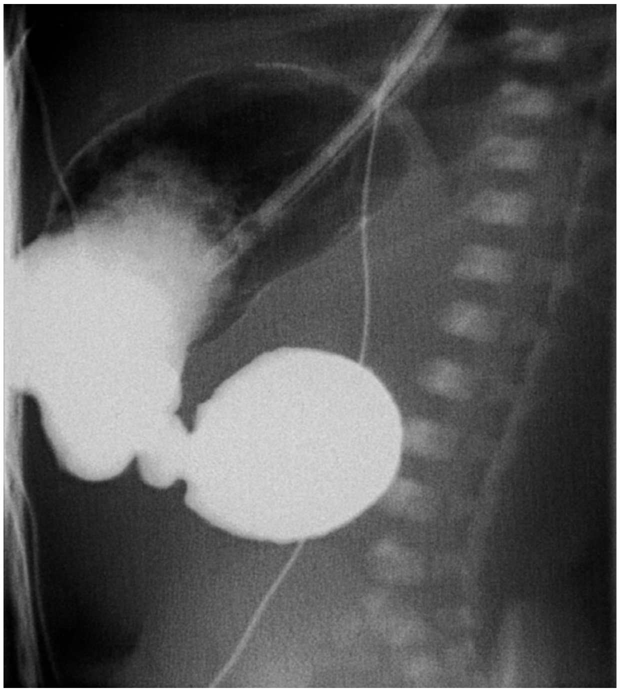

FIGURE 81-6 Upper gastrointestinal (UGI) radiographic contrast study of duodenal atresia.

motility or impaction of food or a foreign body causes more pronounced symptoms.[59–61]

With characteristic findings of duodenal obstruction on plain abdominal radiographs, it is appropriate to proceed directly to operative intervention without obtaining contrast studies. Occasionally, an upper gastrointestinal study (UGI) may be helpful in differentiating intrinsic duodenal obstruction from midgut volvulus (Fig. 81-6). With intrinsic obstruction, a smooth, rounded end will usually be seen at the level of obstruction in the second portion of the duodenum, and a ligament of Treitz may be visible if the obstruction is incomplete. A distal "beaking" effect in the third portion should arouse concern about volvulus and the need for an urgent operation.[62] The UGI is the most useful study for the evaluation of older infants and children with symptoms of chronic partial obstruction.[51] Gastroduodenoscopy may also be a useful diagnostic and sometimes therapeutic tool in these patients.[63,64]

## Treatment

Neonates with duodenal obstruction are initially managed with nasogastric or orogastric tube decompression and intravenous fluids. Gastrointestinal (GI) losses are replaced appropriately, and placement of a peripherally inserted central catheter (PICC) line for parenteral nutrition is recommended, because feeding is commonly delayed for up to several weeks following repair. Assuming that a diagnosis of midgut volvulus has been reasonably excluded, surgical correction of duodenal obstruction is not emergent. It can take place once the infant is optimized and associated anomalies have been appropriately studied.[34] Pulmonary status and size may preclude early operative intervention in very premature infants.

The operation is best accomplished through a right upper quadrant transverse incision halfway between the liver edge and the umbilicus. Following abdominal exploration, the right colon and hepatic flexure are then mobilized medially to allow full exposure of the proximal duodenum. Eviscerating and positioning the small bowel and colon cephalad and to the left of the incision best achieves access to the third and fourth portions of the duodenum. This maneuver will fully expose the root of the mesentery and ligament of Treitz. Although many patients with high-grade duodenal obstruction will have accompanying malrotation, on closer inspection, a number will actually be found to have a pseudomalrotation, because the underlying grossly dilated duodenum may cause abnormal leftward displacement of the right colon and hepatic flexure. Absence of the ligament of Treitz will be noted in patients with true malrotation.

The entire duodenum is inspected, and the probable location and type of the obstruction are noted. In a complete or nearly complete obstruction, the proximal duodenum appears as a large, boggy, thickened sphere. In type 1 cases, diminutive, gasless bowel distal to this point indicates that the obstruction is complete. In type 2 and 3 cases, the discontinuity of the bowel will become evident during dissection. In patients with annular pancreas, pancreatic tissue will be seen extending circumferentially around the second portion of the duodenum.

When there is gross dilatation of the proximal segment, a tapering duodenoplasty, as the initial part of the procedure, may hasten the postoperative return of effective peristalsis.[65–71] This is accomplished by either suture plication or by resection using a gastrointestinal anastomosis (GIA) stapler or needle-tip electrocautery and suture closure. The tapering is positioned on the anterior or anterolateral surface to avoid damage to the common bile duct, pancreas, and ampulla (Fig. 81-7).[72] In addition, division of the ligament of Treitz to help mobilize the distal segment may greatly facilitate an eventual untwisted, tension-free anastomosis.

When there is continuity of the proximal and distal duodenum, it is best to open the distal bowel near the apparent point of obstruction, in a position and direction suitable for a potential bypass. If filmy or thin webs are identified as the cause of

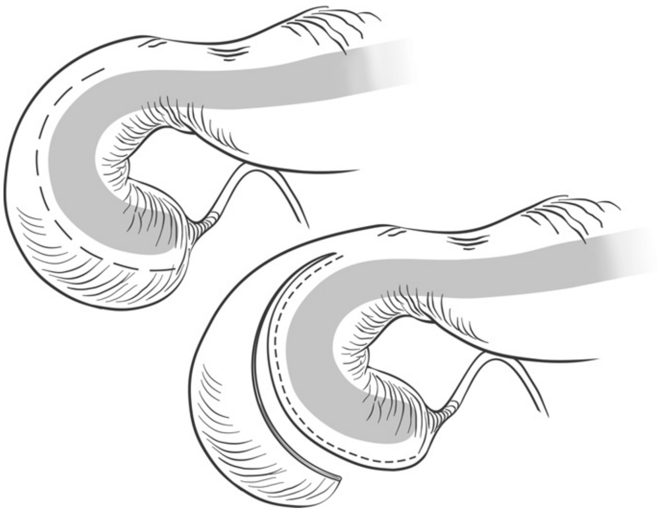

FIGURE 81-7 Tapering of distended proximal duodenum over dilator.

the obstruction, they may sometimes be excised rather than bypassed. In this case, the incision is carried over the web into proximal lumen, and the web is excised with cautery. If the ampulla is on the medial aspect of the web, or is not well visualized, excision should include only the lateral portion of the web. The duodenum is closed as a duodenoplasty in a transverse manner, to shorten and widen the bowel overlying the resection to minimize the risk of stenosis. Web excision should only be attempted when the web is thin, and when it is clearly the only cause of obstruction.

In almost all situations, a duodenoduodenostomy, joining the bowel just proximal and distal to the obstruction, is the best corrective option. It is the most direct, physiologic repair and, of the available options, has the least potential for later complications. When this procedure is difficult because of patient anatomy, particularly in some small, premature infants, duodenojejunostomy is the next best choice. A loop of proximal jejunum is chosen that will comfortably reach the proximal duodenal segment and is brought through the mesentery of the right transverse colon in a retrocolic position (Fig. 81-8). Duodenojejunostomy provides postoperative results that are generally equivalent to those obtained with duodenoduodenostomy. Gastrojejunostomy, the third bypass option, suffers from the frequent late complications of marginal ulceration and blind loop syndrome, and therefore should be avoided.

In a recent series of patients with duodenal obstruction, duodenoduodenostomy was the procedure of choice in the great majority of patients (>80% ), with duodenojejunostomy used in approximately 10% and web excision in 5% to 10%. Gastrojejunostomy was a rarely chosen option.[1,33,49,73]

When performing a bypass anastomosis, a “diamond anastomosis” (proximal transverse and distal longitudinal incisions) (Fig. 81-9, *A*), first described by Kimura, is preferred

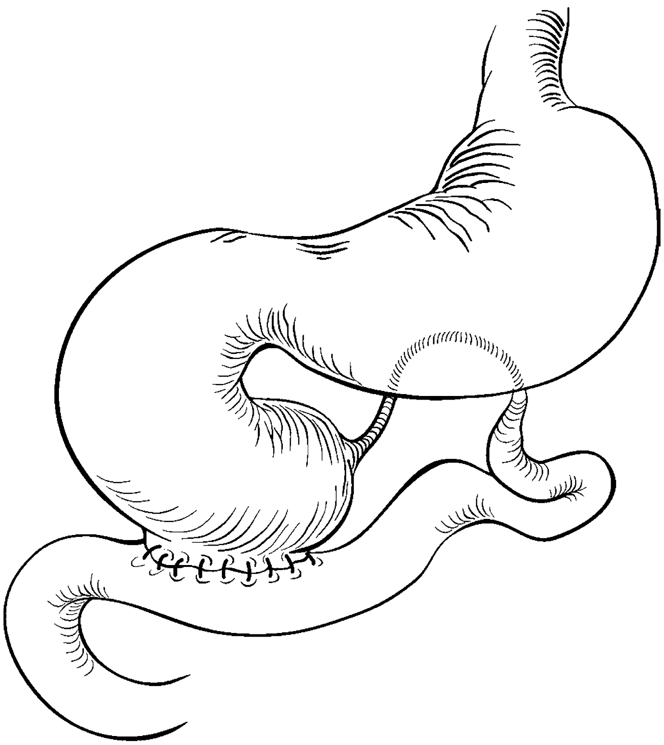

**FIGURE 81-8** Duodenojejunostomy.

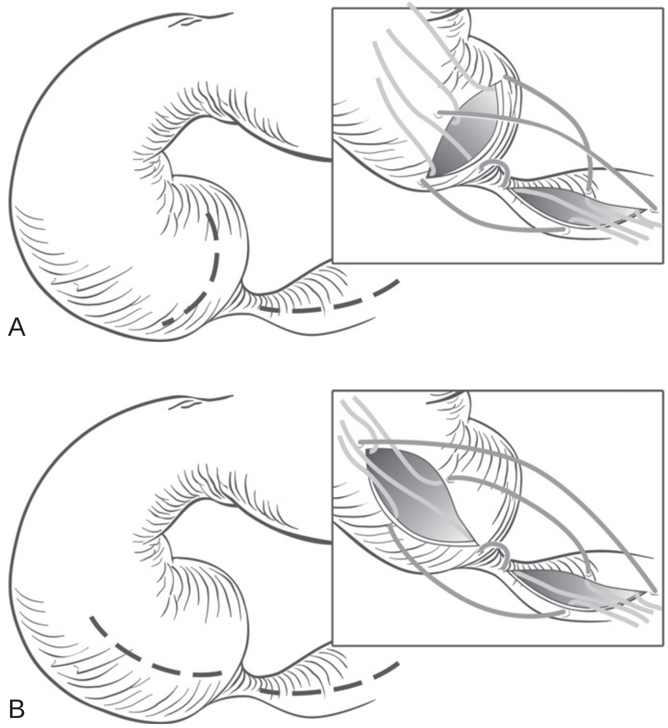

**FIGURE 81-9** **A,** “Diamond” anastomosis. **B,** “Simple” anastomosis.

over the “simple anastomosis” (proximal and distal longitudinal incisions) (Fig. 81-9, *B*).[74–76] This asymmetric anastomosis will maintain itself in a more wide-open position, and permit earlier transit of duodenal contents.

The antimesenteric incisions in each segment should be 1 to 2 cm in length, depending upon the size of the patient, to ensure an adequately patent anastomosis. With type 3 deformities, the end of the distal segment is spatulated appropriately. Before making the incision in the distal segment, it is useful to inject saline into the lumen while occluding the bowel distally to slightly stretch the wall, thus enabling a technically easier anastomosis. In addition, a 10-Fr Foley catheter should be passed proximally into the stomach and distally into the jejunum and pulled back with the balloon inflated, to ensure that no additional web or a windsock deformity is overlooked. Before starting the anastomosis, small retractors can be placed in the duodenum to inspect the point of obstruction and to determine the position of the ampulla of Vater. This anatomic landmark is usually easily visible, and identification can prevent injury to it. In addition, the distal intestine should be examined, because there is an association with additional atresias.

The diamond anastomosis is constructed by placing initial stay sutures joining the midpoints of each incision to the ends of the other. Placement should anticipate a posterior row of knots inside the lumen and an anterior row on the outside. The posterior row of the anastomosis is constructed using a repeating bisecting technique, to ensure even placement of the sutures and good coaptation of the bowel edges. The anterior row of the anastomosis is then completed in a similar fashion. The anastomosis is checked for patency, and the intestine is returned to the abdominal cavity in its usual position. Proper positioning of a nasogastric tube is also confirmed. Although commonly used in the past, gastrostomy tubes are now considered useful only in selected infants

who are not expected to feed orally in the near future. Some surgeons routinely position transanastomotic feeding tubes, although their benefit has not been clearly delineated.[76,77]

Congenital obstruction of the distal duodenum at or near the ligament of Treitz presents an especially difficult problem. The long segment of atonic dilated duodenum is difficult to effectively taper; so, the reconstructed bowel and anastomosis are likely to function poorly for a lengthy time period or not at all. In this situation, subtotal removal of the dilated duodenum with preservation of the ampulla is recommended.[78,79] The anterior wall of the second portion of the duodenum is opened, and the ampulla of Vater is located. The ligament of Treitz is taken down, and the dilated duodenum is dissected from the pancreas in a retrograde fashion to just distal to the ampulla. The first and second portions of the duodenum are then tapered to near the level of the ampulla, with the resected proximal duodenum removed in continuity with the distal duodenum. The end of the normal jejunum distal to the obstruction is spatulated and anastomosed to the tapered proximal segment (Fig. 81-10).

When an annular pancreas is encountered in association with duodenal obstruction, bypass is always the procedure of choice. The ring of pancreatic tissue should never be transected because of the major ductal structures that traverse it. Damage to these structures will lead to leakage of pancreatic fluid and/or pancreatitis. An obstructing preduodenal portal vein is bypassed in a similar manner.

The introduction of advanced laparoscopic techniques in the neonate has more recently led to a new surgical approach, the laparoscopic duodenoduodenostomy.[80–82] Depending on the size of the patient, 3- or 5-mm ports can be used. Three ports are used, one at the umbilicus for the camera and two working ports in the left/right midabdomen for suturing. A fourth port in the left upper or right lower quadrant can aid with retraction of the liver. The technique of repair is the same as the open approach using a diamond-shaped anastomosis. Either running sutures or single interrupted sutures can be used for the anterior and posterior walls. Intracorporeal knot tying is used. The apical stitches can be tied extracorporeally and left on tension through the abdominal wall to help align the enterotomies. Alternatively, U-clips can be used to perform the anastomosis.[81] The approach becomes more difficult in infants weighing less than 2 kg, because there is little working space. As a result, experience with advanced laparoscopy is necessary. It is currently impossible to compare the long-term outcomes of this technique with those of the classic open approach, because of the limited number of selected patients and the lack of prospective randomized results. However, the procedure can be performed with no bleeding, no conversions, no difference in operative times, and no postoperative anastomotic leaks.[81,82]

Postoperatively, total parenteral nutrition (TPN) is continued, and nasogastric tube output is monitored. As with other neonatal intestinal procedures, feedings may be started when the volume of the nasogastric output has diminished and its color has lightened and it becomes clear. This stage is commonly reached within several days to a week, but it may be prolonged. Small feedings are then initiated, with volume and concentration advanced as tolerated. This is a rapid process in most infants, and the majority may be discharged within one to several weeks.

## Complications (Intraoperative and Postoperative)

### INTRAOPERATIVE

Several intraoperative judgmental and technical pitfalls can lead to postoperative difficulties.[83] Incorrect identification of the site of obstruction most commonly occurs when a long, floppy web

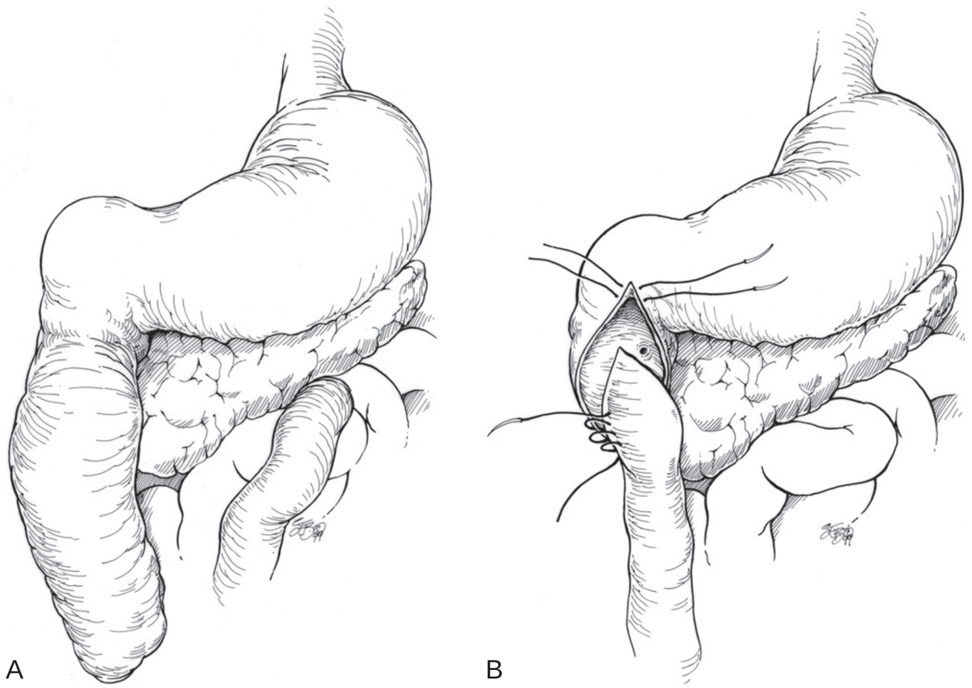

**FIGURE 81-10** Subtotal duodenectomy and jejunal onlay patch procedure.

(windsock deformity) is present. The proximally based web fills with gastrointestinal secretions and balloons out into the distal duodenum, distending it and causing the site of obstruction to appear much more distal than it actually is. The unwary surgeon, not recognizing the true attachment of the web, may then construct a bypass anastomosis entirely distal to it. In addition, on rare occasions, there will be more than one obstruction present. A distal web is easily missed because of the lack of any obvious adjacent proximal dilatation. The careful passage and withdrawal of balloon catheters both proximally into the stomach and distally into the jejunum before starting an anastomosis should prevent both of these situations.[51,84,85]

### POSTOPERATIVE

Prolonged feeding intolerance is the most common complication following surgery to relieve duodenal obstruction. There is a great deal of variability in the time required for a bypass anastomosis or web excision to function adequately. Although a variety of prokinetic agents have been proposed to hasten this process, none have been found to be of any consistent benefit. In general, if no specific difficulties were encountered at the initial procedure, there should be concern if relatively normal function has not been achieved by 3 weeks. At that time, an upper gastrointestinal series is helpful to search for residual anatomic obstruction, anastomotic stenosis, previously unrecognized obstruction at a different location, or poor peristalsis. Any decisions as to further surgical procedures should be based on a combined assessment of both imaging studies and clinical gastrointestinal function. A dilated proximal duodenum may be visualized radiographically for at least several months in the presence of a fully functional bypass anastomosis.[86] If prolonged poor function should occur, the finding of an anatomic obstruction is far less likely than identifying persistently poor peristalsis. Additional simple tapering of the proximal duodenum may suffice to provide adequate additional motility. Once adequate gastrointestinal function has been achieved, further problems may develop but are uncommon.

Late duodenal obstruction may occasionally be noted in older infants and children. This may occur following a seemingly successful neonatal bypass procedure or excision of web, or de novo, when a diagnosis of partial duodenal obstruction was initially missed. In the former, a piece of fibrous food or a foreign body may become impacted at the site of a partially resected web, or when a relatively narrow anastomosis was constructed to an inadequate size, and has become strictured over time or has failed to grow with the child. In the latter, it may occur at the site of a relatively low-grade stenosis that has become progressively symptomatic because of the development of proximal dilatation and ineffective peristalsis. In others, no persistent anatomic obstruction can be demonstrated following initial surgical correction, but poor peristalsis can be demonstrated in an area of persistent, and sometimes increasing, dilatation.[87]

Proximal tapering is often helpful at this time, either in conjunction with correction of an obviously inadequate initial procedure, or by itself, in situations where no distinct anatomic narrowing is found.[88,89] Most of these older infants and children are large enough for full-function upper gastrointestinal endoscopy, which may aid in the diagnosis and may be therapeutic by permitting dilatation of anastomotic strictures or resection of webs.[63,64]

## Outcomes

Survival of infants with duodenal obstruction has increased from 45% to 95% over the past half century.[48,90–92] This dramatic improvement is primarily related to improved diagnosis and surgical and postoperative management, although selective pregnancy termination has likely played a role. Almost all mortality is now related to associated anomalies of other organ systems, primarily those of the heart, lungs, and brain.

CHAPTER 82

# Jejunoileal Atresia and Stenosis

Jason S. Frischer and Richard G. Azizkhan

## History

Jejunoileal atresia and stenosis are the most common congenital anomalies of the small intestine and are a major cause of intestinal obstruction in neonates. Atresia (complete occlusion of the intestinal lumen) accounts for 95% of cases, whereas stenosis (partial intraluminal occlusion) accounts for only 5%. The first description of ileal atresia appeared in 1684 and is attributed to Goeller.[1] Other early commentaries on this anomaly were recorded in the 1770s by Calder[2] and Osiander.[3] By the early 1800s, Voisin had performed an enterostomy for intestinal atresia and Meckel had published a review of this condition and speculated on its etiology. Decades later (1889), Bland-Sutton[4] proposed a classification of the types of intestinal atresia and postulated that these defects occurred at the sites of obliterative embryologic events such as atrophy of the vitelline duct. In 1894 Wanitschek performed the first, though unsuccessful, resection and anastomosis.[3] In 1900 Tandler[5] theorized that intestinal atresia was secondary to a failure of recanalization of the solid-cord stage of bowel development; this concept was reaffirmed a decade later by Johnson's clinical observations.[6] The first successful anastomosis for intestinal atresia was achieved by Fockens in 1911.[7] A year later, Spriggs[8] suggested that causality for intestinal atresia could be attributed to mechanical accidents including vascular occlusions. This concept was later substantiated by the clinical observations of Davis and Poynter (1922)[9] and Webb and Wangensteen (1931).[2] In 1955 a landmark study conducted by Louw and Barnard[10] documented that late intrauterine mesenteric vascular accidents were responsible for most jejunoileal atresias. Their findings laid the foundation for our contemporary understanding of the wide range of intestinal defects seen in clinical practice.

As reported by Evans (1951),[1] the survival of children with intestinal atresia in the first half of the twentieth century was dismal, with only 139 of 1498 cases having a successful outcome. During the past 3 decades, a better understanding of etiologic factors and impaired intestinal function, as well as refinements in pediatric anesthesia, operative techniques, and preoperative and postoperative care (especially in the area of nutritional support), have led to a significant improvement in survival.[11–13]

## Prevalence

Reports of the prevalence of jejunoileal atresia vary significantly across the globe, ranging from as low as 1.3 to 2.25 cases per 10,000 live births in Spain, Latin America, and France to as high as 2.9 cases per 10,000 live births in various regions of the United States.[12–16] Several authors[14–16] have reported a higher prevalence of small-bowel atresia in African-American children and in twins, regardless of race. Consistent with the latter finding, a population-based study conducted in the Netherlands found a higher incidence of jejunal atresia in fraternal twins.[17] A population-based study in Hawaii found a higher incidence of jejunoileal atresia in Far East Asians compared with whites.[16] Factors that increase the risk of developing small intestinal atresias include use of pseudoephedrine alone or in combination with acetaminophen and receiving ergotamine tartrate and caffeine (Cafergot) for the management of migraine headaches during pregnancy.[18–19] Nixon and Tawes[20] reported a 2:1 ratio in the frequency of jejunoileal to duodenal atresias. In contrast, a review of 387 patients with intestinal atresia and stenosis treated over a 32-year period (1972 to 2004) at the Riley Children's Hospital in Indianapolis revealed that 50% of cases involved the jejunoileal region, 44% were duodenal, and the remaining 6% were colonic.[21] In a study of 619 patients representing the combined experience of members of the Surgical Section of the American Academy of Pediatrics, de Lorimier and colleagues[22] noted that boys and girls were equally affected by intestinal atresia. Although the mean birth weight of this cohort was 2.7 kg (range 0.9 to 4.8 kg), 33% of the infants with jejunal atresia, 25% of those with ileal atresia, and more than 50% of those with multiple atresias were infants with low birth weight.[22] Furthermore, infants with intestinal atresia detected on prenatal ultrasound (US) frequently have low birth weight.[23] Although trisomy 21 is seen in 30% of infants with duodenal atresia or stenosis, it is uncommon in those with jejunoileal atresia. More specifically, the previously cited studies conducted by Nixon and Tawes[20] and deLorimier and colleagues[22] noted that only 2 of 127 patients and 5 of 619 patients, respectively, with jejunoileal atresia had trisomy 21. In the study conducted at Riley Children's Hospital only 1 of 194 infants with jejunoileal atresia had this disorder,

and this patient also had duodenal atresia.[21] The incidence of extraintestinal anomalies in patients with intestinal atresia ranges from 25% to 35%, with a higher incidence of anomalies associated with jejunal atresia as compared with ileal atresia.[11,13,24,25] Furthermore, concomitant extraintestinal anomalies more commonly occur (>50%) in patients with duodenal atresia.[11,24,26] Though rarely observed, jejunoileal atresia reportedly coexists with biliary atresia, duodenal atresia, colonic atresia, gastric atresia, Hirschsprung disease, and arthrogryposis, and it also occurs in identical twins.[25,27–32]

# Etiology

The work of Lynn and Espinas (1959)[33] confirmed the earlier observations by Tandler[5] suggesting that epithelial plugging could be a cause of the failure of recanalization, resulting in intestinal atresia. Nevertheless, this etiology is likely to apply to duodenal atresia but not jejunoileal atresia. It is common knowledge that the bowel segments proximal and distal to jejunoileal atresias are separated by either a cordlike structure or a gap between the segments of bowel with an obvious mesenteric defect. The clinical observations of a number of authors[10,34,35] document that bile pigments, squames, and lanugo hairs are often found distal to atretic segments, implicating that events other than epithelial plugging may cause intestinal atresia and that these perturbating events occur later in utero.[36] Moreover, fetal bile secretion and the swallowing of amniotic fluid begin in the eleventh and twelfth weeks of intrauterine life, well after the luminal revacuolization process. The concept of other intrauterine events causing intestinal atresia was proposed by Davis and Poynter[9] in 1922. Since that time, others have maintained that mesenteric defects, volvulus, and infarction or other interruption of local blood supply can and do produce this anomaly in the fetus.[37,38] Endeavoring to understand the etiology of intestinal atresia, Louw and Barnard (1955)[10] subjected dog fetuses to ligation of mesenteric vessels and strangulation obstruction late in the course of gestation. Examination of affected fetal intestine 10 to 14 days later showed a variety of atretic conditions similar to those seen in human neonates. These findings strongly suggest that most jejunoileal atresias are the result of late intrauterine mesenteric vascular occlusions. Additionally, Courtois (1959)[34] observed that fetal rabbits undergoing experimental intrauterine intestinal perforation can manifest intestinal atresia or stenosis or can heal completely (with or without evidence of meconium peritonitis). Further, if an intestinal loop is isolated, resorption of the loop occurs if its blood supply is poor.[38] Later research conducted with fetal rabbits, sheep, dogs, and chick embryos confirms these findings.[35,39–41]

Glüer (1995)[42] reported the occurrence of jejunoileal atresia in four sets of twins after intraamniotic injection of dyes and theorized a teratogenic mechanism. In 2001 Sweeney and colleagues[43] reported that infants with jejunal atresia had a higher incidence of associated anomalies than those with ileal atresia (42% vs. 2%, respectively) and suggested that some cases of jejunal atresia may arise from a broader malformative process. In a rat model using doxorubicin (Adriamycin), Gillick and colleagues (2002)[44] reported that abnormal development of the notochord in the area of the developing midgut was associated with multiple intestinal atresias.

Grosfeld and Clatworthy[45] observed the occurrence of jejunal atresia with infarction of the entire midgut in a tight gastroschisis defect. Intestinal atresias secondary to late intrauterine mesenteric vascular insults are often seen in patients with volvulus, intussusception, internal hernia, and tight anterior abdominal wall defects.[38,45–48,50,51] de Lorimier and colleagues[22] found evidence of bowel infarction in 42% of 619 patients with jejunoileal atresia. Nixon and Tawes[20] observed macroscopic or microscopic intrauterine peritonitis in 48% (61 of 127) of patients with atresia, with an obvious volvulus noted in 35% (44 of 127). Murphy[52] noted that 5% of atresias were related to fetal internal hernias. Other studies[20,35,53] document instances of atresia related to bowel incarceration in an omphalocele. Iatrogenic postpartum ileal atresia as a result of umbilical clamping of an occult omphalocele has also been reported.[54,55] Although results of an American Academy of Pediatrics survey published in 1962 indicate that jejunoileal atresia associated with gastroschisis is observed in 2% of patients,[22] later studies consistently report an increase.[56–58]

Evans' review[1] of 1498 patients with atresia yielded only 9 patients with associated intussusception, whereas Komuro[59] described intrauterine intussusception as a cause of intestinal atresia in 25% of patients with a single mid-small-bowel atresia. In the latter study, intussusception was not detected as a cause of atresia in patients with high-jejunal, *apple-peel,* or multiple atresias. The cause of intrauterine intussusception is as yet unknown[48,50]; however, most of these infants are full term and without associated anomalies or cystic fibrosis.[28,60–63] Postnatal intussusception as a cause of jejunal atresia in a premature infant has also been described.[64] In the previously cited study conducted at Riley Children's Hospital,[21] volvulus was detected in 33% of patients, malrotation in 16%, intussusception in 3%, internal hernia in 1%, and gastroschisis in 14%; evidence of meconium peritonitis was found in 12%.

A study conducted by Komuro and colleagues (2004) clearly documents the association of placental vascular anomalies and the occurrence of complex jejunoileal atresia (multiple atresias, apple-peel deformity).[23,65] All of these patients had low birth weight, consistent with the impact of placental vascular compromise on fetal growth. Multiple atresias have also been noted in patients with congenital and acquired immunodeficiency.[66–69]

The genetic contribution to jejunoileal atresia is unclear. Gross and colleagues[66] reported familial instances of combined duodenal and jejunal atresia. Numerous authors have reported hereditary multiple intestinal atresias.[67,70–72] Furthermore, both autosomal recessive and autosomal dominant transmission has been documented.[73,74] On the basis of a review of the literature, Shorter and colleagues (2006)[36] proposed a novel classification system (Table 82–1) for the five distinct types of familial atresia documented to date (i.e., pyloric atresia, duodenal atresia, hereditary multiple atresia syndrome, apple-peel atresia, and colonic atresia). The basic premise of these authors is that the identification of familial cases of these various forms indicates the existence of specific embryologic pathways; when disrupted, these pathways give rise to intestinal atresias. The authors maintain that nonfamilial cases result from disruption of the same pathways by nongenetic mechanisms. The conceptual difference between

**TABLE 82-1**
**Classification of Familial Cases of Gastrointestinal Atresia***

| *Class* | *Description* | *Genetics* |
|---|---|---|
| 1 | Pyloric atresia (may include antral atresia or atresia of the proximal duodenum) | Autosomal recessive |
| 2 | Duodenal atresia—second or third portion of duodenum, no other atresias | Autosomal recessive |
| 3 | Multiple atresia syndrome, rotation is usually normal | Autosomal recessive, uniformly lethal |
| 4 | Apple-peel atresia, proximal atresia is typically at the duodenojejunal junction, almost always associated with malrotation | Autosomal recessive |
| 5 | Colonic atresia, rarest type, usually in the sigmoid colon | X-linked recessive |

From Shorter NA, Georges A, Perenyyi A, Garrow E: A proposed classification system for familial intestinal atresia and its relevance to the understanding of the etiology of jejunoileal atresia. J Pediatr Surg 2006;41:1822-1825.
*All classes have a nonfamilial counterpart.

this model and the previously discussed vascular accident model is that in the latter, the atresia results from the loss of a preexisting vessel; in the former, however, the vessel fails to develop altogether.

# Diagnosis

## CLINICAL PRESENTATION

A number of key prenatal and postnatal clinical signs should elicit suspicion of jejunoileal atresia. These signs include maternal polyhydramnios, bilious emesis, abdominal distention, jaundice, and failure to pass meconium on the first day of life (Table 82-2).[22,52,75–78] Polyhydramnios is observed in 24% of intestinal atresia cases and is more common in patients with proximal jejunal atresia (38%).[22] Bilious emesis is slightly more common in patients with jejunal atresia (84%), whereas abdominal distention is more common in patients with ileal atresia (98%).[75] Jaundice, which is characteristically associated with an elevation of indirect bilirubin,[79,80] occurs in 32% of infants with jejunal atresia and 20% of those with ileal atresia.[22] Although most infants with jejunoileal atresia fail to pass meconium in the first 24 hours of life, either meconium or necrotic tissue is occasionally passed.[20,47,63,75,77] Upper abdominal distention is often associated with more proximal atresia; more generalized distention usually indicates a more distal obstruction (e.g., distal small bowel or colon) in which many loops of bowel are filled with air proximal to the level of obstruction. Severe distention may be associated with respiratory distress as a result of elevation of the diaphragm. Because the abdomen is thin, the outline of the abdominal loops may be visible through the abdominal wall. Occasionally, peristaltic waves are visible on physical examination. Although distention usually develops 12 to 24 hours after birth, abdominal distention may be noted at birth. This suggests the presence of giant cystic meconium peritonitis.[75,81]

**TABLE 82-2**

## PRENATAL IMAGING

Prenatal ultrasonography (US) in mothers with polyhydramnios has identified small-bowel obstruction associated with atresia, volvulus, and meconium peritonitis[23,82–84]; however, it is more reliable in detecting proximal versus distal intestinal atresia. The presence of small-bowel atresia is suspected when US reveals multiple distended loops of proximal bowel with vigorous peristalsis.[85] In these patients, the distal bowel is decompressed. Intestinal atresia is also suspected in fetuses with gastroschisis and marked intestinal dilatation on prenatal US.[57,82]

Phelps and colleagues[86] reported that only 42% of prenatally diagnosed gastrointestinal malformations were confirmed postnatally and only 16% of gastrointestinal anomalies observed at birth had been detected antenatally. Further, although the appearance of echogenic bowel on prenatal US is frequently associated with a gastrointestinal malformation, only 27% of cases were confirmed after delivery. Basu and Burge[23] found that only 31% of patients with small-bowel atresias were diagnosed on antenatal US and noted that the later in gestation the US is performed, the more likely it is to detect the malformation. Studies reported by both Dalla Vecchia and colleagues[87] and Tam and Nicholls[88] corroborate the infrequency of US detection of small bowel atresias. When recognized, the atresia was more often in a proximal location and the infants required prolonged postnatal treatment. Collectively, these studies suggest that antenatal US findings have a relatively poor predictive value for bowel abnormalities and are also unreliable in detecting or excluding fetal gastrointestinal malformations. Moreover, these findings do not affect neonatal outcomes in patients with intestinal atresia.[89]

Over the past decade, studies of the utility of fetal magnetic resonance imaging (MRI) indicate that this modality can identify gastrointestinal abnormalities and suggest that it may be more accurate than US in the prenatal diagnosis of bowel atresia.[90–91] In view of these findings, we recommend that abnormalities or ambiguities on prenatal US be followed up with fetal MRI (Fig. 82-1).[92]

## POSTNATAL RADIOGRAPHIC FINDINGS

In most instances, radiographic examination of the abdomen demonstrates the presence of intestinal obstruction in the neonate. Supine and lateral decubitus abdominal radiographs are obtained in each case. Thumb-sized intestinal loops and air-fluid levels are highly suggestive of intestinal obstruction.[45] Proximal jejunal atresia may present with only a few air-fluid levels and no distal gas beyond the atresia

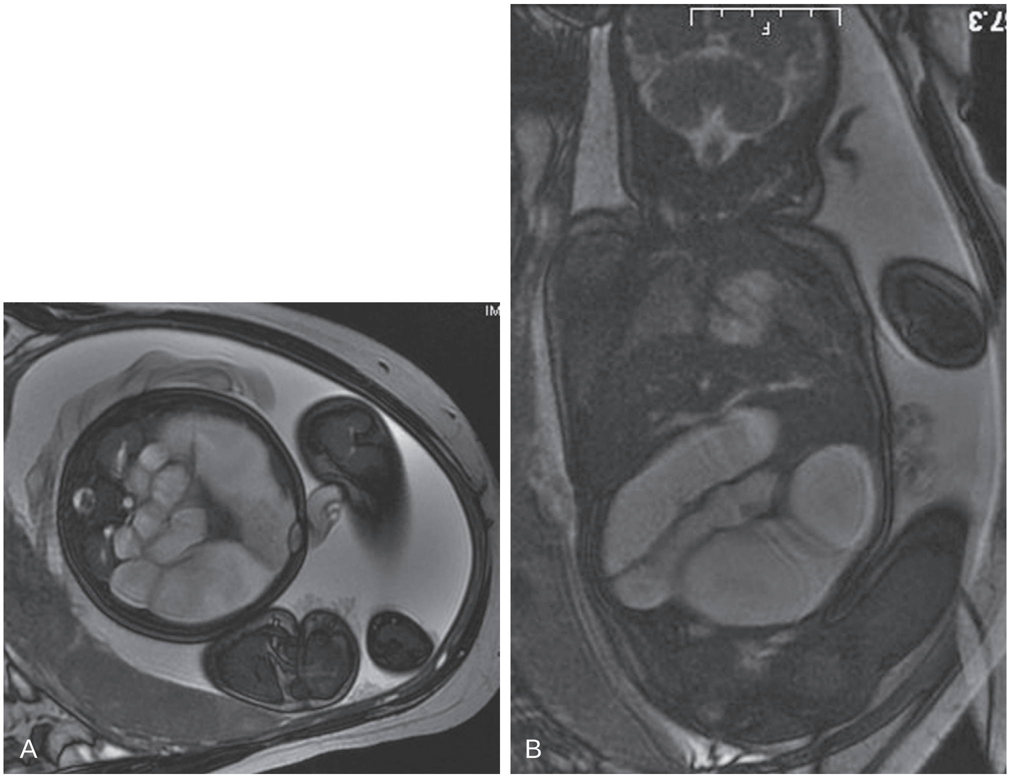

**FIGURE 82-1** Fetal magnetic resonance imaging (MRI). **A,** Axial. **B,** Coronal. Prenatal ultrasound demonstrated a bowel obstruction. MRI shows multiple dilated, fluid-filled bowel loops with no meconium. Findings are suggestive of distal bowel obstruction.

(Fig. 82-2). The more distal the atresia, the more apparent the abdominal distention and the greater the number of distended intestinal loops and air-fluid levels. Just proximal to the atresia, a larger loop with a significant air-fluid level may be seen (Fig. 82-3). Peritoneal calcifications are seen in 12% of cases on plain abdominal radiographs; these calcifications signify the presence of meconium peritonitis, a sign of intrauterine intestinal perforation (Fig. 82-4). In addition, instances of intraluminal calcification may be observed, indicating an antenatal volvulus with partial absorption of necrotic bowel.[93,94] In instances of giant cystic meconium peritonitis, plain radiographs of the abdomen may demonstrate a large air-fluid level in a meconium pseudocyst.[81] This type of occurrence is related to a late intrauterine perforation, resulting in an encapsulated mass (pseudocyst) of perforated bowel and contained meconium.[75,77]

Colonic haustral markings are rarely seen on abdominal radiographs in the newborn. Differentiating between dilated loops of small and large intestine thus becomes difficult. In these patients, a contrast enema can be extremely useful in distinguishing between small- and large-bowel distention; in determining if the colon is used or unused (microcolon); and in locating the position of the cecum in regard to the possible presence of anomalies of intestinal rotation and fixation.[75] The vast majority of infants with jejunoileal atresia demonstrate a microcolon, which is directly related to the fact that little meconium has passed the area of obstruction in the distal fetal small intestine, and the unused colon is therefore not distended.[95] If the intrauterine vascular event leading to atresia occurs extremely late in gestation, the colon may appear of normal caliber. This is particularly true in instances of atresia related to intrauterine intussusception (Fig. 82-5).[47,63,96] Malrotation has been observed in approximately 10% of patients with jejunoileal atresia[20,22] and was noted in 16.5% of patients with jejunoileal atresia at Riley Children's Hospital.[21]

When it is clear on a plain radiograph that there is a complete intestinal obstruction, contrast studies may not be necessary; however, in cases of intestinal stenosis where there is an incomplete obstruction, a small-bowel contrast enteroclysis study has a higher diagnostic yield than a routine small-bowel series.

## DIFFERENTIAL DIAGNOSIS

A neonate with a bowel obstruction from other causes may present with a clinical picture that is similar to that of a neonate with jejunoileal atresia. The differential diagnosis includes malrotation with or without volvulus, meconium ileus, intestinal duplication, internal hernia, colonic atresia, adynamic ileus secondary to sepsis, and total colonic aganglionosis.[10,29,97] The contrast enema yields valuable information that frequently rules out specific causes of obstruction such as colonic atresia. Because of the potential coexistence of jejunoileal atresia and malrotation (10% to 18%), meconium peritonitis (12%), meconium ileus (9% to 12%), total colonic aganglionosis, and rarely, intestinal neuronal dysplasia, a definitive preoperative diagnosis is not always possible.[10,20,29,75,98–101]

Radiographic subtleties may help distinguish uncomplicated meconium ileus from other neonatal intestinal obstructions. Radiographs of meconium ileus often show substantial distension of multiple bowel loops that have few, if any, air-fluid levels. This is related to the fact that the meconium in

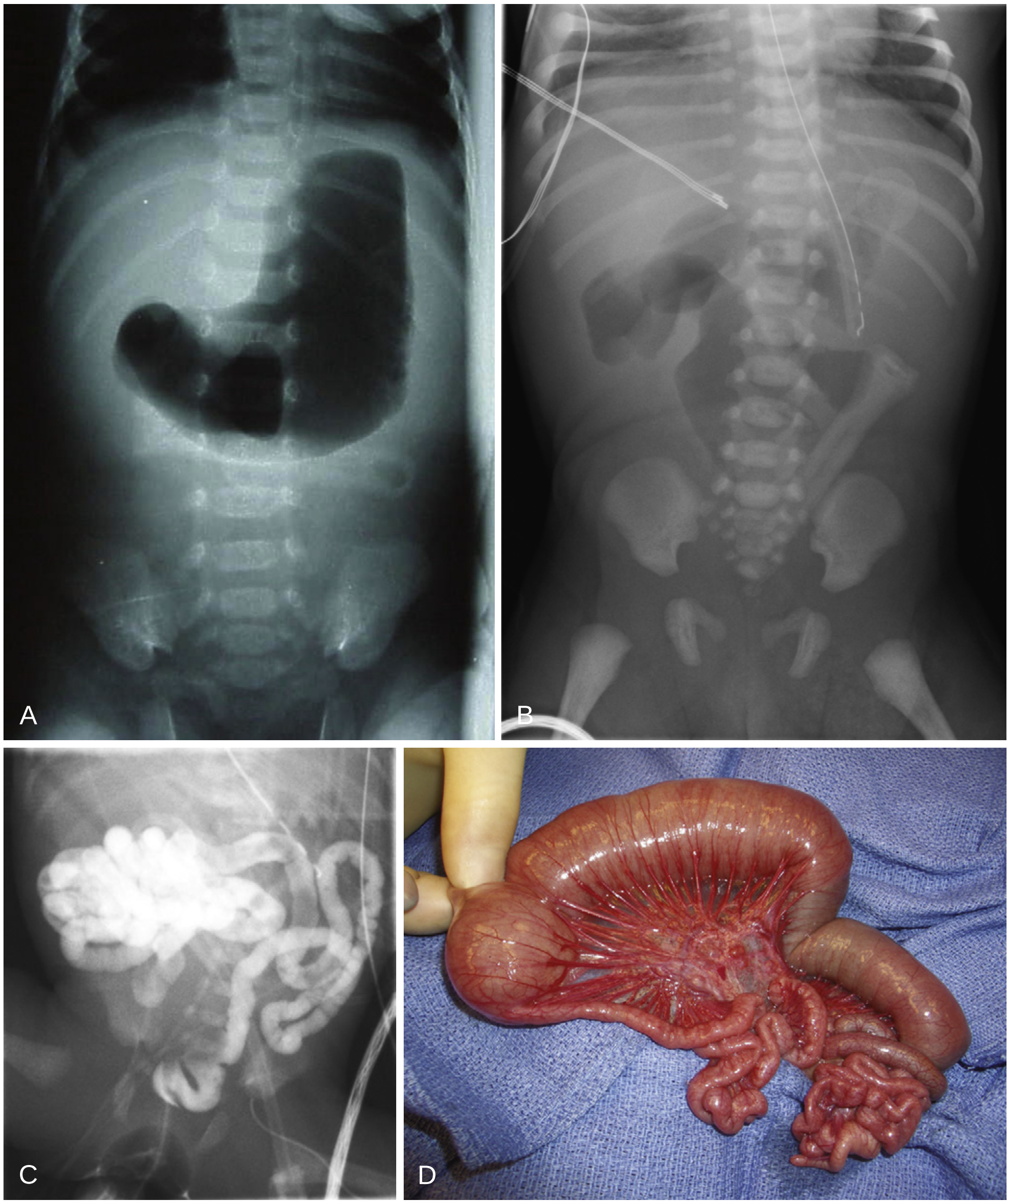

FIGURE 82-2 Jejunal atresia. **A** and **B,** Plain abdominal radiographs demonstrating a proximal small bowel obstruction. **C,** Contrast enema revealing an unused colon (microcolon) with incomplete rotation (cecum in the right upper quadrant). Contrast fills multiple decompressed loops of small intestine hinting at a proximal obstruction. **D,** Type I jejunal atresia seen at laparotomy. The appendix and cecum are seen in the bottom right of the photograph.

these patients is viscous and therefore fails to layer out as an air-fluid interface.[75] Other signs of meconium ileus include the ground-glass appearance (also referred to as Neuhauser sign) or the soap-bubble sign of Singleton, which may be observed in the right lower quadrant and is representative of the viscid meconium mixed with air.[102,103] Separating out patients with uncomplicated meconium ileus can avoid unnecessary operations. In cases where meconium ileus complicates an atresia, surgical intervention is required.

## PATHOLOGIC FINDINGS

Jejunoileal atresias are nearly equally distributed between the jejunum (51%) and the ileum (49%). Most atresias (36%) occur in the distal ileum; 13% occur in the proximal ileum; 31% occur in the proximal jejunum; and 20% occur in the distal jejunum.[22] Intestinal atresias are generally a single event (>90%); however, multiple atresias can occur (6% to 20%)[9,22,27] and most often involve the proximal jejunum.[72,104,105]

Since the observations of Bland-Sutton and Spriggs in the late nineteenth and early twentieth centuries,[4,8] the classification of jejunoileal atresia has changed only slightly. In 1955 Louw and Barnard described three different types of jejunoileal atresia: type I referred to a mucosal (septal) atresia with an intact bowel wall and its mesentery (Fig. 82-2, *D*); type II referred to two atretic blind ends connected by a fibrous cord with an intact mesentery; and type III comprised two separated segments of bowel with a V-shaped gap within the mesentery (Fig. 82-5, *C*).[10] In a study evaluating 559 cases

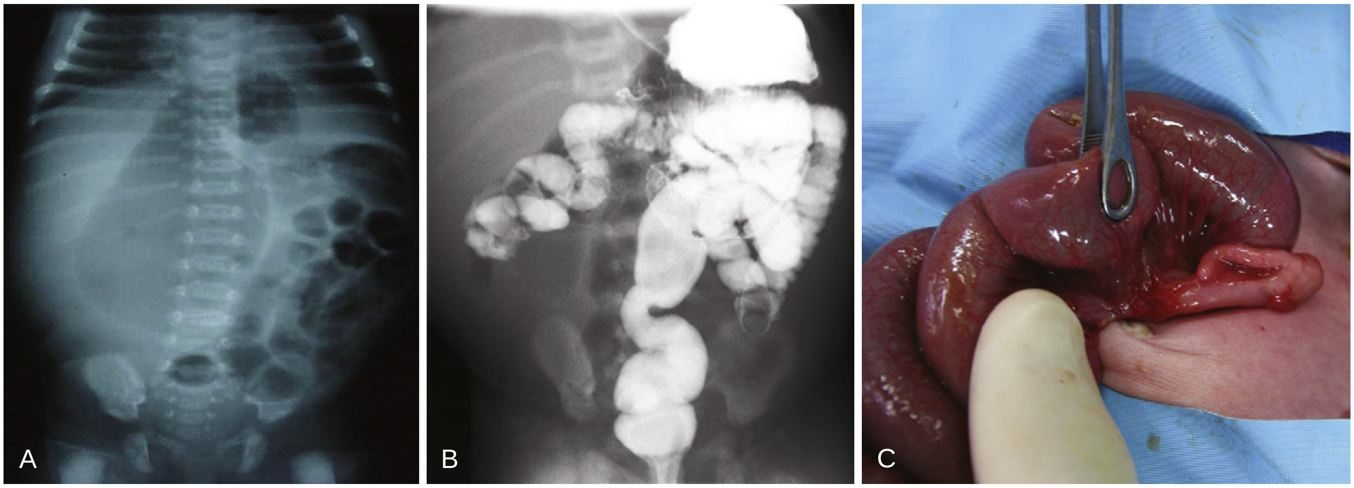

**FIGURE 82-3** Ileal atresia. **A,** Radiograph of the abdomen showing dilated loops of intestine with a very distended loop inhabiting most of the right abdomen. **B,** Contrast enema showing a small colon that does not fill the dilated loops of bowel. **C,** Distal ileal atresia with the terminal ileum and cecum seen on the right side of the photograph.

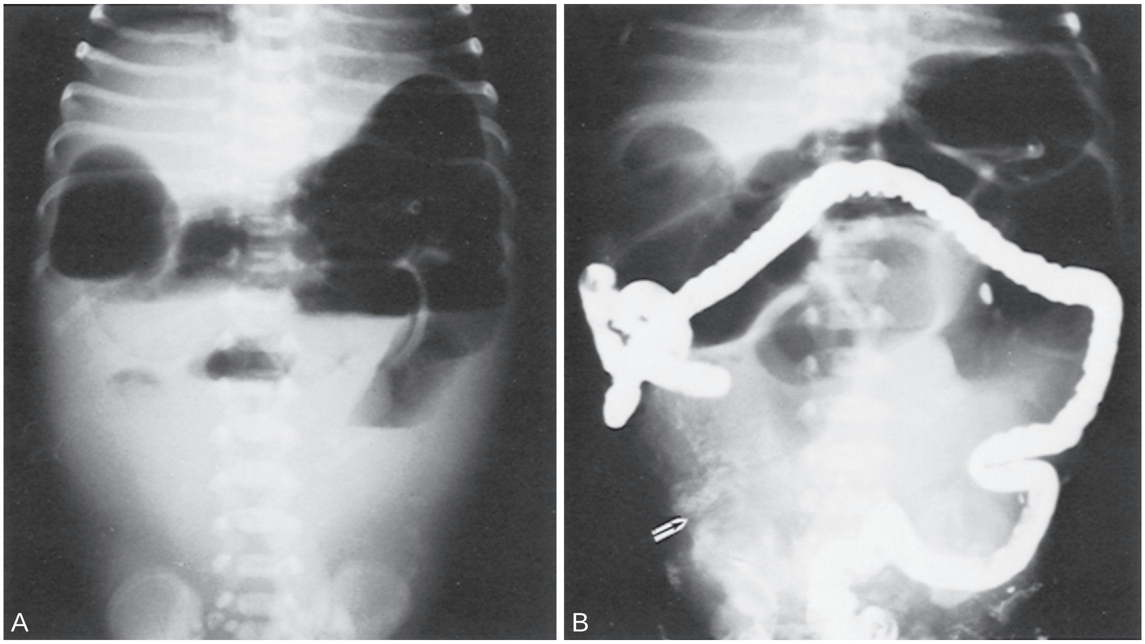

**FIGURE 82-4** Meconium peritonitis. **A,** Erect radiograph of the abdomen demonstrates greater than thumb-sized loops of intestine with multiple air-fluid levels. **B,** Barium enema demonstrates a microcolon with incomplete rotation (cecum in right upper quadrant) and calcification in the right lower quadrant (*arrow*) indicative of meconium peritonitis (From Grosfeld JL: Alimentary tract obstruction in the newborn. Curr Probl Pediatr 1975;5:3).

of jejunoileal atresia, de Lorimier and colleagues[22] reported that 19% were type I, 31% were type II, and 46% were type III. The authors noted that type I and type II atresia typically have a normal length of intestine as compared with the type III lesions, which are associated with a shorter bowel length caused by resorption of the fetal gut after a vascular accident.[22]

Although multiple atresias reportedly occur in 6% to 20% of cases,[9,22,27,106] they are not mentioned in the classification system of Louw and Barnard.[10] These atresias are associated with a foreshortened intestinal length, prematurity, and a high mortality. The appearance of the intestine at operation resembles a string of beads or string of sausages (Fig. 82-6).[106] A diffuse inflammatory process has been proposed as a contributing factor.[107]

Another unusual group of patients are those with apple-peel or *Christmas-tree* deformity, which occurs in 11% to 32.4%[108,109] of jejunoileal atresias. These patients present with proximal atresia near the ligament of Treitz, a large mesenteric defect, and foreshortened bowel. Additionally, the blood supply to the distal bowel is precariously supplied in a retrograde fashion by arcades from the ileocolic, right colic, or inferior mesenteric arteries (Fig. 82-7).[3,109–113]

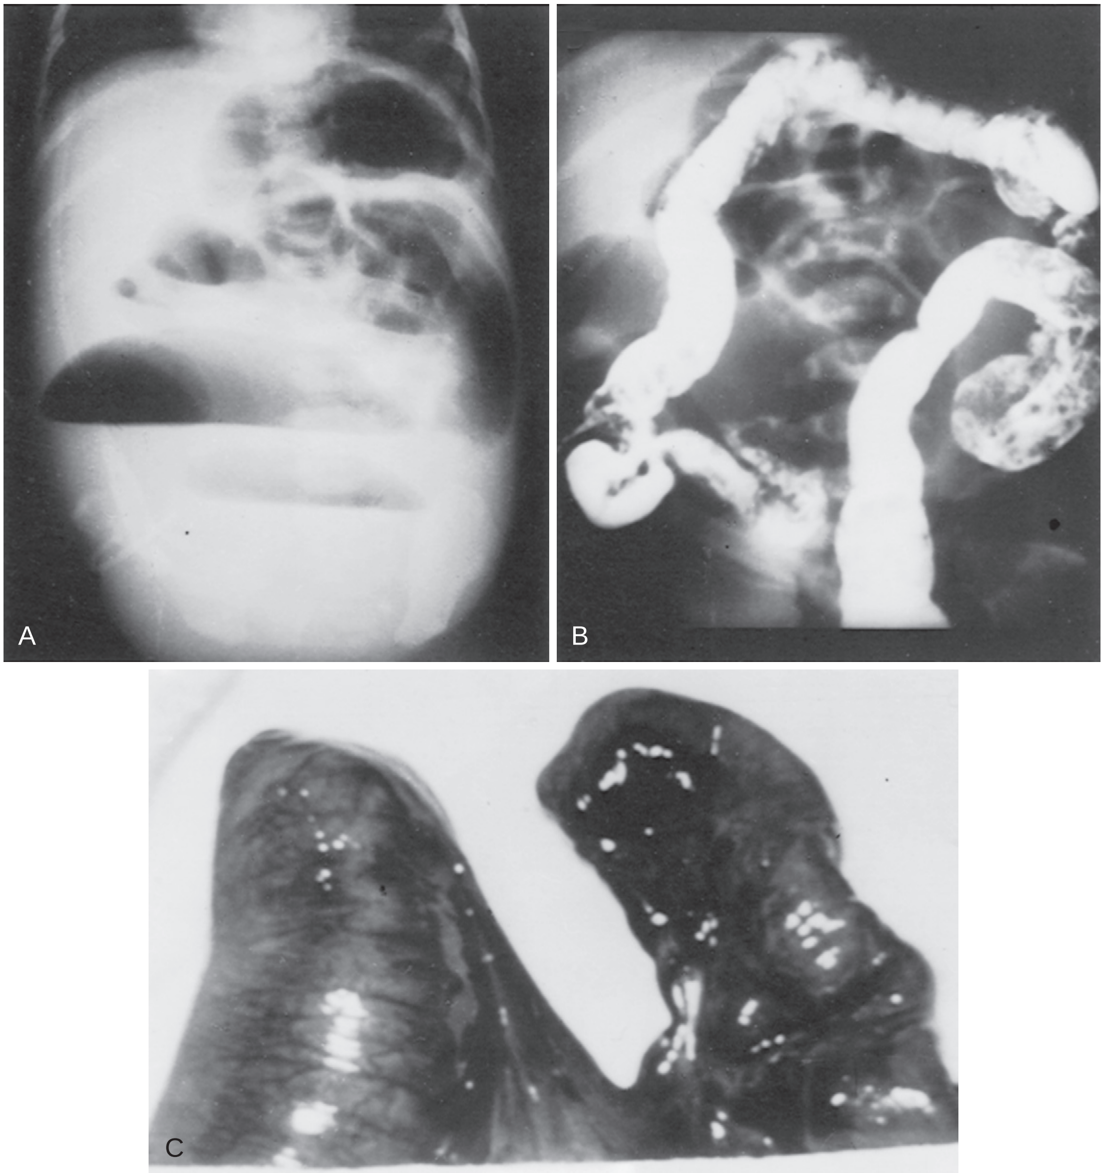

**FIGURE 82-5** Ileal atresia. **A,** Upright radiograph of abdomen showing distended loops of intestine with air fluid levels. **B,** Contrast enema showing normal-caliber colon filled with debris. **C,** At laparotomy, ileal atresia with a V-shaped defect in the mesentery (type IIIa) and evidence of an intrauterine intussusception were found. (From Grosfeld JL: Alimentary tract obstruction in the newborn. Curr Probl Pediatr 1975;5:3).

The apple-peel variant is associated with a familial pattern. Patients with this variant typically are premature (70%), of low birth weight (70%), have a high rate of malrotation (54%), and are associated with an increased number of congenital anomalies.[58,114] Apple-peel deformity has also been seen in siblings with ocular anomalies and microcephaly.[115]

A number of studies have focused on the genetic aspects of multiple atresias. In 1973 Guttman and colleagues[67] reported a familial pattern of multiple atresias affecting the stomach, duodenum, small intestine, and colon occurring in French Canadians near the St. John River in Quebec. Because of the high degree of consanguinity observed in this group, a number of authors[67,116] proposed that extensive multiple atresias are most likely an expression of a rare autosomal recessive gene. A report describing the natural history of the patients reported by Guttman was reported by Bilodeau and colleagues in 2004.[117] These authors found that all of these patients had an IgM deficiency and had died. The etiology remains unclear due to a specific gene mutation not yet elucidated.

The contemporary classification system that incorporates both multiple atresias and the apple-peel variant was first described by Martin in 1976[118] and later revised by Grosfeld and colleagues,[27] who incorporated these lesions into the previous nomenclature of Louw.[10] Type III atresias have been divided into type IIIa, which describes the previously designated type III lesion, and type IIIb, which refers to the apple-peel or Christmas-tree anomaly. Multiple atresias are referred to as type IV lesions (Fig. 82-8).[27]

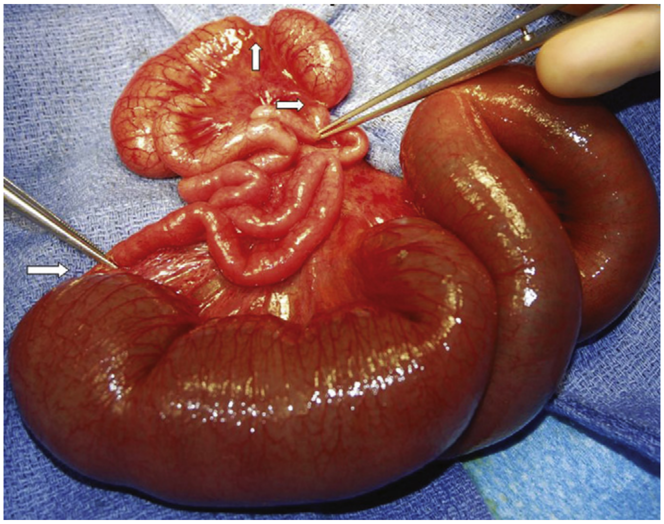

**FIGURE 82-6** Multiple atresias (type IV). Intraoperative photograph demonstrating multiple ileal atresias (*arrows*). This was repaired with a tapering enteroplasty and multiple single-layer anastomoses.

**FIGURE 82-7** *Apple-peel* atresia or *Christmas-tree* deformity (type IIIb). Presents with a proximal jejunal atresia with foreshortened bowel and a large mesenteric defect. The distal bowel has a precarious blood supply delivered in a retrograde fashion.

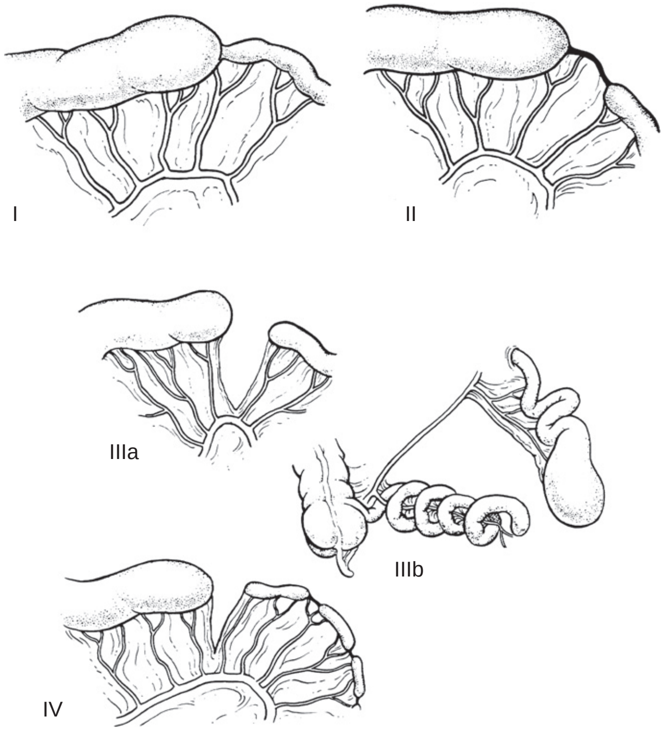

**FIGURE 82-8** Classification of intestinal atresia. Type I, mucosal (membranous) atresia with intact bowel wall and mesentery. Type II, blind ends are separated by a fibrous cord. Type IIIa, blind ends are separated by a V-shaped (gap) mesenteric defect. Type IIIb, apple-peel atresia. Type IV, multiple atresias (string of sausages). # Treatment

Optimally, the newborn is maintained in a warm humidified environment. A 10-Fr orogastric or nasogastric sump tube (Replogle tube) is placed, though smaller tubes may be required for premature infants. The color of the gastric contents is then noted because bile-stained fluid is commonly identified with intestinal obstruction. On suction, the tube allows decompression of the stomach and helps prevent gaseous distention of the bowel from swallowed air. This is helpful in preventing emesis and aspiration, especially during transport of the infant to radiology or another medical facility. Intravenous access is secured, and a laboratory workup is obtained. This workup includes basic electrolytes, a complete blood count, and a type and crossmatch. If a delay in diagnosis occurs or a more extensive workup is required, aggressive fluid resuscitation may be necessary. Close monitoring of the patient's fluid balance, especially urine output, is crucial, and significant fluid loss from the nasogastric tube should be replaced intravenously.

Once resuscitation is adequate, the neonate is taken to the operating room for an abdominal exploration. The entire operating room environment needs to be appropriate for an infant, with special attention paid to ensuring that the infant is kept warm. Abdominal access is typically gained through a right supraumbilical transverse incision that can be extended either medially or laterally as needed. Excellent communication between the surgical and anesthesia teams is vital to the maintenance of electrolyte and glucose homeostasis. This should include precise calculations for fluid and blood loss in order to accurately determine the appropriate replacements.

## OPERATIVE TECHNIQUES

The operative technique used for each patient with jejunoileal atresia is individualized and often depends on the pathologic type of atresia. Associated circumstances such as the presence

of malrotation, volvulus, meconium ileus, or meconium peritonitis may alter the type of operation performed. Additionally, if an abdominal wall defect is present (i.e., gastroschisis or omphalocele), the condition of the bowel and the stability of the patient influence the procedure performed.

Historically, cases in which the very distal segment of the proximal atresia was used to construct the anastomosis often resulted in a functional obstruction. A side-to-side anastomosis was also commonly used in early attempts to surgically correct jejunoileal atresia; however, these patients not only had a functional obstruction but also developed blind loop syndrome.[10,20,95,119] Studying the pathophysiology of the proximal segment of bowel has provided convincing evidence that this segment has ineffective peristalsis and fails to function with lower pressures seen postoperatively. At the microscopic level, Nixon[20,119] noted that the proximal atretic segment of bowel demonstrated significant smooth muscle hypertrophy and enlargement of the bowel diameter. These findings were confirmed by de Lorimier[120] and Cloutier,[121] who suggested that hyperplasia was the primary change occurring to the intestinal smooth muscle proximal to an obstruction. This hyperplasia may become so extreme proximal to a complete obstruction (as seen in an atresia) that the bowel may decompensate to the point that even a strong contraction cannot approximate the intestinal walls sufficiently to adequately generate a luminal pressure that permits efficient propulsion.[121] Several studies have also demonstrated an effect on the enteric nervous system in association with jejunoileal atresia. Investigations looking at chicks with experimentally induced small bowel atresias demonstrated structural changes to the enteric nervous system and attributed these abnormalities to the proximal bowel dilation.[122] In neonatal human specimens of the excised proximal atretic bowel, Masumoto and colleagues demonstrated the presence of hypoplasia of the enteric intramural nerves and C-kit positive pacemaker cells.[123] Elaborating on these findings, Tander and colleagues recently demonstrated a remarkable decrease of interstitial cells of Cajal (pacemaker cells of the gastrointestinal tract) in the wall of the small bowel of patients with intestinal atresia.[124] These investigators were unable to ascertain whether the reduction in these cells is a primary event or is secondary to other possible etiologies such as ischemia. In another relatively recent (2005) study, Ozguner and colleagues[125] observed segmental defects in muscular and neural structures of the intestinal wall on both mesenteric and antimesenteric sides of the atretic small bowel, thus supporting the vascular insult theory. The authors recommend adequate resection rather than tapering enteroplasty to avoid intestinal dysmotility.[125]

When dealing with a proximal jejunal atresia, resection of the proximal dilated atretic segment of bowel up to the ligament of Treitz, followed by an end-to-oblique anastomosis, can be performed if an adequate length of intestine is present. This scenario is typically successful and often avoids the complications of functional anastomotic obstruction and later development of the blind loop syndrome.[21] In the clinical setting of inadequate bowel length that could potentially lead to dependence on parenteral nutrition (short-bowel syndrome), tapering of the dilated bowel on the antimesenteric border should be performed with an end-to-end anastomosis.[126] Numerous authors have reported the applicability of tapering enteroplasty in selected cases.[127–131] de Lorimier and Harrison reported that intestinal imbrication effectively reduces the luminal diameter and restores function while preserving mucosal surface area. Nevertheless, this method tends to break down over 1 to 2 years, resulting in recurrent dilation.[132] Because of this complication, imbrication is no longer favored. For patients with a very proximal jejunal atresia, a lateral duodenectomy with a duodenojejunostomy is occasionally performed.[133]

At the start of the laparotomy, the bowel is gently eviscerated to allow for inspection of the intestine. The entire intestine is visualized, and the proximal and distal ends of the atresia are identified. The inspection process should include the identification of possible malrotation, volvulus, or segments of partially resorbed fetal intestine. If volvulus is identified, this is carefully reduced to ensure a complete evaluation of the pathologic anatomy. The bowel and its mesentery are displayed in their entirety, and the proposed anastomosis is aligned. Next, assessment of the distal segment of bowel is performed by placing a pursestring suture in the distal atretic segment of bowel; this segment is opened to allow for the placement of an 8-Fr red rubber catheter within the lumen of the distal bowel. The bowel is then injected with saline to rule out another atretic segment or distal mucosal membrane or web. If the distal bowel is unobstructed, a short segment of the distal atretic segment is resected at a 45-degree angle (more distal on the antimesenteric side).

A soft, atraumatic infant bowel clamp (Allen clamp) is applied on the proximal bowel at a 90-degree angle. This should be located slightly proximal to the planned resection site. If adequate bowel length is present, the proximal dilated atretic segment is resected back to the level at which the diameter of the intestine approaches 1 to 1.5 cm in circumference for ileal atresias. When the atresia is located in the very proximal jejunum, resection should be taken back toward the ligament of Treitz, but only so far that an anastomosis can be fashioned without difficulty. If a significant size discrepancy exists between the proximal and distal segments, which have been opened at an oblique angle, a Cheatle slit on the distal segment should be considered to alleviate the size discrepancy. A Cheatle slit is a longitudinal incision into the antimesenteric border of the small intestine. This incision ultimately allows for a wide-caliber elliptical anastomosis to be performed (Fig. 82-9).

A one- or two-layer anastomosis is then performed depending on the surgeon's preference. The single-layered anastomosis is typically performed with simple interrupted sutures using any of a number of suture types. For a two-layer anastomosis, the posterior outer layer is initiated with interrupted 5-0 silk sutures. The bowel clamp is removed, and the crushed tissue is trimmed. The inner layer can be approximated with simple interrupted sutures or in Connell fashion (in-out, out-in) with the knots on the inside. Absorbable 5-0 or 6-0 suture (i.e., Vicryl, PDS, or Maxon) can be used for the inner layer. The outer anterior layer is completed with a seromuscular interrupted Lembert closure using 5-0 silk or Vicryl sutures. Differences in the leak and stenosis rates between the two techniques have not been clearly established. The mesenteric defect is carefully approximated, avoiding injury to the mesenteric blood vessels and ensuring that the geometric lie of the anastomosis does not compromise the blood supply or obstruct the lumen of the distal bowel.

In the case of type IV atresias, especially when intestinal length is in question, a concerted effort is made to preserve as much bowel as possible. To accomplish this goal, multiple

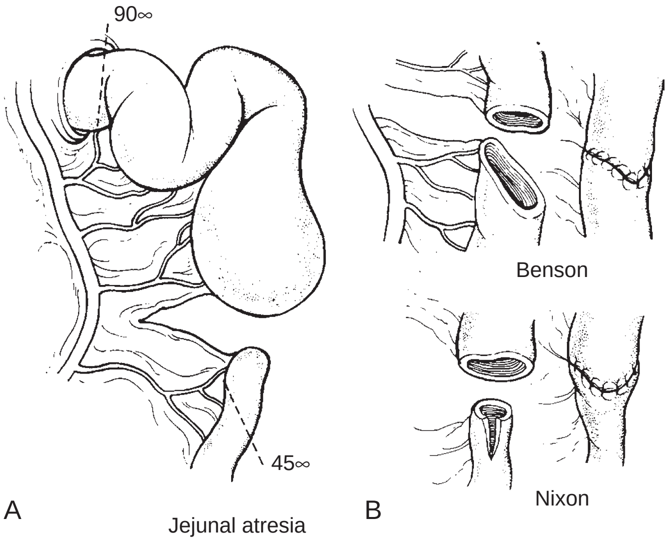

**FIGURE 82-9** Techniques of anastomosis. **A,** The proximal atretic segment is resected at a 90-degree angle and the distal segment at a 45-degree angle. **B,** End-to-oblique anastomosis is carried out by the techniques of Benson (one-layer) or Nixon (two-layer) with fine interrupted sutures. The Nixon anastomosis depicts a Cheatle slit on the antimesenteric border of the distal limb.

anastomoses may be necessary.[134,135] Typically, the distal atretic segments are decompressed, and if the lumina are patent, end-to-end anastomoses can be fashioned (Fig. 82-10). The technique of stenting multiple atresias has been described, with reports of excellent outcomes, albeit in limited patient populations.[136–138]

If the length of bowel is perceived to be inadequate and the proximal segment (typically the jejunum) is significantly dilated, a tapering antimesenteric jejunoplasty is performed. This is accomplished by using either a hand-sewn or stapling enteroplasty. The most bulbous portion of the proximal atretic segment is resected, and the remaining bowel is tapered over a 24- to 26-Fr catheter guide, which is placed within the lumen on the mesenteric side of the intestine. The enteroplasty is then carried out to the ligament of Treitz. If a stapler is used, the staple line is typically oversewn with interrupted 5-0 sutures and the anastomosis is completed in an end-to-oblique fashion in either one or two layers, as previously described (Fig. 82-11). Ismail and colleagues[139] described a new option for a dilated proximal segment in conjunction with short bowel. These authors performed a serial transverse enteroplasty (STEP), which lengthens the bowel and increases the mucosal surface area.

At completion of operation the orogastric or nasogastric tube position is confirmed and secured in place. Alternatively, when there is concern of short gut, gastrostomy tube placement may be beneficial for long-term management.

Although a primary anastomosis is the preferred method of treatment, this method is inadvisable in certain circumstances. In the setting of an atresia with a volvulus when the vascular integrity of the intestine is in question, or in severe cases of meconium peritonitis, the creation of an enterostomy is warranted. The most expeditious procedures are either a side-by-side (modified Mikulicz)[140–143] double-barrel enterostomy brought out through the wound or separate proximal and distal stomas brought out at opposite ends of the wound

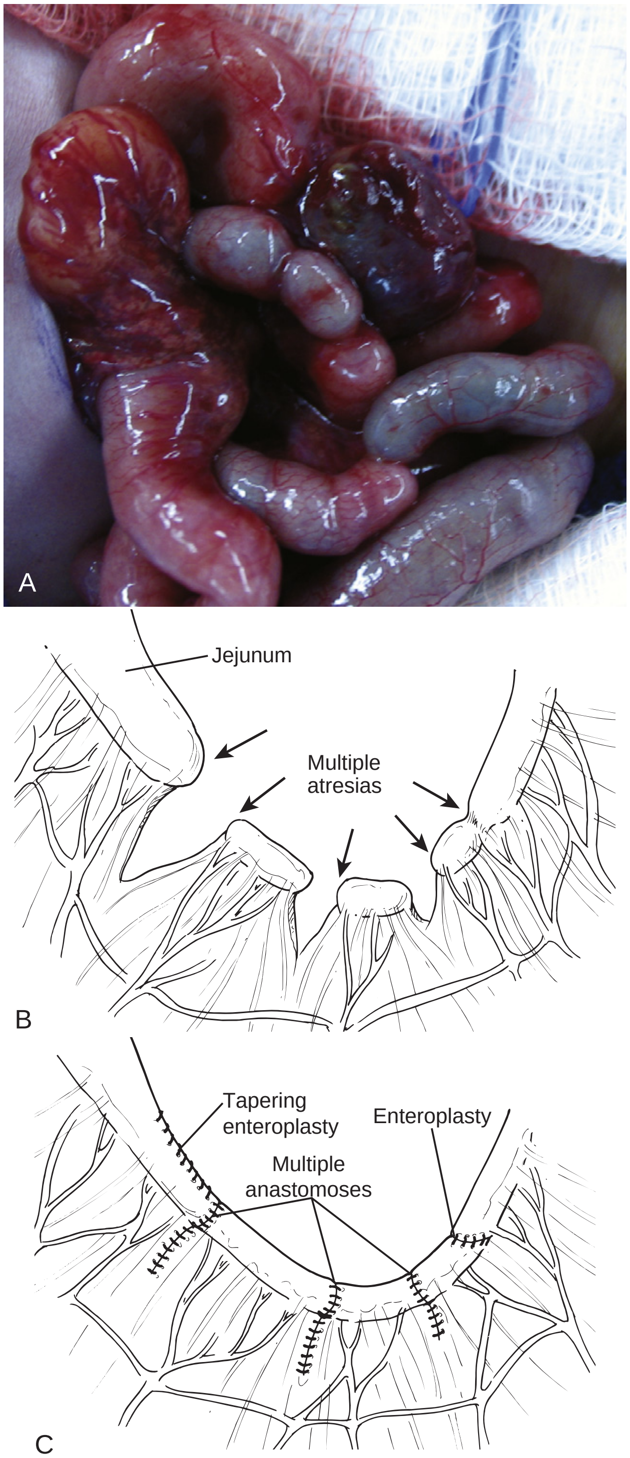

**FIGURE 82-10** Repair of type IV jejunoileal atresias. **A,** Operative photograph of a neonate with multiple small bowel atresias. **B,** Illustration documents multiple atresias. The distal atresias are not dilated. **C,** Proximal tapering jejunoplasty and multiple anastomoses for types II and IIIa atresias and a transverse enteroplasty for type I atresia were performed to preserve bowel length.

and fixed to the abdominal wall with a minimal number of interrupted 5-0 or 6-0 absorbable sutures. Depending on anatomy, as well as the surgeon's preference, the location of the enterostomy and the mucous fistula can also be positioned outside of the wound. Less frequently used but acceptable

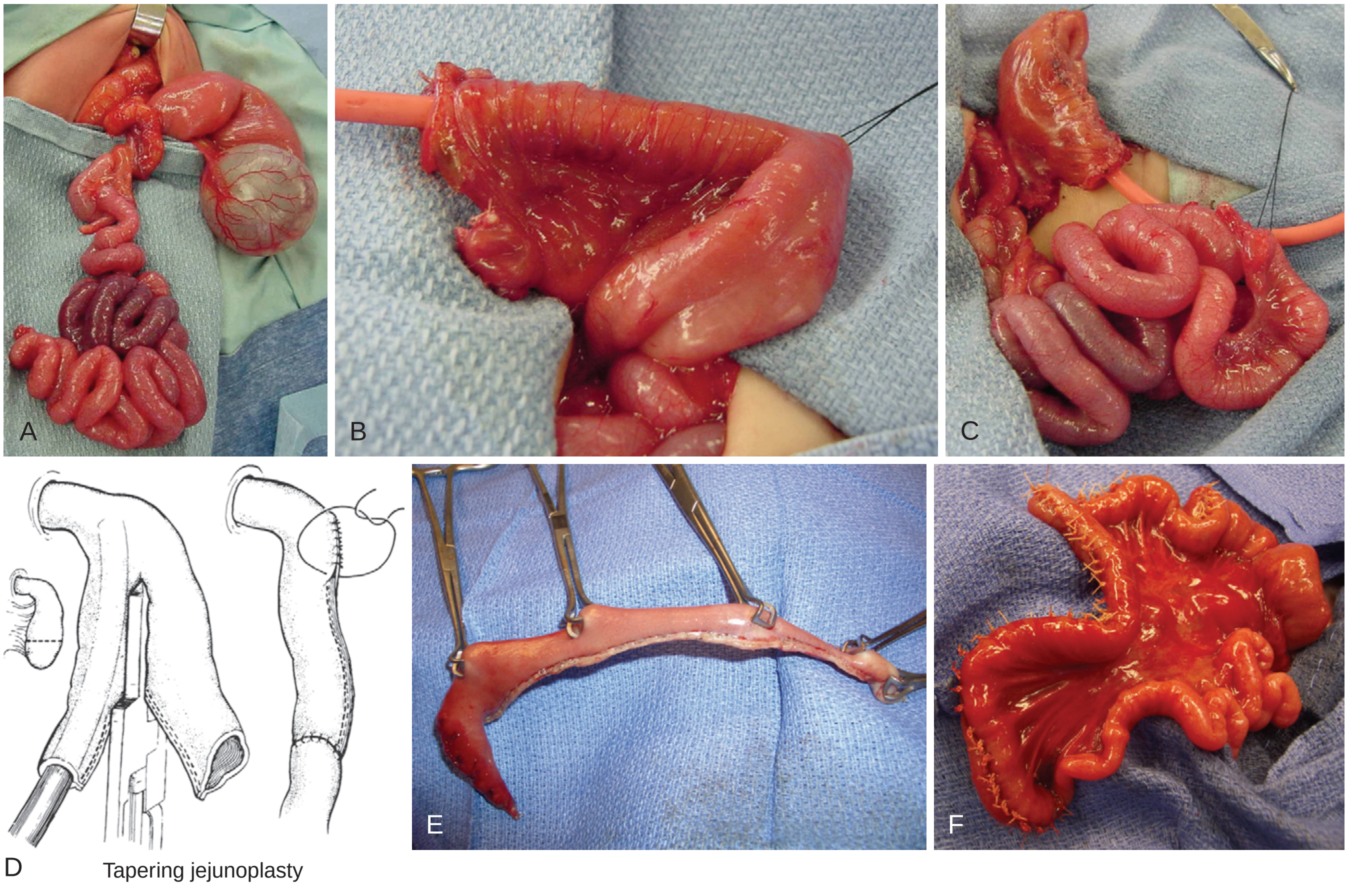

**FIGURE 82-11** Tapering enteroplasty. **A,** Dilated proximal jejunal atresia (type IIIb). Repair was performed with a tapering enteroplasty. **B,** Dilated jejunum is decompressed, and a 26-Fr catheter is positioned on the mesenteric side of the lumen to help size the enteroplasty. **C,** Operative photograph demonstrating a hand-sewn jejunoplasty. **D,** Illustration of a stapled enteroplasty with an antimesenteric resection. alternatives in these situations are the creation of a Bishop-Koop (distal stoma),[98] Santulli (proximal stoma),[35] or Rehbein tube[61] anastomotic enterostomies (Fig. 82-12). If an atresia is present in the setting of a gastroschisis, the unrepaired atretic segments of bowel are typically returned to the abdominal cavity, either as part of a primary closure or following silo placement with delayed abdominal closure. The volume of gastrointestinal succus is monitored closely with the use of a Replogle tube. Delayed anastomosis to restore intestinal continuity is performed 3 to 12 weeks after abdominal closure.

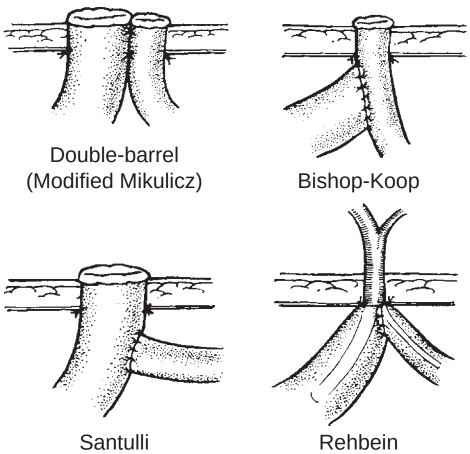

**FIGURE 82-12** Types of exteriorization procedures. These procedures can be used in instances of severe peritonitis, questionable bowel viability, and meconium ileus.

## Postoperative Care

At completion of the procedure, care is taken to ensure the baby is kept warm and is well monitored during transport back to the neonatal intensive care unit (NICU). Maintaining fluid and electrolyte balance is a key component of postoperative care. Intravenous fluids (10% dextrose in 0.25% normal saline along with 2 to 3 mEq/kg/day of potassium chloride) are administered, with a total fluid volume goal of approximately 100 mL/kg/day. If the gastric output is clear and greater than 30 mL/kg/day, it is replaced with 0.45% normal saline. If the output is bilious, it is replaced with lactated Ringer solution. Hydration status should be closely observed, primarily by monitoring urine output. An output of 1.5 to 2 mL/kg/hr, specific gravity of 1.005 to 1.015, and body weight stability usually indicate appropriate hydration. Because of excessive third-space losses, additional fluid boluses with 0.9% normal saline may be required. Postoperative laboratory examination includes serum electrolytes, glucose level, a complete blood

count, and acid-base balance. Serum electrolyte values are monitored over the first few postoperative days. Total parenteral nutrition is initiated after the first 24 hours, with a gradual increase in the glucose infusion rate.

When bowel function returns and the gastric drainage fluid is clear and of minimal volume, the Replogle tube is removed. This tube can be placed to gravity or elevated with a Farrell bag before removal, which tests for gastric or intestinal reflux. Once satisfactory return of bowel function is confirmed, enteral feeding is initiated. The approach to introducing feeds varies, depending on both the institution and the physician. One option is to use a small nasogastric feeding tube with the gradual introduction of either breast milk or formula. Once tube feeds are tolerated, the patient is transitioned to oral feeds. An alternative approach is starting with small amounts of oral clear liquids (Pedialyte) and transitioning to milk-based feeds. The quantity with which to initiate feeds ranges from 5 mL to 15 mL and depends on patient factors such as the size and the length of the gut. The overall feeding goal is to provide the nutritional requirements sufficient for growth; for the newborn, this is approximately 120 calories/kg/day. Breast milk is the preferred feeding choice; however, if this is not available, a low osmolar small-curd formula (Isomil) is initially given. Lactose intolerance is frequently a problem after major bowel resection, and milk-curd obstruction of the small intestinal anastomosis may occur if a large-curd formula is given at this time.[144]

In the case of an extended bowel resection or conditions in which bowel function is compromised, diarrhea or malabsorption may be significant. Formulas that contain long-chain fats should not be used. Rather, a medium-chain triglyceride or casein hydrolysate formula (Pregestimil) is given. Parenteral nutrition, with special attention to lipid and protein administration, should be carefully watched and liver-sparing strategies should be optimized. Further details about the treatment of short-bowel syndrome are discussed in Chapter 88.

## Morbidity and Mortality

Infections related to pneumonia, peritonitis, or sepsis are the most common causes of early death in infants with jejunoileal atresia.[22] Functional intestinal obstruction at the site of the anastomosis and anastomotic leak are the two most significant postoperative complications and are associated with a reported mortality rate of 15%.[20,22] Other factors affecting morbidity and mortality include the presence of associated anomalies, respiratory distress, prematurity, short-bowel syndrome, and postoperative bowel obstruction resulting from volvulus with bowel infarction[22] Before the 1990s, the survival rate of infants with jejunal atresia was lower than that of infants with ileal atresia (58% vs. 75%, respectively). Also, the mortality rate was higher in infants with multiple atresias (57%) and apple-peel atresias (71%) and when atresia was associated with meconium ileus (65%), meconium peritonitis (50%), and gastroschisis (66%).*

Before the routine use of parenteral nutrition, Nixon and Tawes[20] proposed a risk stratification schema to allow for a more critical evaluation of survival in infants with jejunoileal atresia. According to this schema, infants were placed into one of three risk groups: group A comprised infants weighing more than 5.5 lb and having no other significant abnormalities; group B comprised infants weighing from 4 to 5.5 lb or those having a moderately severe associated malformation; and group C comprised infants weighing less than 4 lb or having a severe associated abnormality. The authors reported a much higher survival rate in infants in groups A and B (81%) as compared with those in group C (32%). In conjunction with this risk assessment, infants were further subdivided by anatomic location of the atresia into those with high-jejunal, mid-small-bowel, and distal ileal atresias. Findings showed that patients with high-jejunal atresia in group A or B had a 60% survival, whereas all of the patients in group C died. Infants with mid-small-bowel atresia in group A or B had an 82% survival, whereas those in group C had only a 32% survival. Survival for atresias involving the distal ileum in infants in group A or B was 100%; for those in group C, survival dropped to 50%.

In 1969 de Lorimier and colleagues[20] investigated the effect of wide proximal resection and end-to-end anastomosis on survival. Their findings demonstrated that resection improved survival in patients with jejunal atresia, increasing it from 39% to 66%; however, resection had little effect on the survival of patients with ileal atresia. Louw[147] reported a 94% survival rate after wide proximal resection with an end-to-oblique single-layered anastomosis in 33 patients with jejunoileal atresia. In this series, two patients had anastomotic leaks and two deaths occurred in neonates categorized as group C patients. In 1976 Martin and Zerella[118] reported a 100% survival rate in a series of 23 patients with jejunoileal atresia.

A number of reports published from 1985 to 2001 describe overall survival rates in patients with jejunoileal atresia that range from 80% to 90% or greater.[43,77,87,148] Owing to advancements in NICUs in regard to ventilation management, infection control, and treatment of sepsis, prematurity and low birth weight have a less adverse impact than indicated in earlier reports. Factors currently considered to have an adverse impact include the presence of malrotation, associated anomalies, and the need for stomas, particularly those that are multiple or proximal.[145] Late death occurs in patients with jejunoileal atresia when complicated by gastroschisis and short-bowel syndrome; these patients may succumb to infectious complications or liver failure.

A review (1999) of 449 cases of intestinal atresia at the Beijing Children's Hospital indicated a reduction in mortality from 64.7% to 18.6%; this reduction was attributed to successful parenteral nutrition and adoption of longitudinal oblique anastomoses.[149] Excellent long-term outcomes (80% survival) have been achieved with this approach, even in patients with apple-peel atresia.[87,150,151] Parenteral nutrition avoids protein-calorie malnutrition, establishes positive nitrogen balance, and allows for a relatively safe waiting period in infants with short-bowel syndrome and in those who have undergone temporary exteriorization procedures. A recent (2009) study by Stollman and colleagues looking at infants with jejunoileal atresia in the Netherlands over more than 3 decades reported decreased mortality but increased morbidity.[11] The authors report that short-bowel syndrome presents a significant management challenge and often results in a longer hospital stay, more feeding problems, and higher morbidity and mortality rates.[11] In another recent (2008) study, Piper and colleagues[152] found that infants with

*References 22, 72, 75, 77, 111, 118, 145, 146.

intestinal atresia, a birth weight less than 2 kg, and associated anomalies are at an increased risk for prolonged hospital stay and mortality. Twenty-five percent of patients in this study required a second operation, including lysis of adhesions (33%), a tapering enteroplasty (33%), and resection of a stenotic segment of bowel with tapering (33%). Despite these complications, overall mortality was only 3.3%.

Several studies[26,32,153] have shown that infants with more distal ileal resections are more prone to malabsorption (fat, bile salts, vitamin $B_{12}$, calcium, magnesium), diarrhea (steatorrhea), and increased bacterial proliferation and overgrowth. Although many infants with short-bowel syndrome survive, they require ongoing monitoring for renal stones, gallstones, and malabsorption. Late anastomotic ulcers presenting as either melena or iron-deficiency anemia have also been reported.[154,155] In view of these collective findings, we strongly recommend long-term follow-up of all neonates treated for complicated jejunoileal atresia.

CHAPTER 83

# Meconium Ileus

Moritz M. Ziegler

## History

Meconium ileus was first described in 1905 when Landsteiner linked the observation of meconium obstructing the small bowel with pathologic changes in the pancreas, which he attributed to a putative enzyme deficiency. Subsequent authors recognized a similar association of a thickened and tenacious meconium with a mechanical pancreatic duct obstruction or stenosis.[1–4] The term *cystic fibrosis* of the pancreas was first coined in 1936 by Fanconi to describe the association of chronic pulmonary disease of infancy with pancreatic insufficiency.[5] However, it was Anderson who described, in 1938, the relationship of the histologic likeness of pancreatic abnormalities in both meconium ileus and cystic fibrosis (CF) and described meconium ileus as an early and more severe manifestation of the overall lung and pancreatic insufficiency.[6,7] Subsequent authors defined the inspissated nature of meconium, linking the finding to both pancreatic insufficiency, as well as to abnormal mucus secreted by the intestine of patients with CF.[8–13]

With progress in the science of genetics, CF is now recognized as the most common potentially lethal autosomal recessive disease in the Caucasian population. Meconium ileus itself carried an almost uniformly fatal prognosis into the late 1940s,[13–15] when a series of interventions were devised that by design either eliminated or bypassed the obstructing inspissated intraluminal meconium, minimizing the operative intestinal manipulation and even the need for a general anesthetic to minimize the physiologic insult to the infant. In 1969 a novel therapy applied a transrectal irrigation and solubilization of the desiccated and tenacious meconium with the use of the hyperosmolar diatrizoate (Gastrografin) enema, permitting treatment of uncomplicated meconium ileus without the need for any operative intervention, a success that has been sustained for more than two thirds of patients.[16] By the early 1970s these advances along with an improved management of the electrolyte, nutritional, and pulmonary abnormalities of CF had improved patient survival to almost 75%.[17,18]

In the past 2 decades we have seen continued progress. First, the genetic lesion of a mutation in the CF transmembrane regulator *(CFTR)* gene was defined as the causal lesion of CF,[19,20] and it is now recognized that patients with meconium ileus likely represent a distinct phenotype with earlier presentation and worse pulmonary function.[21,22] Second, the diagnostic criteria remain largely the same clinically, with definitive diagnosis achieved by a combination of biochemical and now genetic testing. Interestingly, when enema irrigation is not successful in managing meconium ileus and relieving its bowel obstruction, the preferred operative intervention is that described originally in 1948, namely, enterotomy followed by irrigation, typically using meconium-solubilizing agents. These strategies, coupled with aggressive attention to the pulmonary and nutritional status of the patient, have seen a continued improvement of patient survival now approaching 95% to 100%.[17,23,24]

## Pathophysiology

### GENETICS

Cystic fibrosis is an autosomal recessive disease that occurs among whites with a heterozygote frequency of 1 in 29 births. It is rare in blacks (1/17,000 live births), and it is almost unheard of in Asians (1/90,000 live births) and Africans. The 5% to 6% carrier rate of the abnormal gene in whites results in a CF incidence of 1 per 1150 to 2500 live births. An offspring of two heterozygous parents has a 1 in 4 chance of developing the disease.[25] Meconium ileus, potentially unique to CF, represents a disorder of neonates characterized by intestinal obstruction secondary to the intraluminal accumulation of inspissated and desiccated meconium. Meconium ileus is the earliest clinical manifestation of CF because such patients are typically diagnosed and treated in the immediate neonatal period.[26] Meconium ileus has been reported to be the presenting feature of 20.8% of the CF population in the United States. Importantly for in-utero diagnosis, a family history of CF has been found in 10% to 40% of new patients with meconium ileus. In the presence of an index case of meconium ileus complicating CF, reports have suggested that an incidence of subsequent meconium ileus in the presence of CF varies from 30% to 40%.

In 1989 the genetic mutation that codes for the cell membrane protein termed the *CF transmembrane regulator* was identified by Francis Collins as that locus associated with the diagnosis of CF.[27,28] This locus was identified on the long arm of chromosome 7, band q31.[29] The protein was identified as a cyclic adenosine monophosphate–induced chloride channel that regulates ion flow across the apical surface of

epithelial cells.[30] One of more than 400 mutations of the *CFTR* that have been identified produces abnormal electrolyte content along the external apical environment of epithelial membranes. Tubular structures lined by such affected epithelia will be characterized by desiccation and reduced clearance of their secretions, and the affected systems include epithelial cells of respiratory, gastrointestinal, biliary, pancreatic, and reproductive systems. The clinical correlate of this pathophysiology has included pancreatic insufficiency (90%), meconium ileus (10% to 20%), diabetes mellitus (20%), obstructive biliary disease (15% to 20%), and azoospermia (nearly 100%). The exact mechanism of the epithelial glandular abnormality and the elaboration of a hyperviscous mucin remain unsolved. Certainly, the tenacious meconium protein and water content and its increased viscosity have all been described.

The *ΔF508* mutation is the most common of many *CFTR* gene locations, occurring as a homozygous pair in almost 50% of CF patients, whereas another 25% to 30% of patients will have one copy of this mutation. Such homozygous individuals nearly always phenotypically express pancreatic exocrine insufficiency, and they also present with a higher incidence of meconium ileus. A similar higher frequency of meconium ileus is also seen in *ΔF508*-expressing patients who also express *G542X*. However, the disease etiology is less clear when it is recognized that not all such genotypic patients will have meconium ileus. The association of obstructive lung disease with meconium ileus suggests other *CFTR* modifier genes or even environmental factors that may play a role in this disorder. Furthermore, large patient consortia have failed to identify predictors of the complications of CF including an incidence for meconium ileus.

## PATHOGENESIS

The defect of CF is an exocrine-eccrine gland dysfunction, particularly of the mucus-secreting and sweat glands.[31] Pancreatic achylia was thought to be the mechanism responsible for meconium ileus because of early reports of meconium-induced bowel obstruction in patients with congenital stenosis of the pancreatic ducts. However, data that began accumulating in the 1940s suggested that lesions in the pancreas of patients with CF were variable and were most profound in children older than 1 year of age. In contrast, the preponderance of intestinal mucosal gland abnormalities in the subset of patients with CF and meconium ileus was more striking, suggesting that these glandular lesions were the more likely origin of the tenacious material that causes the intraluminal obstruction in patients with meconium ileus.[32] Additional pathologic data have been interpreted to suggest that intestinal glandular disease plays the dominant role and pancreatic disease a secondary role in the pathogenesis of meconium ileus.[33,34]

The glandular abnormality accounting for or producing these changes is less certain. Various explanations include the glandular secretion of hyperpermeable mucus mediated by calcium that influences the physicochemical properties of mucus to be viscid and permeable to the loss of water, further concentrating intraductal secretions. This glandular-obstructing mucus would lead to the pathologic lesions noted earlier. A second hypothesis is that an impairment of fluid movement to and from the extravascular space through secretory cells exists that may prevent the normal dilution of the cellular lumen.[26,35] The highly concentrated material then becomes toxic to those cells laden with the product.

Soon after the *CFTR* gene was located on chromosome 7 by restriction fragment length polymorphism analysis, it was recognized that *CFTR* was itself a membrane chloride channel and that it further regulated chloride conductance through other channels.[36] This may be the mechanism that forms the basis for the increased levels of sodium and chloride in the eccrine sweat gland secretions that characterize patients with CF. Here a defect in electrolyte resorption of sodium and water by ductular cells and the impermeability of these cells to chloride ions result in an excretory product high in both sodium and chloride. This theory may be supported by the known characteristics of the CFTR membrane protein, which as a chloride channel, functions to regulate salt and water transport onto epithelial surfaces. Thus a disturbed function alters exocrine secretion electrolyte content and may lead to desiccation and reduced clearance of such secretions.

Meconium itself has a variable composition, as seen from samples from varying intestinal locations of normal infants at varying gestational ages that are contrasted to meconium isolated from patients with CF with and without meconium ileus.[37] The meconium concentrations of sodium, potassium, and magnesium are almost twice as high in samples from normal children or well siblings than in samples from children with CF with or without meconium ileus. Similarly, the enzyme-catalyzing heavy metals are also at higher levels in meconium from control and well siblings than from children with CF with or without meconium ileus. Samples from patients with meconium ileus also differ from normal meconium by containing greater amounts of protein nitrogen and lesser amounts of carbohydrate. Analysis of the protein content of abnormal meconium results in a further identification of abnormal mucoproteins. These products are two-thirds protein and one-third carbohydrate, a composition similar to duodenal fluid from patients with CF. The origin of these proteins is uncertain, but they may arise from either glandular secretions or swallowed amniotic fluid in utero. Because most of this protein is albumin, it is speculated that the intraluminal proteins are of plasma origin. They react with mucopolysaccharides, and, in the absence of degrading enzymes, they impart a highly viscid rubbery character to the involved secretions. The viscosity of these mucoproteins could be further influenced by the surrounding electrolyte environment. Finally, this increased albumin content of meconium from patients with CF has led to the development of a meconium screening test for the diagnosis of the disease.

In summary, two simultaneous pathogenetic events in meconium ileus appear to begin in utero and result in an intraluminal accumulation of a highly viscid and tenacious meconium: the developments of pancreatic exocrine enzyme deficiency and the secretion of hyperviscous mucus by pathologically abnormal intestinal glands. The thickened meconium accumulates and begins in utero to obstruct the intestine lumen. This accumulation accounts for the mechanism of the complications of meconium ileus (i.e., twist of a heavy loop with perforation, peritonitis, and cyst or atresia) and the pattern of abdominal distention and obstruction seen in the neonate. The proximal ileum dilates, and its wall thickens as it becomes filled with the tenacious and tarry meconium. Concomitantly, the narrowed distal small bowel

and, at times, the colon contains beaded or "boxcar" concretions of gray-white, putty-like inspissated meconium. The more distal colon is small or unused, a microcolon.

## Clinical Features

### SPECTRUM OF THE DISORDER

Meconium ileus presents in the neonate as uncomplicated or simple or as complicated. In the older child or young adult the presentation is as a meconium ileus equivalent or distal ileal obstruction syndrome.

Uncomplicated meconium ileus typically presents immediately at birth with the recognition of abdominal distention, a unique feature of inspissated meconium filling and obstructing the distal small bowel. This problem may first have been heralded by an in utero genetic diagnosis of CF and an ultrasound suggestive of intestinal obstruction with echogenic bowel. In addition to the distention, intestinal obstruction is heralded by bilious vomiting and failure to stool.

In contrast, complicated meconium ileus will present either in utero or postnatally with evidence of bowel obstruction complicated by evidence of previous intestinal perforation and/or necrosis: Crescents or speckles of intra-abdominal calcification may be present, or on clinical assessment there may be evidence of peritonitis including an erythematous or edematous abdominal wall and/or demonstrable abdominal tenderness.[38]

### CLINICAL HISTORY

A family history of CF is present in 10% to 33% of patients with meconium ileus.[39] This history, coupled with in utero amniocentesis with restriction fragment length polymorphism analysis, permits the accurate diagnosis of the fetus afflicted with CF. Coupling this information with the results of serial in utero sonography permits the accurate predication of which infants are at risk for the development of the intestinal obstruction of meconium ileus (about 20% of the CF population) with or without a complicating meconium cyst. Maternal polyhydramnios may be a feature of in utero meconium ileus, a finding putatively resulting from the high-grade intestinal obstruction. Such excess maternal fluid accumulation occurs in the mothers of almost 20% of newborns with meconium ileus and at a frequency still higher for the patient with a complicated meconium ileus. Although in utero growth retardation is common, prematurity and other associated anomalies are rare.

### PHYSICAL EXAMINATION

Neonates with meconium ileus are often born with abdominal distention (Fig. 83-1). In fact, meconium ileus is the only variety of neonatal intestinal obstruction that produces abdominal distention at birth before the neonate swallows air. Visible peristaltic waves and palpable, doughy bowel loops are often present. Finger pressure over a firm loop of bowel may hold the indentation, the so-called putty sign. In simple or uncomplicated meconium ileus, no findings of peritoneal irritation are present. The findings of a rectal examination are unremarkable, but characteristically on withdrawal of the examining finger a spontaneous expulsion of meconium does not follow. In the presence of an in-utero perforation with meconium peritonitis and "cyst" formation, a palpable abdominal mass, discoloration of the abdominal wall, and signs of peritoneal irritation are often observed. Physical evidence of hypovolemia may rapidly develop in infants with peritonitis. On passage of a nasogastric tube, a quantity of bile-stained gastric fluid usually exceeds 20 mL.

FIGURE 83-1 Newborn with abdominal distention at birth. The family had a history of cystic fibrosis, and this newborn had a cytogenic diagnosis of cystic fibrosis in utero. On fetal ultrasound examination there was evidence of a hyperechoic bowel wall compatible with a diagnosis of meconium ileus.

### RADIOLOGIC STUDY

In utero, meconium ileus bowel may be distended but an echogenic bowel wall in the third trimester may be diagnostic as well.[40–42] After delivery, uncomplicated meconium ileus is characterized by a typical plain obstruction radiographic series of the abdomen (Fig. 83-2).[43,44] In addition to the supine and erect films appearing remarkably similar, the characteristic findings include (1) great disparity in the size of the intestinal loops because of the configuration of different segments of the bowel; (2) no or few air-fluid levels on the erect film because swallowed air cannot layer above the thickened inspissated meconium; and (3) a granular, "soap bubble," or "ground-glass" appearance seen frequently in the right half of the abdomen, a finding that requires swallowed air bubbles to intermix within the sticky meconium (Fig. 83-3).[45] Each of these features alone is not exclusively diagnostic of meconium ileus and may be seen with other causes of intestinal obstruction. Collectively, however, they strongly suggest meconium ileus. Plain radiography done for differential diagnosis will include any cause of a distal small bowel obstruction including ileal atresia, Hirschsprung disease, or the meconium plug syndrome. A confirming study that may support the plain radiographic diagnosis of meconium ileus is the contrast enema. A contrast enema (whether with barium, Gastrografin, or any water-soluble contrast agent) will outline a normally positioned colon of appropriate length but of small caliber (see Fig. 83-3).[46] It will be empty or will contain pellets of inspissated meconium. The colon will be the typical "unused" colon or "microcolon." If reflux of contrast agent into the terminal ileum occurs, it will outline pellets of inspissated meconium.[44,47] If the contrast agent refluxes more proximally

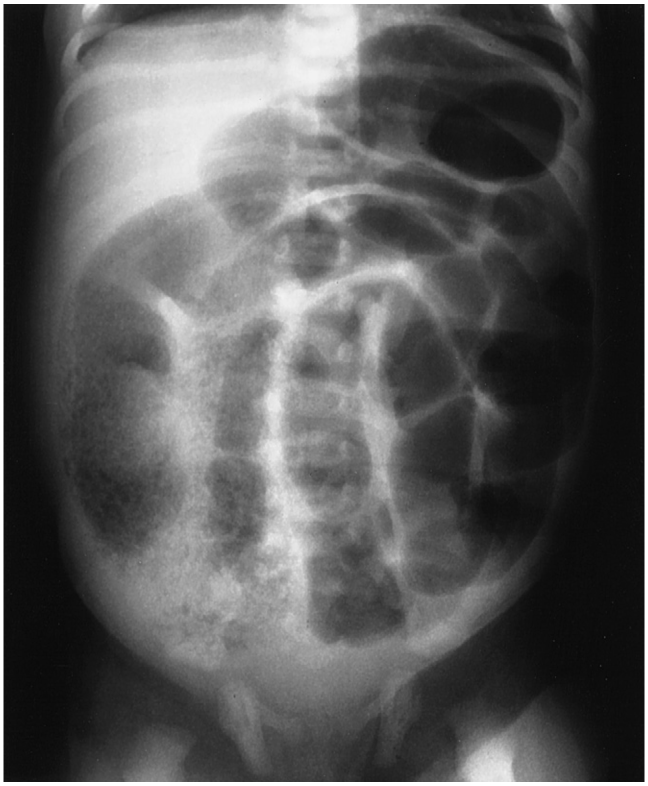

FIGURE 83-2 An abdominal plain upright radiograph is compatible with the diagnosis of meconium ileus. There are dilated small bowel loops of disparate size, few air-fluid levels, and a "ground-glass" or "soap-bubble" appearance in the right lower quadrant. (From Rescorla FJ, Grosfeld JL: Contemporary management of meconium ileus. World J Surg 1993;17:381.)

into the ileum, the transition into dilated loops of small bowel will be encountered. Failure to reflux contrast medium into the proximal dilated small bowel will neither prove the diagnosis of meconium ileus nor determine the exact level of the intestinal obstruction; and with this failure of the contrast medium to reflux into the dilated segment, operative intervention for diagnosis and treatment becomes necessary.

## Laboratory Testing

The definitive study to confirm the diagnosis of CF is the sweat test. With the use of the pilocarpine iontophoresis method, sweat is collected from the infant's forearm, leg, or back; the amount is quantified, and the concentration of sodium and chloride in the sample is measured.[48,49] The minimum amount of sweat to be collected is 100 mg, and a measured concentration of sweat chloride in excess of 60 mEq/L is diagnostic of CF. The adequacy of the size of the sweat sample is the factor that usually precludes application of this test to the newborn, despite reports to the contrary. A few individuals have been identified with elevated sweat chloride levels but with no other features of CF. These problems, plus a potentially elevated sweat sodium and chloride level in normal newborns, may make it necessary to defer application of the sweat chloride test until the neonate reaches several weeks of age.

Genetic testing for CF can be done by analyzing cellular DNA for CFTR, thus establishing the carrier status of parents of a putative child with CF presenting with features of meconium ileus. However, because of the minimum number of mutations tested by these commercial analyses, negative results become less meaningful. If a family has known CFTR mutations, then amniocentesis with fetal DNA restriction

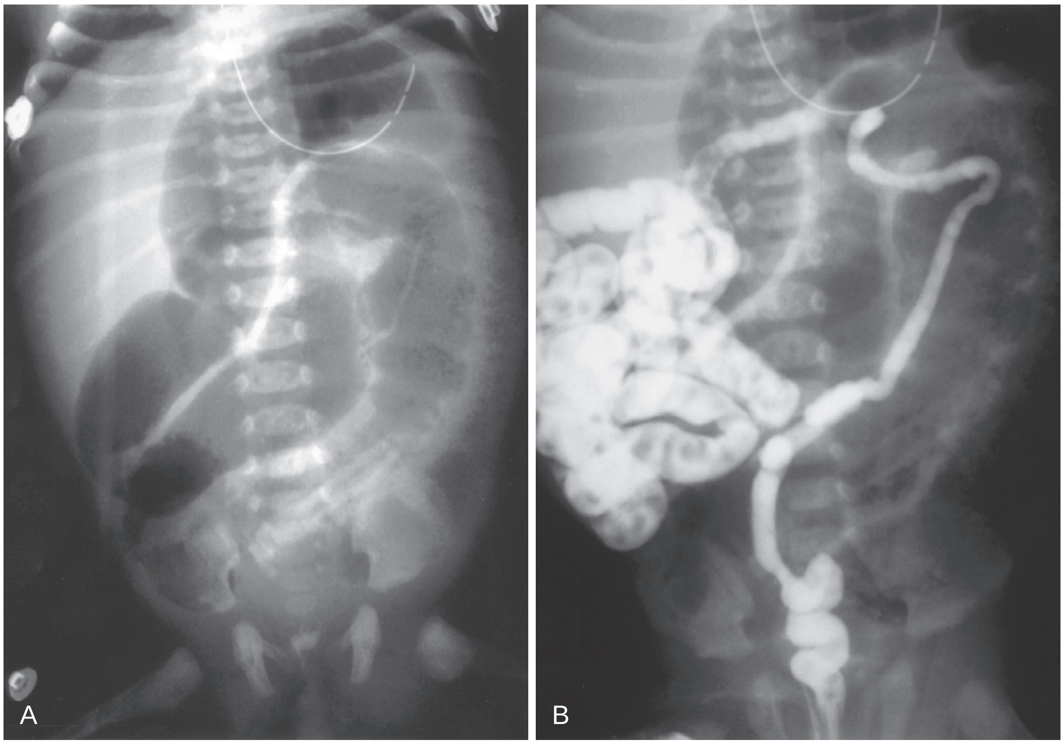

FIGURE 83-3 **A,** Abdominal plain radiograph is compatible with the diagnosis of meconium ileus. There are distended bowel loops of disparate size, few air-fluid levels, and a "soap bubble" right lower quadrant appearance. **B,** Same patient as in A is studied further with a contrast enema. A microcolon or unused colon is demonstrated, and contrast agent refluxes into dilated, more proximal small bowel where inspissated intraluminal pellets of meconium are seen. These findings strongly suggest the diagnosis of meconium ileus.

fragment length polymorphism analysis may predict a fetal CF diagnosis.

The pathophysiologic alteration of an increased albumin concentration in meconium may prove useful as a diagnostic screening tool for meconium ileus.[50,51] This test, which uses a tetrabromophenolethylester blue indicator, detects meconium albumin concentrations in excess of 20 mg/g of stool; however, a persisting incidence of false-positive results was seen from such factors as prematurity, melena, gastroschisis, and intrauterine infection. A false-negative rate has been reported as well. This simple and relatively inexpensive tool is straightforward and rapid, and the colorimetric indicator is easy to interpret.[23,52] Meconium from normal neonates has an albumin concentration of less than 5 mg/g of stool, whereas meconium from neonates with CF has values at times in excess of 80 mg/g.[53,54]

Stool trypsin and chymotrypsin analysis has historically been a popular screening test for meconium ileus.[53–55] A trypsin level less than 80 mg/g of stool, coupled with operative findings, supports the diagnosis of meconium ileus. Some centers have advocated for population CF screening using a measurement of immunoreactive trypsinogen in blood.

Operative tissue specimens that aid in the diagnosis of CF include intestinal (rectal) or appendiceal pathognomonic changes that include goblet cell hyperplasia and the accumulation of secretions within the crypts or within the lumen.[56] If operation is done for putative meconium ileus and an appendicostomy is used as a bowel intraluminal irrigation site, appendectomy may be warranted to obtain such a diagnostic pathologic specimen.

## DIFFERENTIAL DIAGNOSIS

The combination of family history, physical examination, and radiologic evaluation in the neonate are the three criteria of high sensitivity that permit an accurate clinical diagnosis of meconium ileus. The addition of linkage analysis on maternal amniocentesis samples or a sweat test confirms the diagnosis of CF. A definitive diagnosis depends on the confirmation of the cause of intestinal obstruction. Meconium ileus accounts for 10% to 25% of cases in large series of patients with neonatal intestinal obstruction. Therefore the major differential diagnosis lies with the variety of causes of neonatal intestinal obstruction including ileal atresia, Hirschsprung disease, neonatal small left colon, and the meconium plug syndrome.[57]

Ileal atresia is usually suggested by a distal bowel obstruction pattern on plain radiographs with the associated presence of air-fluid levels.[58,59] If a microcolon is demonstrated on contrast enema, the contrast agent will not reflux into the proximal dilated "atretic" bowel as it might in both meconium ileus and Hirschsprung disease (Fig. 83-4). Once ileal atresia is suspected, the final confirmation of the diagnosis requires operative exploration. Meconium ileus can be associated with ileal atresia, and at operation the findings characteristic of the sticky meconium of meconium ileus should raise this possibility (Fig. 83-5). Hirschsprung disease, especially total colonic aganglionosis, as well as extended small bowel aganglionosis, may also mimic meconium ileus.[60–62] In fact, nearly all cases of total intestinal aganglionosis were initially misdiagnosed as meconium ileus.[63] A definitive diagnosis of Hirschsprung disease may be suggested both radiographically and by anorectal manometrics, but ultimately it depends on the histochemical findings of increased acetylcholinesterase content or the histopathologic findings of aganglionosis seen on rectal biopsy. The radiographic features of colonic Hirschsprung disease likely will include a transition zone; in patients with total colonic Hirschsprung disease, a reflux of contrast medium into the terminal ileum will typically not demonstrate the filling defects of meconium ileus but, rather, will show air-fluid levels and a proximally dilated bowel.

FIGURE 83-4 A contrast enema is done in a newborn with a distal bowel obstruction evident on plain radiography. A microcolon is found leading to a small-caliber distal ileum, and contrast agent does not reflux into the dilated intestine. This is most compatible with the diagnosis of a distal intestinal atresia. (From Rescorla FJ, Grosfeld JL: Contemporary management of meconium ileus. World J Surg 1993;17:381.)

FIGURE 83-5 Operative findings of a case of meconium ileus complicated by an acquired ileal atresia. The small bowel is distended proximal to the atresia, and there are inspissated pellets of meconium in the distal ileum and colon.

Neonatal small left colon syndrome may also require the differentiation from meconium ileus.[64–66] This abnormality is confined to the left colon, appears as a funnel-shaped tapering on contrast enema, and is often associated with a diagnosis of maternal diabetes, hyperthyroidism, drug abuse, or

eclampsia (Fig. 83-6). Rectal biopsy is required to exclude Hirschsprung disease. Other features of meconium ileus are usually not present.

Meconium plug syndrome is usually confirmed by a contrast enema radiograph with the finding of "plugs" or "casts" of meconium in the sigmoid or descending colon (see Fig. 83-6).[67–70] Such plugs will often spontaneously pass after withdrawal of the enema catheter and expulsion of the enema. There is a significant association of meconium plug syndrome with other gastrointestinal anomalies, and up to 14% of neonates with CF will be seen to have meconium plug syndrome.[71] The pathogenesis of the meconium plug is poorly understood but may relate to a bowel hypomotility. Meconium plug syndrome has also been associated with prematurity, hypotonia, hypermagnesemia, respiratory distress, sepsis, hypothyroidism, diabetes, and Hirschsprung disease.[72,73] These associations suggest that patients with meconium plug syndrome should be studied with both a sweat test to exclude CF and a rectal biopsy to exclude Hirschsprung disease after symptoms of obstruction have been relieved.[74,75]

Meconium ileus may occur in the absence of CF in term or preterm infants with pancreatic or intestinal insufficiency from a variety of causes.[39,76,77] These intraluminal obstructions result from the accumulation of an inspissated sticky meconium in the terminal ileum or right colon, but the meconium is neither tarlike nor resistant to conventional enema irrigation that usually proves to be therapeutic. Whether intestinal secretion insufficiency or a pancreatic achylia is etiologic is variable, but rarely has pancreatic insufficiency been documented. Definitive exclusion of CF clinically requires a sweat chloride analysis, DNA analysis, or both.

## Nonoperative Management

Nonoperative management of meconium ileus depends on the dissolution of the inspissated intraluminal meconium in an otherwise patent and uncompromised ileocolon.[47,78,80] Although various solubilizing agents historically had been administered by mouth, intraoperatively, or by rectum, the mainstay of meconium ileus treatment remained an operative procedure.[80] In 1969 several additional reports suggested that solvents were effective and the value of nonoperative application of such solvents was suggested both clinically and experimentally.[81] Noblett reported the successful use of a hypertonic contrast enema in four neonates with uncomplicated meconium ileus. She described the need to fulfill the flowing criteria before applying such therapy: (1) an initial diagnostic contrast enema should exclude other causes of distal intestinal obstruction; (2) the complications of volvulus, atresia, perforation, or peritonitis must be excluded; (3) the enema must be performed with careful fluoroscopic control; (4) intravenous antibiotics should be administered; (5) the patient should be attended by a pediatric surgeon during the procedure; (6) the patient should have a full fluid resuscitation with fluids given aggressively (one to three times maintenance) during the procedure; and (7) the patient should be prepared for imminent operation should

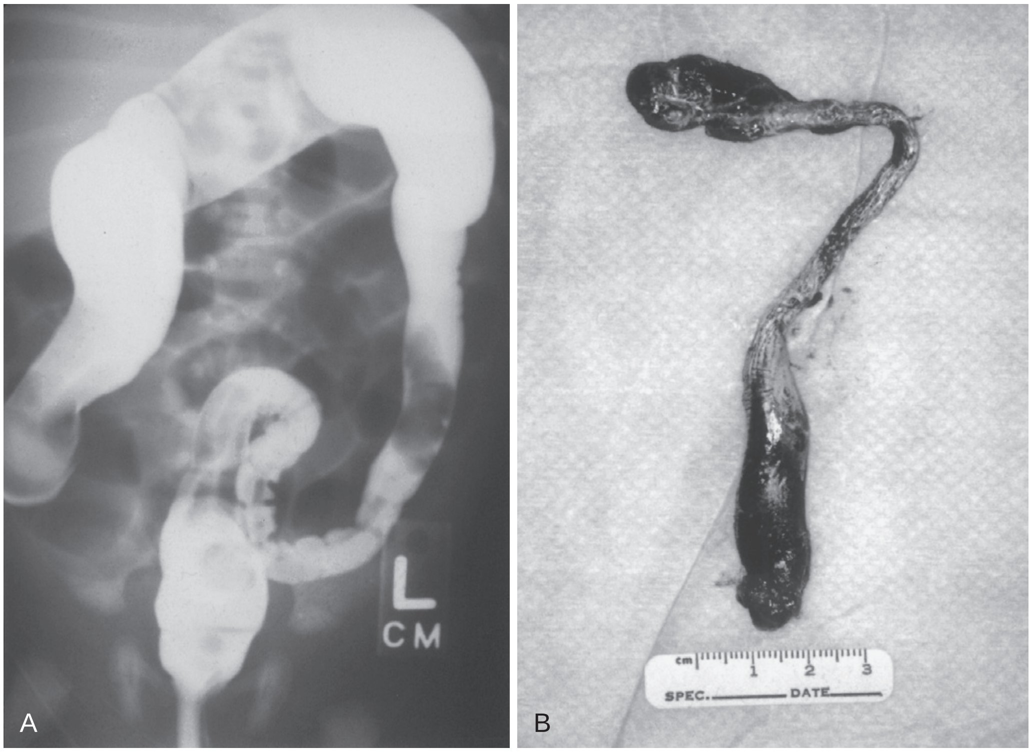

FIGURE 83-6 The differential diagnosis of meconium ileus includes several entities characterized by left colon pathology. **A,** A contrast enema in a newborn presenting with a plain radiographic pattern of a distal bowel obstruction depicts tapering of the colon below the splenic flexure and an intraluminal filling defect in the rectosigmoid colon. These findings would suggest Hirschsprung disease, neonatal small left colon syndrome, or meconium plug syndrome. **B,** After the removal of the enema catheter, the patient spontaneously passed a "plug" of meconium and the obstruction was relieved. A sweat test and a rectal biopsy may be indicated to exclude the diagnoses of cystic fibrosis and Hirschsprung disease, respectively.

complications develop.[82,83] Since that report, a Gastrografin enema has been the standard of nonoperative treatment. Meglumine diatrizoate is a hyperosmolar, water-soluble, radiopaque solution containing 0.1% polysorbate 80 (Tween 80), a solubilizing or wetting agent, and 37% organically bound iodine. The meglumine is a 76% aqueous solution of sodium-methyl-glucamine salt of n1n1-diacetyl-3,5-diamino-2,4,6-triiodobenzoic acid, and this hypertonic solution has an osmolality of 1900 mOsm/L, a property that draws fluid into the intestinal lumen and aids in the release of the inspissated meconium. After administration, both a transient osmotic diarrhea and a putative osmotic diuresis occur, factors that emphasize the importance of aggressive fluid resuscitation. In addition, the product is radiopaque, which enables a safe fluoroscopically monitored administration. Polysorbate 80 (Tween 80) is a nonionic surface-active emulsifier that may not only better define radiographically the bowel mucosal pattern but also facilitate the passage of the hypertonic Gastrografin between the mucosa and the adherent meconium at the site of obstruction. Polysorbate 80 as a 10% solution has been administered intraoperatively by way of an enterostomy to liquefy meconium. Other hypertonic water-soluble agents (e.g., 40% sodium diatrizoate [40% Hypaque]) not containing polysorbate 80 are also effective in relieving the obstruction, and they may prevent the adverse influence of Gastrografin on colonic mucosa.[79,84]

The technique of solubilizing enema treatment of meconium ileus continues to use the aforementioned guidelines of Noblett. After fluid resuscitation and nasogastric decompression have been performed and after physical examination assessment and plain abdominal radiographs have excluded the diagnosis of peritonitis or perforation, the diagnostic contrast enema with barium or water-soluble agent is administered. When the preliminary diagnostic study has been completed, an enema-tip nonballoon catheter is inserted into the anorectum and the buttocks are taped together around the catheter. With fluoroscopic guidance and an initial solution of 50% Gastrografin in water, the contrast agent is slowly injected by a catheter-tipped syringe. When contrast medium traverses the colon and reaches the dilated meconium-impacted ileum, the study is terminated and the infant is returned to a bed for monitoring, fluid administration (two times maintenance), and normalization of body temperature. Spontaneous passage of the inspissated meconium per rectum should follow. An abdominal radiograph should be repeated in 8 to 12 hours to determine whether the obstruction has been relieved. If instead the evacuation is incomplete and obstruction persists, the enema may be repeated with the same concentration of Gastrografin. If either no evacuation occurs after a successfully refluxing enema or if contrast medium cannot be refluxed into dilated bowel, then this technique should be abandoned and operative intervention planned. Similarly, signs of worsening obstruction, clinical distention, greater distention of loops on radiograph, or signs of peritonitis resulting from a possible perforation are also indications for operative intervention. Noblett suggests that after a successful enema, 5 mL of a 10% N-acetylcysteine solution should be administered every 6 hours through a nasogastric tube to liquefy upper gastrointestinal secretions.[85] Furthermore, when formula feedings are begun, supplemental pancreatic enzymes must be administered with each feeding.[86,87]

The success of nonoperative treatment is variable.[88,89] The initial report of Noblett suggested that up to two thirds of patients were successfully treated by this technique. Advantages of the nonoperative therapy include a reduction in pulmonary morbidity and a reduced length of hospital stay. Disadvantages of therapy include a delay in operative intervention for those unsuccessfully treated by the enema, the risk of immediate and delayed intestinal injury or perforation, and the induction of hypovolemia. Bowel injury leading to a potential perforation may be a product of repeated enemas, injudicious inflation of an enema catheter balloon, or a direct mucosal injury induced by the enema agent.[90–94] The mechanism of such an injury may be related to bowel distention or to the polysorbate 80 content. The latter injury may be prevented by using a solubilizing enema agent containing 1% to 2% polysorbate 80 with isotonic Gastrografin diluted with water to a final osmolality of 320 to 340 mOsm/L or by using an alternate isotonic contrast agent.

# Operative Management

Multiple indications for operative intervention in the management of meconium ileus exist.[95–97] One third to one half of patients undergoing operation represent cases of simple or uncomplicated meconium ileus that have failed to respond to nonoperative treatment with enema solubilizing agents. The remaining one half to two thirds of patients have complications of meconium ileus, which include intestinal atresia, volvulus, perforation, meconium cyst formation with peritonitis, intestinal gangrene, or combinations of these events. In the management of simple meconium ileus, the goal of operation is the relief of intraluminal ileocolonic obstruction by either the evacuation of the adherent intraluminal meconium or by resection of the portion of bowel filled with inspissated material.[98]

## SIMPLE MECONIUM ILEUS

A variety of operative procedures are available for the management of patients with meconium ileus (Figs. 83-7 and 83-8).[98] The initial patient survivors underwent enterotomies with irrigation coupled with a limited resection. This operative technique is the one most commonly in use today. Irrigating solutions may include warmed saline, a 50% diatrizoate solution, a 1% solution of pancreatic enzymes (Viokase; A.H. Robbins Co., Richmond, Va.), hydrogen peroxide, and, most commonly, either a 2% or a 4% solution of N-acetylcysteine (Mucomyst; Apothecon, Princeton, N.J.).[85,99] More concentrated solutions of N-acetylcysteine or Gastrografin or the use of hydrogen peroxide and its attendant risk of air embolism may produce greater risk than benefit. After solubilization by the irrigant, injected through an enterotomy catheter, the meconium is gently milked distally into the colon or evacuated through the enterotomy (see Fig. 83-7). The enterotomy and the abdomen may then be closed, an enterostomy may be created, or the site can be controlled by insertion of a T tube.[100–103] This last treatment has been designed to be located at the junction of proximal distended ileum with distal (more collapsed) ileum where intraluminal balls of inspissated meconium are found. Leaving this tube in place and attaching the enterotomy site against the anterior abdominal wall ensures a controlled fistula, as well as a route

of gastrointestinal access for the instillation of pancreatic enzyme solutions beginning on the first postoperative day. By the seventh to fourteenth postoperative day, the irrigant should pass freely into the colon, the obstruction should be relieved, and thereafter the catheter can be removed. This avoids the need for reoperation and enterostomy closure. An alternative technique is appendectomy with appendicostomy, with meconium evacuation or irrigation through this route.[104] A temporary indwelling tube cecostomy may alternatively be left in place. For such an irrigant technique to be successful, the bowel must be handled gently, not overdistended, and not excessively massaged or "milked" in an effort to evacuate the inspissated meconium.

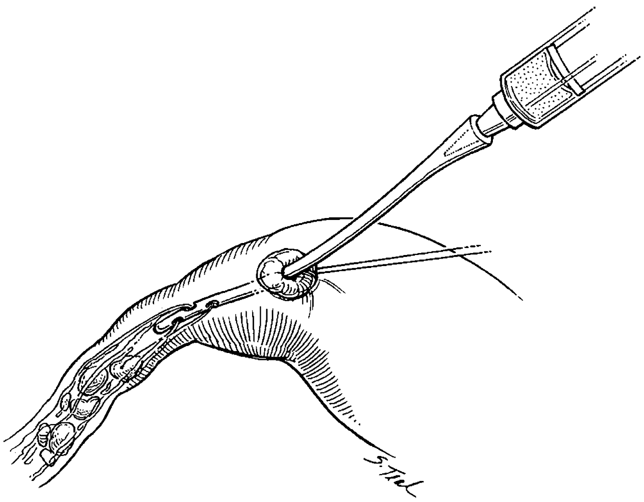

**FIGURE 83-7** The most commonly preferred contemporary operative management of meconium ileus is shown. An enterotomy is made in the dilated small bowel segment just proximal to the site of inspissated distal meconium, and an irrigating catheter is inserted. After instillation of solubilizing agent, the catheter may be removed and the enterotomy closed; instead, the catheter may be left in place or replaced with a T tube for continued postoperative solubilizing agent instillation. (From Rescorla FJ, Grosfeld JL: Contemporary management of meconium ileus. World J Surg 1993;17:381.)

An alternative operation to enterotomy-irrigation is placement of a temporary obstruction-relieving stoma with or without an associated partial resection. Gross initially advocated placement of the Mikulicz double-barreled enterostomy, which could be performed quickly and which did not require intraoperative meconium evacuation (see Fig. 83-8). The exteriorized bowel loop could be opened after the abdominal incision has been closed, thereby minimizing intraperitoneal contamination. After the obstruction is relieved and the infant has recovered, a spur-crushing Mikulicz clamp can be applied externally at the stoma to complete a side-to-side anastomosis. It may not be necessary to return to the operating room to close the stoma because after the clamp-induced anastomosis, the residual enterocutaneous fistula may spontaneously close. An alternative to such an "extraabdominal resection" and delayed stomal closure was the primary resection and anastomosis recommended a decade later by Swenson and Noblett. After meconium had been evacuated, a primary intraperitoneal anastomosis could be performed, or the infant could be allowed to recover more fully, after which the stoma could be closed in delayed fashion by an end-to-end anastomosis. An alternative operation is resection coupled with a distal chimney enterostomy, the so-called Bishop-Koop procedure (see Fig. 83-8).[105] This technique was developed with the

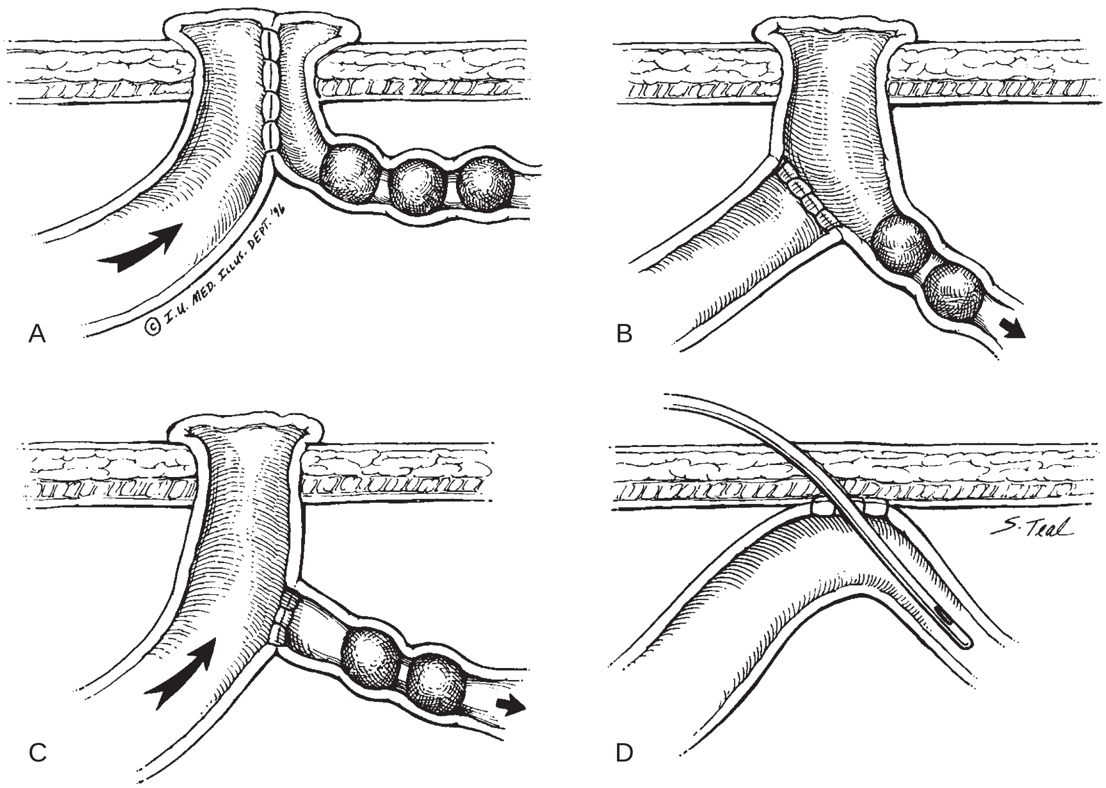

**FIGURE 83-8** The operative options for simple meconium ileus. **A,** The Mikulicz resection and enterostomy. **B,** The Bishop-Koop resection and enterostomy. **C,** The Santulli enterostomy. **D,** Tube enterostomy. (From Rescorla FJ, Grosfeld JL: Contemporary management of meconium ileus. World J Surg 1993;17:381.)

following criteria: (1) limit intraoperative bowel trauma in the neonatal period; (2) resect the disparately enlarged ileal loop filled with inspissated thickened meconium; (3) create an appropriately sized end of proximal to side of distal ileum anastomosis close to the abdominal wall exiting the distal ileum, to serve as a functionally decompressing "proximal stoma" while distal obstruction persisted; (4) provide access for insertion of a catheter into the distal bowel containing inspissated meconium pellets so that solubilizing pancreatic enzymes could be instilled postoperatively; and (5) permit an eventual enterostomy closure by bedside ligation of the "chimney stoma," putatively avoiding the risks of an additional anesthetic in a child with known CF. Intraoperatively, an 8-Fr rubber catheter is passed through the ostomy chimney into the distal ileum. Within 12 to 24 hours after the operation, catheter irrigations are begun with a pancreatic enzyme solution (1 teaspoon Viokase per 1 oz water) repeated every 4 to 6 hours until the distal intraluminal obstruction is relieved, at which time the catheter is removed. After an initial large volume of enterostomy output, the ostomy drainage will diminish as the more distal obstruction is relieved. The transcolonic passage of stool will follow. Thereafter, the output from the stoma may cease altogether. Eventually the chimney may be treated by one of two techniques. At the bedside the "stoma" may be ligated. If the result of this noninvasive technique is a persistent enterocutaneous fistula, then a formal intraperitoneal or extraperitoneal stomal closure can be performed with the patient under a general anesthetic. This latter procedure is necessary in approximately 75% of patients treated by this technique.[17]

Santulli described a proximal chimney enterostomy, an operation that in essence is the reverse of the resection coupled with a distal chimney enterostomy (see Fig. 83-8). The distal ileal end is anastomosed end-to-side to the proximal ileum at a level corresponding to an immediate subfascial plane, and the proximal ileum is exited as an end enterostomy. With this stoma arrangement, irrigation and decompression of the proximal ileum is enhanced. As with the Bishop-Koop procedure, an intraoperative catheter passed through the stoma is positioned into the distal ileum for the postoperative instillation of solubilizing agent. Because a high-output functional end enterostomy has been created, it is necessary to close such a stoma early to avoid the complications induced by excessive fluid and electrolyte losses.

### COMPLICATED MECONIUM ILEUS

The treatment of complicated meconium ileus almost always requires an operation,[106] an exception being the rare in utero perforation that has left a telltale remnant of extraluminal intraperitoneal calcified meconium, a spontaneously sealed perforation, and no interruption in intestinal continuity.[105] Another finding for the latter process is calcified meconium seen in a patent processus vaginalis during a hernia operation or by abdominal radiograph later in life. In contrast, operative indications include persisting intestinal obstruction, an enlarging abdominal mass, and signs of peritonitis, which may include abdominal wall edema and discoloration, tenderness on physical examination, and clinical and laboratory signs of ongoing sepsis (Fig. 83-9).

Meconium peritonitis may be seen as one of several varieties. A meconium pseudocyst is a result of meconium accumulating in the peritoneal cavity for weeks to months. A calcified

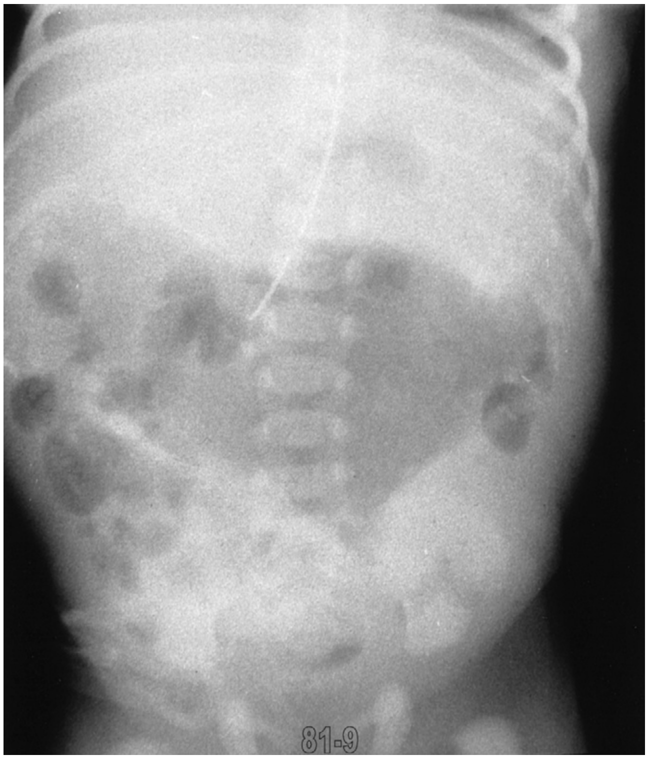

**FIGURE 83-9** A plain abdominal radiograph compatible with the diagnosis of complicated meconium ileus. The large, central, air-filled mass suggests intestinal perforation and giant meconium cyst formation. If the perforation has been of longer standing, intraperitoneal calcification may also be present. (From Rescorla FJ, Grosfeld JL: Contemporary management of meconium ileus. World J Surg 1993;17:381.)

"pseudocyst" fibrous wall forms around an accumulation of meconium, and spared bowel loops are peripheral to this cyst (see Fig. 83-9). Adhesive meconium peritonitis follows meconium contamination of the peritoneal cavity for days to weeks before delivery. Dense and vascular adhesions make operative relief of the adhesive intestinal obstruction difficult. Scattered calcifications may be present. When intestinal perforation occurs only a few days before delivery, an abdomen filled with meconium ascites results and calcification is absent. The fourth variant of meconium peritonitis is bacterially infected ascites, which occurs when colonized intestinal organisms penetrate from the perforated intestine into the peritoneal cavity.

At operation, it is mandatory to assess residual intestinal length, and it is critical to use conservative resection. An effective armamentarium of operative options is necessary to optimize treatment of meconium peritonitis, volvulus, atresia, or the ischemic intestine that may be encountered. Only the presence of a diffuse bacterial peritonitis precludes a primary anastomosis. The Bishop-Koop, Mikulicz, and Santulli procedures each have application in the management of patients with complicated meconium ileus.

## Postoperative Management

After the operative management of meconium ileus, care must be centered on support of the infant's general physiology, as well as on the evacuation of any residual proximal or distal gastrointestinal inspissated intraluminal meconium. Generally, the

latter can be treated by instillation of 2% or 4% acetylcysteine (Mucomyst) delivered through a nasogastric tube, which will solubilize the residual meconium. When gut patency is verified clinically or by plain film radiograph, enteral nutrition may begin with an elemental formula such as Pregestimil (Mead-Johnson, Evansville, Ind.). When enteral feedings begin, supplemental pancreatic enzymes must also be started (Viokase, Pancrease [McNeil Pharmaceuticals, Spring Hill, Pa.] and Cotazym-S [Organon Inc., West Orange, N.J.] are alternatives). If postoperative ileus is prolonged or if short-bowel syndrome is a product of the operative treatment, then total parenteral nutrition becomes an important early and potentially prolonged form of postoperative nutritive therapy. Early enteral or parenteral nutrition therapy must include maintenance of salt and mineral balance; appropriate vitamin supplementation including vitamin K; and aggressive management of any associated short-bowel syndrome deficiencies. The association of the inherent malabsorption of CF coupled with the potential of an extreme short-bowel syndrome resulting from complicated meconium ileus makes for an extremely difficult management combination.[107,108]

Short-term postoperative parenteral antibiotics are used for the care of either simple or complicated meconium ileus, but directed and more prolonged antibiotics may be continued to minimize potential pulmonary complications. Vigorous pulmonary physiotherapy is initiated early after operation and is continued indefinitely. Teaching parents to perform such pulmonary physiotherapy that includes postural drainage is a mandatory component of predischarge planning. In those patients with an enterostomy, teaching parents appropriate stomal care is also important. Only in those circumstances in which a Bishop-Koop ileostomy or a Mikulicz ileostomy was created would bedside ligation of the chimney or application of a Mikulicz clamp, respectively, be considered before hospital discharge.

Perhaps the most important feature of postoperative care is to secure the diagnosis of CF as the cause of the patient's meconium ileus. A series of reports exist in which neonatal intraluminal inspissated meconium is the cause of small bowel obstruction and the same management scheme as outlined earlier is applied. However, postoperatively these patients are not found to have abnormal sweat electrolytes. Such cases have been carefully distinguished from the colonic meconium plug syndrome because the plugging has been confined to the small bowel. This condition has been reported in premature infants, in siblings without CF, in patients with partial pancreatic aplasia, and in patients with pancreatic ductal stenosis.[109] These findings remain an important distinction if the alternative diagnosis is meconium ileus associated with CF.

# Complications

## GASTROINTESTINAL

Many gastrointestinal complications of meconium ileus exist and include an increased incidence of intussusception and rectal prolapse. However, in the child and adolescent with CF, the most common gastrointestinal problem is distal intestinal obstruction termed *meconium ileus equivalent* or *distal intestinal obstruction syndrome.*[110] A partial bowel obstruction by intraluminal material may be a product of steatorrhea or noncompliance with oral enzyme therapy. Signs and symptoms are heralded by crampy abdominal pain, distention, and a palpable right lower quadrant mass; and a high-grade obstruction is associated with obstipation, distention, and vomiting. It is important to consider a broad differential diagnosis that may include constipation, intussusception, and even appendicitis; and the plain abdominal radiograph supplemented with contrast body imaging should prove diagnostic. Once the diagnosis is established, the preferred treatment is solubilizing agents such as acetylcysteine and Gastrografin, given both orally and per rectum. Operative intervention is rarely required. Adjustment of oral enzyme therapy supplemented with better hydration and the use of stool softeners may be used to prevent recurrence. Both histamine $H_2$ blockers and proton pump inhibitors may prove efficacious by increasing intestinal pH, and prokinetic agents have also been used.

Appendiceal luminal obstruction that produces signs and symptoms compatible with both acute and "chronic appendicitis" may also occur.[111] The diagnosis of appendiceal pathology depends on both clinical assessment and the potential use of contrast medium-enhanced computed tomography. These complications and the most common gastrointestinal complication, malabsorption, are improved with appropriate enzyme replacement therapy. Malabsorption of carbohydrates, protein, and fat may all occur, a problem worsened both by the extent of peritoneal inflammation and the magnitude of the short-bowel syndrome. The latter may be functional or anatomic, an anatomy foreshortened because of atresia or a resection. The malabsorption is worsened by a disaccharidase deficiency and by inspissated biliary secretions that produce both jaundice and impaired fat absorption. This same pathophysiology may account for the occurrence of gallstones in about one fourth of patients with CF, as well as the incidence of symptomatic chronic calculous cholecystitis or biliary dyskinesia, which also characterizes this population. The nutrient malabsorption takes on greater significance if a concomitant increased energy need occurs in the presence of recurrent and chronic pulmonary infection. The application of total parenteral nutrition may prove beneficial to supplement enteral nutrients and to provide gut rest, as well as appropriate calories during periods of prolonged postoperative ileus, especially if anastomotic healing or closure of enterocutaneous fistulas is required. Furthermore, evidence suggests that the malnutrition of meconium ileus is significantly different or even worse than that seen in age-matched peers who have CF without meconium ileus.

Intussusception occurs in approximately 1% of older CF patients, likely secondary to inspissated intraluminal stool serving as the lead point. The site of pathology is typically ileocolic, but small bowel and large bowel intussusception may also occur. Typically, the diagnosis is difficult to establish and distinguish from other right lower quadrant CF pathology, and operation with reduction and/or resection becomes the usual therapeutic outcome.

Rectal prolapse may be the first clinical presentation of a child subsequently proven by sweat test to have CF. Up to one third to one fifth of children with CF develop prolapse typically between the ages of 1 and 3 years of age. The preferred treatment after the diagnosis of CF is established is oral enzyme therapy, and rarely will more aggressive transanal rectal submucosal sclerotherapy or operative rectopexy be indicated.

Colonic strictures[86,87,90,94] presumptively secondary to large-dose oral enzyme therapy have been reported in CF children, half of whom previously have had meconium ileus. Most commonly such disease is localized to the right colon, but segmental colitis and even pancolonic disease has been reported. The local signs of obstruction and pain must be distinguished from the meconium ileus–equivalent patient, and a contrast enema is typically diagnostic. Regulation of enzyme therapy may be tried, but most commonly resection is indicated for intractable strictures.

### PULMONARY

The early morbidity and mortality of meconium ileus predominantly has a pulmonary origin, the products of which include bacterial sepsis and bronchopneumonia. Some authors suggest that beyond 6 months after the treatment of meconium ileus, the prognosis and morbidity assume that of a patient with CF without meconium ileus. However, other studies suggest that children with meconium ileus have worse lung function and more obstructive lung disease between ages 8 and 12 years than those with CF but without meconium ileus. These changes occur with relatively reduced lung volumes. When *Pseudomonas,* coliforms, or other specific colonizing or pathogenic organisms are identified, the early and aggressive use of aminoglycosides and semisynthetic penicillins has been shown to improve survival and outcome, even if used in a prophylactic manner. Finally, the use of aggressive physical therapy and postural drainage may further minimize pulmonary complications.

### INGUINOSCROTAL DISEASE

Children with CF have been reported to have an increased incidence of inguinal hernias and hydroceles, as well as an increased incidence of cryptorchidism.[112,113] Two operative findings at the time of inguinal hernia repair may suggest the underlying diagnosis of CF, namely, the presence of calcified meconium in the hernia sac and the absence of a vas deferens.[114] Both findings in the absence of a previous diagnosis of CF suggest the need for a diagnostic sweat test. In addition, infertile males without a vas deferens may actually be asymptomatic heterozygotes carrying the CF gene.

## Results of Treatment

The outcome of the treatment of patients with meconium ileus, whether the condition is complicated or simple, has steadily improved during the past 3 decades, the most recently reported survival rates approaching 100% (Fig. 83-10).[115,17] In a series of patients treated both nonoperatively and

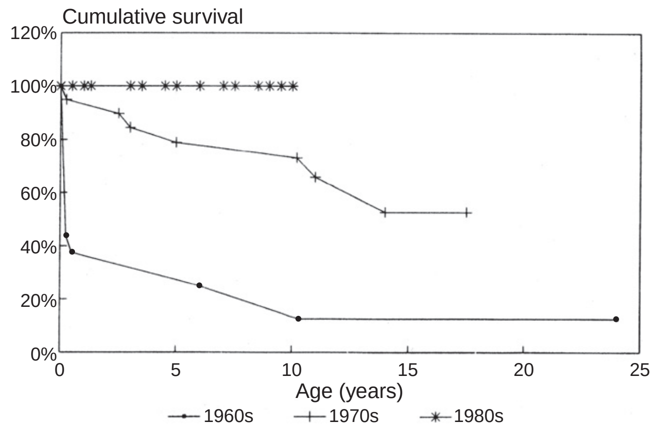

**FIGURE 83-10** Long-term survival rates of patients with meconium ileus depicted by decade. A statistically significant improvement in survival is seen when 1960s, 1970s, and 1980s survival data are compared ($P < 0.0001$). (From Del Pin CA, Czyrko C, Ziegler MM, et al: Management and survival of meconium ileus: A 30-year review. Ann Surg 1992;215:179-185.)

operatively, survival rates at 5 and 10 years for the two categories improved steadily from the 1960s (30% and 10%, respectively) through the 1970s (80% and 70%, respectively) and the 1980s (100% at 5-year follow-up).[27,116–118] In the past, nonoperative treatment had contributed to an improved survival rate. But in the past decade the survival rate for both operative and nonoperative treatment was 100%. The significant improvement in operative survival has come since the 1960s when the 6-month survival rate was only 33%.[119] The operative 6-month survival rate had improved to 60% before 1979 and to 100% between 1979 and 1989.[120] No significant overall differences in outcome were observed with regard to patient gender, whether complication of meconium ileus was present, or with regard to the type of operation performed (ileostomy, resection with primary anastomosis, resection and Mikulicz ileostomy, and Bishop-Koop enterostomy). Additionally, the long-term survival rates (measured at 6 years) of patients treated with the Bishop-Koop procedure (62% survival) did not differ from those of patients with alternate operations. Furthermore, all deaths in patients older than 6 months of age were cardiopulmonary or pneumonitic deaths related to the underlying CF and not to complications of operation. Interestingly, both simple and complicated cases of meconium ileus had 72% 10-year survival rates.[121,122]

Death occurs from multiple causes, which include intraperitoneal sepsis from unrecognized leakage, pulmonary sepsis and bronchopneumonia, or short-bowel syndrome with complicating liver failure.[123–125]

CHAPTER 84

# Meckel Diverticulum

Charles L. Snyder*

## History

In 1598 Fabricus Hildanus first described an "unusual" diverticulum of the small intestine.[1,2] Lavater also reported a diverticulum in 1671.[3] Littre noted its presence in a hernia in 1700.[4] Ruysch published a copperplate illustration in 1701[5] and thoroughly described the anatomy.

Johann Friedrich Meckel (1781-1833) was an eminent anatomic pathologist.[6] His grandfather, also named Johann Friedrich Meckel (1724-1774), was a well-known professor of anatomy, botany, and obstetrics in Berlin. To avoid confusion, the grandson (of eponymous diverticular fame) is known as "the younger" and his grandfather is referred to as "the elder." Meckel the younger's father, Phillip, was also a professor of anatomy and surgery at Halle (Prussia).

Johann Friedrich Meckel the younger became professor of normal and pathologic anatomy at the University of Halle in 1808, where he remained for the rest of his career.[7] Although he was not the first to identify it, he published a series of articles in the early 1800s describing the anatomy, embryology, and clinical attributes of the diverticulum that bears his name.[8–13] In 1812 Meckel suggested that the incidence of complications developing in a diverticulum was about 25%,[9] a figure that is high by current estimates. Obliged to retire at age 50 because of paranoia, he died a recluse 2 years later.[14]

A specimen from 1846 is the first known example of intussusception from a Meckel diverticulum.[15] Heterotopic pancreatic mucosa was reported in the diverticulum by Zenker in 1861,[16] and gastric mucosa was found in 1904 by Salzer.[17] The association of the diverticulum with adjacent ulceration of the ileum was discovered by Deetz in 1907.[18] A carcinoid tumor originating in a Meckel diverticulum was identified in 1907.[19] Gramen described a presentation similar to appendicitis in patients with an inflamed/perforated Meckel diverticulum in 1915.[20]

Harper suggested the technetium-99m pertechnetate scan in 1962 as a method of diagnosing Meckel diverticulum because the material is concentrated in gastric mucosa.[21] However, Jewett and colleagues were the first to apply it clinically in 1970.[22] Attwood performed the first laparoscopically assisted resection of a Meckel diverticulum in 1992.[23] The historical timeline is illustrated in Figure 84-1.

## Embryology

During early embryonic development, the yolk sac nourishes the embryo via the vitelline circulation. *Vitellus* in Latin means "yolk." *Omphalos* is Greek for navel (the term *omphaloskepsis* means "meditation while gazing at the navel").

The intracoelomic yolk sac forms the gut, and the extraembryonic yolk sac begins to regress as it is replaced by the placenta as the primary source of nourishment for the developing fetus.[24,25] With growth, the fetal intestine becomes separated from the yolk sac, leaving only a ductal communication (vitelline/omphalomesenteric duct), which obliterates between the fifth and seventh weeks of fetal life (Fig. 84-2, *A* to *C*). A variety of anomalies can result from failure of involution of the omphalomesenteric duct: The classic Meckel diverticulum accounts for 90% of cases (Fig. 84-3).

Vessels on the yolk sac coalesce to form the paired omphalomesenteric arteries and veins. The enteric portion of the right artery persists as the superior mesenteric artery, and the left regresses. Distal vitelline artery remnants may persist as mesodiverticular bands, extending out to the tip of the diverticulum and occasionally attaching to the abdominal wall. A patent vitelline remnant can regress, even postnatally.[26,27]

## Epidemiology

Meckel diverticulum is the most common congenital anomaly of the gastrointestinal tract and is found in 1.2% to 3% of the population.[28–32] The male-to-female ratio is nearly equal in asymptomatic patients; among symptomatic patients it is twice as frequent in males. The "rule of 2" is often cited with regard to the diverticulum: 2 types of heterotopic mucosa, 2 feet from the ileocecal valve, 2 inches long, 2 cm in diameter, usually discovered before 2 years of age, 2 times as common in males, and it is found in 2% of the population.

*The author would like to express his appreciation to Dr. Raymond A. Amoury, without whom this chapter could not have been written.

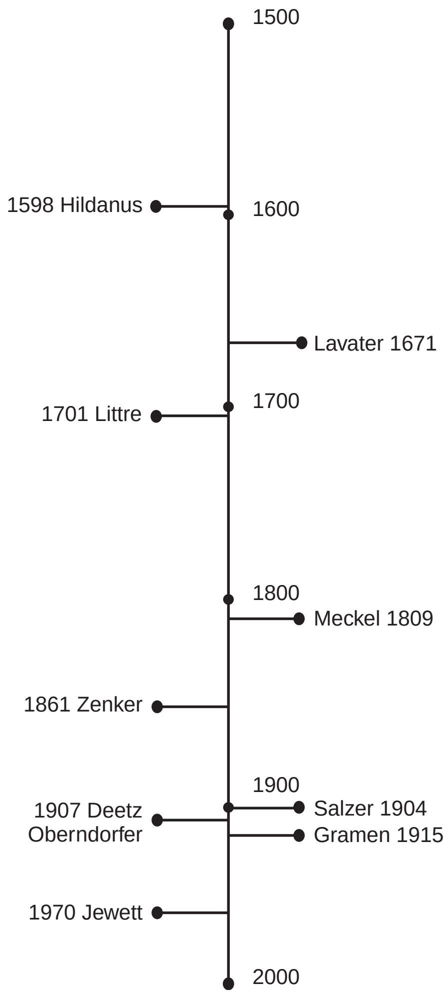

**FIGURE 84-1** The historical timeline of Meckel diverticulum, from original observation to current day. The significant points are discussed in the text.

## Pathology

Meckel diverticulum is a true diverticulum, containing all the normal bowel wall layers. It is almost always on the antimesenteric border. Three fourths of Meckel diverticula are unattached to the abdominal wall and free-floating within the peritoneal cavity.[24,33] Most diverticula are located within 100 cm of the ileocecal valve, but the location can be quite variable. The median distance from the ileocecal valve to the diverticulum was 40 cm in one series, but the range was wide.[30] At least 5 feet of distal small bowel should be thoroughly examined to rule out the presence of a diverticulum. Mean diverticular length is 2 to 3 cm.[24,34,35] Some studies have suggested that symptomatic diverticula tend to be longer and have a narrower base,[35,36] but other reports found no difference in length or diameter of asymptomatic versus symptomatic diverticula.[37]

The incidence of heterotopic mucosa in surgically removed Meckel diverticula is estimated at 15% to 50%, but these reports usually include both incidental cases and symptomatic patients. In autopsy series, the numbers are lower.[29,32,38,39] In collected series the incidence of heterotopic mucosa in asymptomatic patients is about 15%.[31,36,38,40–42] Symptomatic patients are

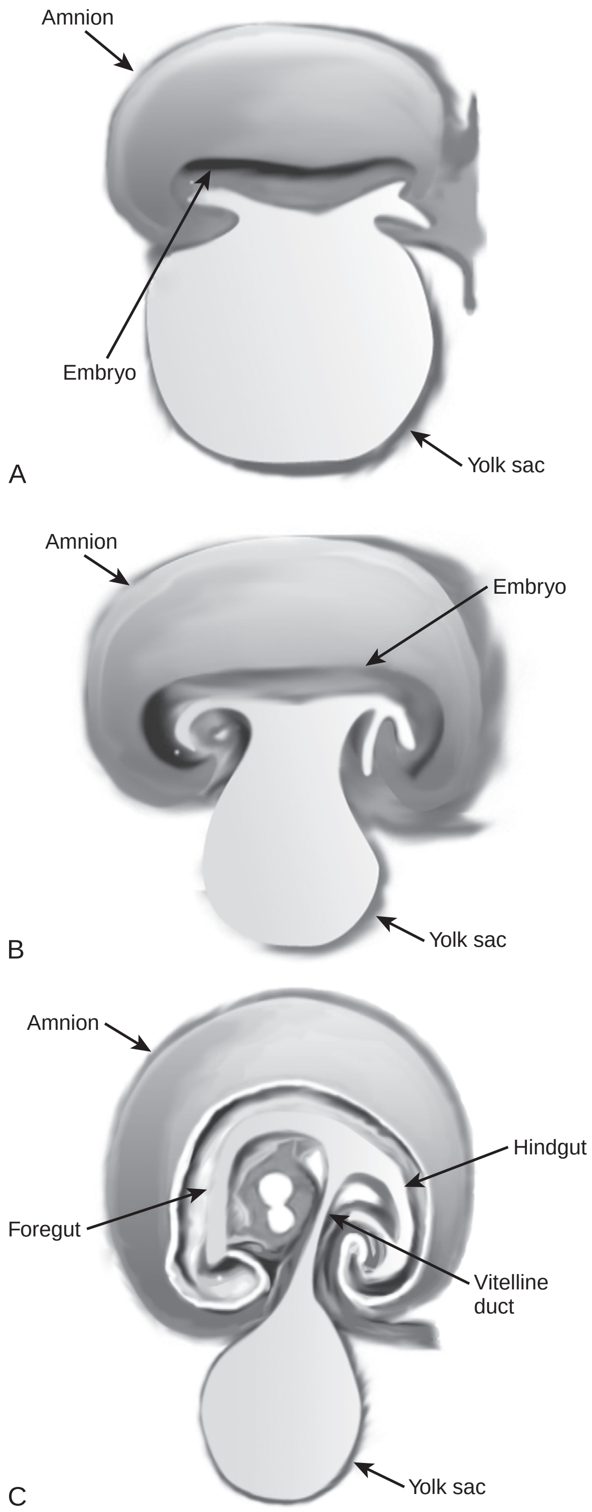

**FIGURE 84-2** Stages in the development of the fetal membranes. **A,** The relatively small amniotic cavity is located atop the embryonic disc, which separates it from the larger yolk sac below. The beginnings of the hind gut and foregut (formed from the yolk sac) are visible. This corresponds to approximately the third week of fetal life. Not pictured are vessels on the surface of the yolk sac. **B,** The amniotic cavity has expanded, and the yolk sac is elongating and diminishing in size (fourth week of fetal life). The allantois and fetal heart tube are visible. **C,** The embryonic gut is forming, and there remains a narrow communication (vitelline duct) with the yolk sac. Further expansion of the amniotic sac and development of the embryo has occurred. This roughly corresponds to the fifth week of development.

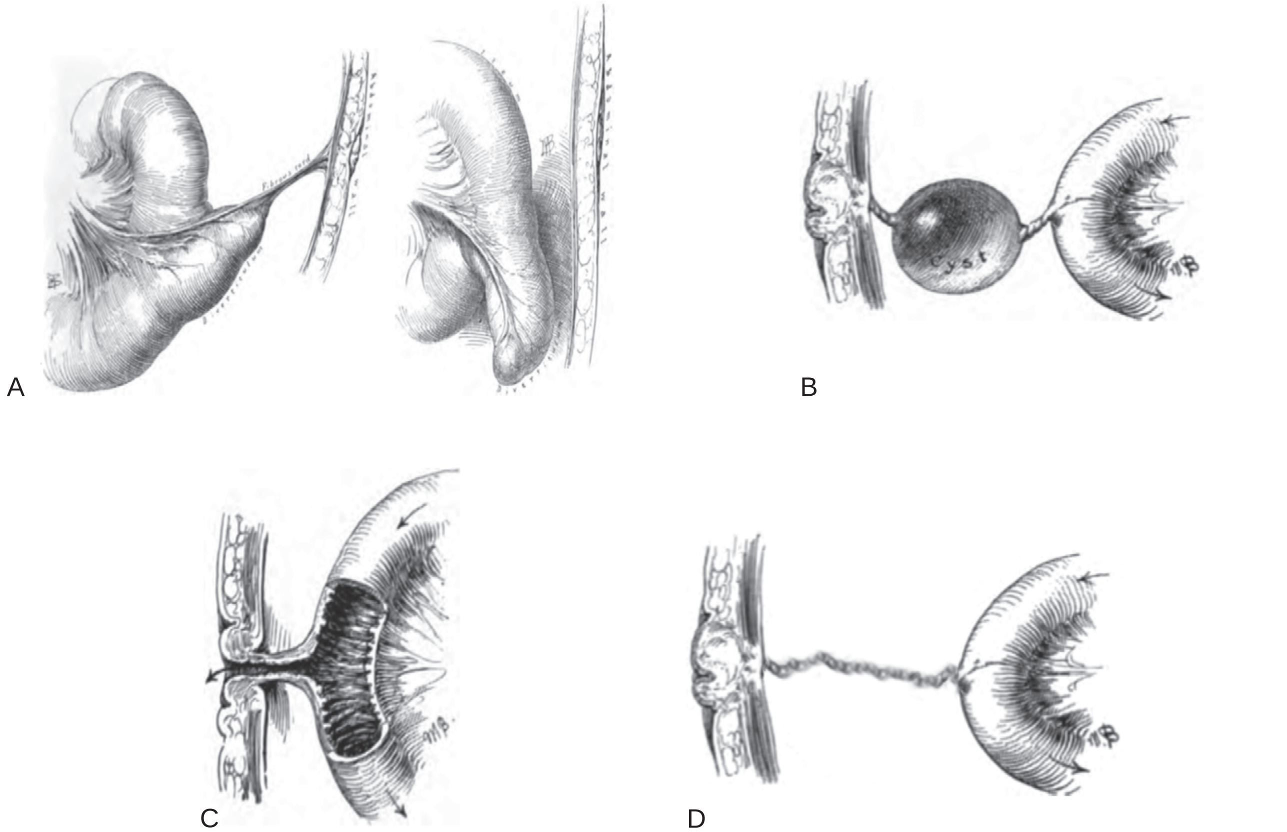

**FIGURE 84-3** Meckel diverticulum and vitelline abnormalities. **A,** Meckel diverticulum with (25%) and without (75%) abdominal wall attachment. **B,** Vitelline cyst with mucosal lining. These may be just under the peritoneal lining of the abdominal wall. **C,** Patent omphalomesenteric duct with mucosal lining (omphalo-ileal fistula). **D,** Fibrous vitelline attachment without a diverticulum. Other variants include vitelline cysts within the umbilical cord but external to the infant; umbilical polyps (although usually independent anomalies, these polyps may penetrate the abdominal wall and connect with deeper structures); or a blind-ending umbilical sinus. (From Cullen TS: Embryology, Anatomy, and Diseases of the Umbilicus. Philadelphia and London, WB Saunders, 1916.)

far more likely (40% to 50%) to have heterotopic mucosa.[31,34,43] Gastric is the most common type, followed by pancreatic. Other types of heterotopia (colonic, endometrial, pancreatic islets) are rare. A review of 21 resected specimens with known heterotopic tissue found that it was palpable in less than half (48%)[38] and was located at the base of the diverticulum in 13% (Fig. 84-4).

Bleeding and inflammatory complications of Meckel diverticula are usually attributable to the abnormal mucosa. The incidence of gastric mucosa in *bleeding* Meckel diverticula has been estimated to be as high as 80%.[44] Gastric acid production causes ulceration, usually at the base of the diverticulum at the junction of ectopic gastric mucosa and normal ileal mucosa. The ulcer may also be found within the ectopic gastric mucosa itself or on the mesenteric side of the ileum opposite the diverticulum.

**FIGURE 84-4** Meckel diverticulum with thickening near the tip from heterotopic gastric mucosa.

## Associations

Most cases of Meckel diverticula are sporadic. The presence of a diverticulum alone does not mandate a search for other anomalies because less than 5% of patients will have any associated abnormalities.

Simms and colleagues[45] reviewed 5919 autopsies over a 20-year period to identify congenital malformations with a higher than expected incidence of Meckel diverticulum. They found a 12% incidence in patients with esophageal atresia, 11% with imperforate anus patients, 6% in those with neurologic abnormalities, 4.6% in congenital cardiovascular abnormalities, and a 4.2% incidence with duodenal atresia.[45]

In their much smaller clinical series ($n$ = 81), there was a surprisingly high incidence of Meckel diverticulum in association with small omphaloceles (24.5%). Several other reports have noted a similar association of Meckel diverticulum and omphalocele minor, with an incidence ranging from 15% to 40%.[42,46,47]

An association with Crohn disease has been suggested: A 5.8% incidence of Meckel diverticulum was found in 294 patients undergoing right hemicolectomy for Crohn disease.[48] However, a review of 877 patients with Crohn disease found an incidence of only 1%.[49] None of the patients had active Crohn disease in the diverticulum. Most series found no evidence of heterotopic mucosa in any patients.

A Littre hernia is defined as one containing a Meckel diverticulum. The usual sites are inguinal (50%), umbilical (20%), and femoral (20%); the most common location in children is umbilical.[50] Most of these rare hernias occur in the elderly population.

# Incidental Diverticulectomy

In the voluminous literature on Meckel diverticulum, the controversy regarding incidental diverticulectomy is longstanding. A systematic review of the population of King's County, Wash., over a 15-year interval found a declining incidence of complications from Meckel diverticula with age (as have others).[51,52] Soltero and colleagues[51] identified 202 symptomatic Meckel diverticula. The total complication rate was estimated to be 4.2%, and they estimated that 800 diverticula would have to be removed to prevent one death.[51] These authors argued that asymptomatic Meckel diverticula should not be removed.

Cullen and colleagues[34] estimated that the lifetime risk of patients with a Meckel diverticula developing a complication was 6.4%. They found that the risk of complications did *not* decrease with age and suggested that the benefits of removing the incidental Meckel diverticula found at operation outweighed the risks. They also noted an increased risk of complications in men compared with women.

Many other series advocated basing the decision to incidentally remove an asymptomatic Meckel diverticulum on its clinical characteristics (length, width, thickened tip); the gender or age of the patient; or other factors.[38,53] Park and colleagues[38] reviewed 1476 patients undergoing diverticulectomy over a 52-year interval; 16% were symptomatic. They performed a logistic regression analysis to identify factors associated with a symptomatic diverticulum. Statistically significant associations included age younger than 50 years (odds ratio—OR 3.5), diverticular length greater than 2 cm (OR 2.2), and male gender (OR 1.8). The presence of histologically abnormal tissue in the diverticulum was strongly associated (OR 13.9) but may not be identifiable before resection. Others have suggested that the risk (albeit small) of neoplastic degeneration supports incidental diverticulectomy.[54]

A recent meta-analysis of 244 studies with more than 3000 patients, by Zani and colleagues,[31] concluded that resection of an incidental Meckel diverticula has a statistically significantly higher early complication risk than simply leaving it in situ (5.3% vs. 1.3%, $P < 0.0001$). Similar to Soltero's report, they estimated that 758 patients would have to undergo elective resection to prevent one death. They estimated that an individual with a Meckel diverticulum has a lifetime chance of complications requiring an operation of 2.9%. The future risk of death attributable to a Meckel diverticulum did not increase significantly with age.

It has been estimated that appendicitis is more than 50 times as common as a symptomatic Meckel diverticulum. Incidental appendectomy is currently rarely recommended—some have argued that this would be a statistically more justifiable proposition than incidental diverticulectomy.

# Clinical

Charles Mayo famously wrote that "Meckel's diverticulum is frequently suspected, often looked for, and seldom found."[55] Most Meckel diverticula are clinically silent. It has been called the "great imitator" because of its relative infrequency and protean manifestations.

Symptomatic patients are usually younger.[35,37,38,40,56] Up to half of symptomatic Meckel diverticula will present in the first 2 years of life, and most complications will develop before 10 years of age. The type of complication also varies with the age of the patient. Hemorrhage and obstruction predominate in the very young, and obstruction and inflammatory symptoms occur in adults.[36,42,43,53,57,58] Neoplasia becomes a more frequent complication in the elderly.

## RADIOLOGY

The technetium-99m pertechnetate radionuclide study ("Meckel scan") is commonly used today (Fig. 84-5). The accuracy of the study is improved by the administration of pentagastrin (which increases gastric mucosal uptake and is a potent stimulator of gastric acid secretion and increased gastric motility) and H2 blockers (which inhibit the excretion of the isotope into the bowel lumen and increase the cellular concentration). Giving both H2 blockers and pentagastrin together is not recommended because the former antagonizes the latter.[59] Glucagon slows bowel transit and allows the isotope to persist longer in the diverticulum.[60] A urinary catheter is used to diminish bladder accumulation, which may obscure the diverticulum.

Technetium 99m has a half-life of 6 hours with a maximum concentration occurring 15 to 30 minutes after intravenous injection.[22] The isotope is taken up by gastric mucosal cells.[61] Estimated radiation dosimetry in a 5-year-old child from a standard Meckel scan is 0.11 to 0.66 milli-Curies, with maximum exposure in the large intestine (0.78 rads).[59] The study is, of course, negative in the absence of heterotopic gastric mucosa.

The relatively high false-negative rate of the Meckel scan in bleeding diverticula has been a significant concern. Several recent summaries of the literature found that the Meckel scan had a sensitivity of only 60% to 84% in children, with a high false-negative predictive value, especially in anemic patients.[44,57,62,63] Repeating the scintiscan is sometimes recommended to decrease false-negatives, but some authors recommend proceeding straight to laparoscopy for both diagnosis and treatment.[44,57,62] False-negatives may be due to rapid dilution of the radiotracer from a high bleeding rate, poor blood supply to the diverticulum, or an inadequate amount of gastric mucosa. Meckel scans are even less accurate in the diagnosis of a bleeding diverticulum in adults, where the accuracy ranges from 15% to 50%.[64–67]

False-positives may be due to intestinal duplications with heterotopic gastric mucosa. Other causes include obstructed

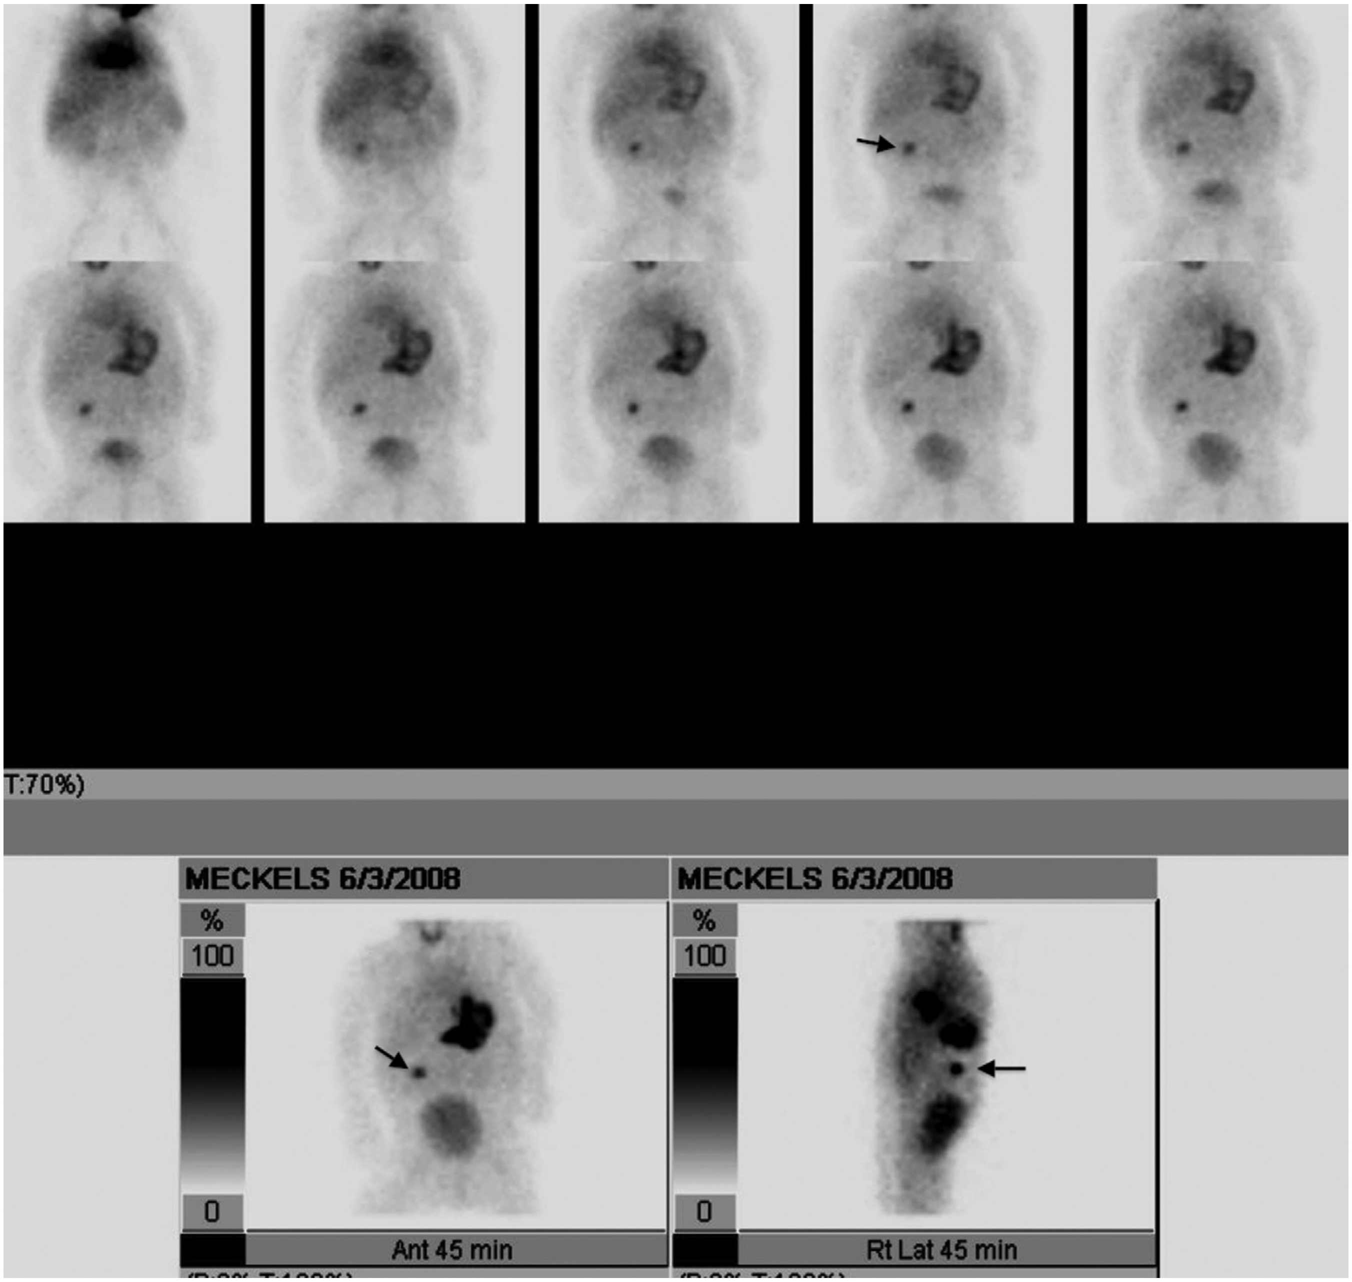

**FIGURE 84-5** Meckel scan. Technetium-99m pertechnetate selectivity concentrates in gastric mucosa whether in stomach or a Meckel diverticulum. It is excreted from the stomach into the duodenum and proximal small bowel. Isotope excreted in the urine collects in the bladder. Sites of isotope accumulation appear as dark areas on the scan. In this case, isotope outlines stomach, proximal intestine, Meckel diverticulum (*arrow*), and urinary bladder. (Photo courtesy Douglas Rivard, MD, Children's Mercy Hospital, Kansas City, Mo.)

loops of bowel, intussusception, inflammatory lesions, arteriovenous malformations, ulcers, and some bowel neoplasms.[39]

Angiography is usually negative unless the bleeding rate is greater than 0.5 mL/min. This study is rarely if ever indicated in the evaluation of a suspected Meckel diverticulum.

A recent review of children with a Meckel diverticulum found that the diagnosis was made by computed tomography (CT) scan findings (small bowel obstruction, intussusception, cystic mass) 2.3 times more commonly than via a Meckel scan.[68,69] This may reflect the type of complications (obstruction, inflammation) seen in the authors' patient population.

Wireless capsule endoscopy has been used to identify a Meckel diverticulum.[70,71] In one multicenter European study, the procedure was performed on 80 children (mean age approximately 6 years) with varying symptoms, and a Meckel diverticulum was identified in 2.

## BLEEDING

In patients who present with bleeding, the correct diagnosis is often made preoperatively; this is uncommonly the case with inflammatory or obstructive symptoms.[67] Meckel diverticulum accounts for nearly 50% of all lower gastrointestinal bleeding in children, usually occurring in infants and toddlers. The differential diagnosis includes intestinal polyps, inflammatory bowel disease, intestinal duplications, hemangiomas, and arteriovenous malformations.

The color of the stools is inconsistent with rectal bleeding and may be bright red (35%), maroon or dark red (40%), or less commonly, tarry (7%).[43] Younger children with bleeding often have anemia (Hgb < 8 g/dL) at presentation.[44] Many children will require transfusion, but life-threatening bleeding is uncommon. Episodic painless bleeding is the most common scenario. Unexplained isolated anemia is the sole presentation in a small fraction of children.

*Helicobacter pylori* is a gram-negative spiral bacterium responsible for most ulcers in the duodenum and stomach. However, it is rarely found in the heterotopic gastric mucosa of a Meckel diverticulum.[29,72–74] A recent analysis (via polymerase chain reaction) of 12 diverticula with heterotopic gastric mucosa demonstrated no *Helicobacter*.[74] Their literature survey of 375 patients noted a 7% incidence of *H. pylori* positivity. Bile, especially in an alkaline pH, causes inhibition of *H. pylori* growth and is the most commonly postulated mechanism for the absence of the bacterium in Meckel diverticula.[75]

## Obstruction

Meckel diverticula can cause a bowel obstruction via intussusception, volvulus, vitelline bands/remnants, incarcerated Littre hernia, and other mechanisms (Fig. 84-6). Intussusception is slightly more common in children, and volvulus in adults. Intussusception is a result of the diverticulum acting as a pathologic lead point. Pathologic lead points are infrequent in children with intussusception younger than the age of 2 years. In Harkin's classic review of 160 intussusceptions from Meckel diverticula, the mean age was 13 years; however, 60% were younger than 10 years of age. Overall, less than 3% of all intussusceptions are due to a diverticulum.[15]

Intussusception usually presents with vomiting, intermittent abdominal pain, bloody stools, a palpable lower abdominal mass, and eventual progression to dehydration and lethargy. Either ultrasound or pneumatic enema usually confirms the diagnosis of intussusception but rarely identifies the underlying cause. Complete reduction is usually unsuccessful when a pathologic lead point is present, and the diverticulum

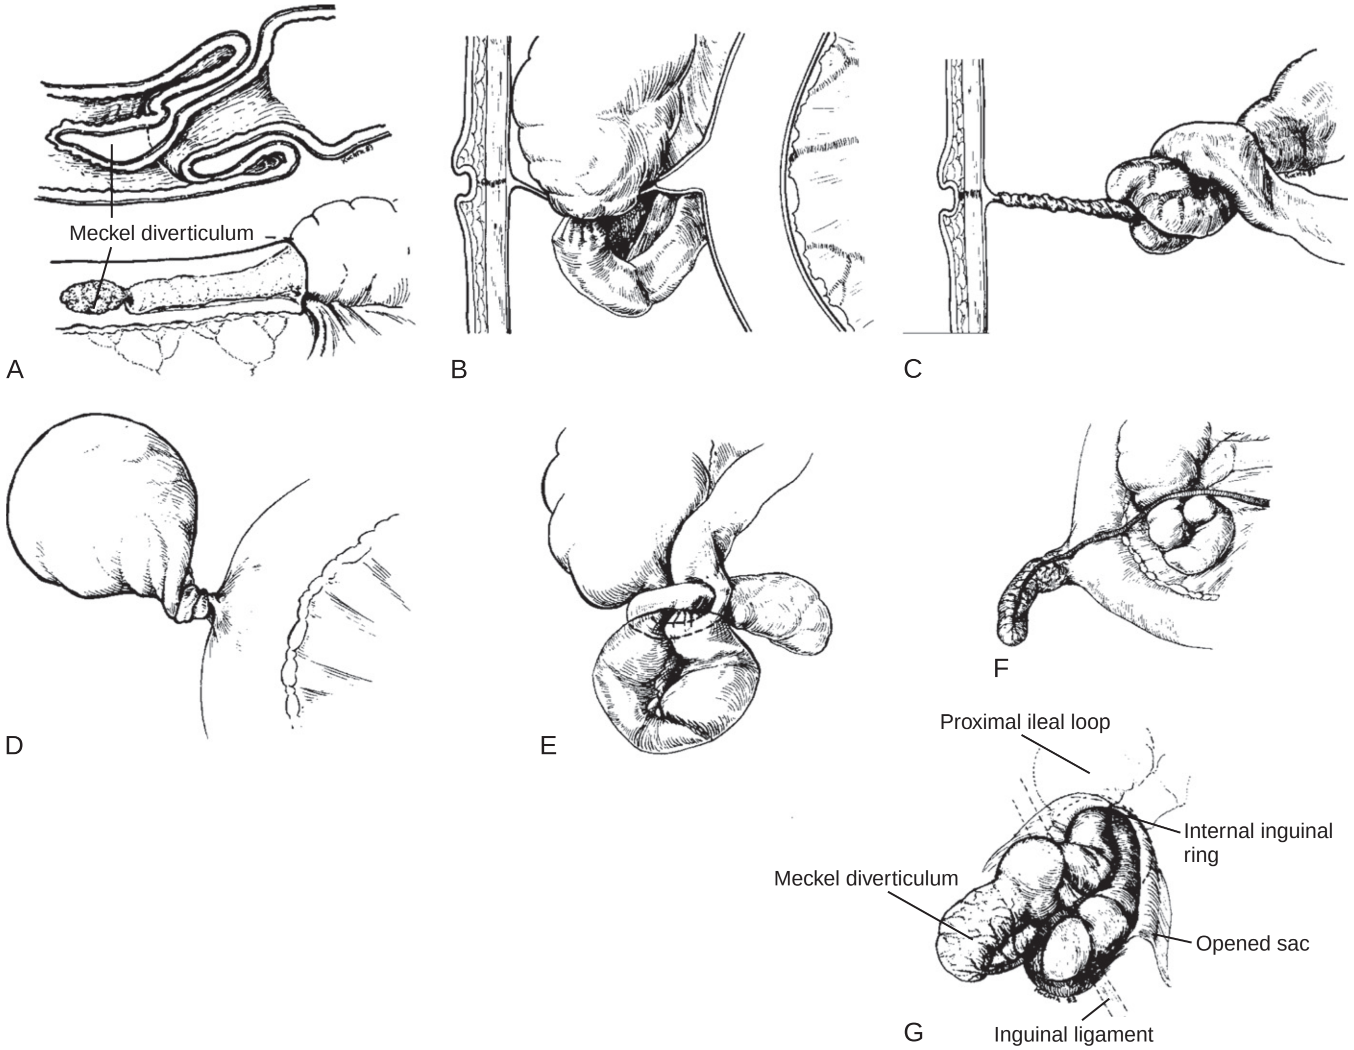

**FIGURE 84-6** Mechanisms of intestinal obstruction due to a Meckel diverticulum. Intussusception and volvulus are the most common. **A,** Intussusception with the diverticulum acting as a pathologic lead point. **B,** Loop of intestine "kinked" around a fibrous vitelline remnant. **C,** Volvulus around a fixed, tethered vitelline remnant attached to the abdominal wall. **D,** Volvulus of a diverticulum around its own base. **E,** "Self-knotting" Meckel diverticulum. **F,** Internal herniation of ileum under a mesodiverticular band/vessel. **G,** Littre hernia, illustrated here in an indirect inguinal location.

is often discovered unexpectedly during surgery or when the resected specimen is examined. Surgical management usually consists of resection of the obstructed bowel with end-to-end anastomosis.

Volvulus can result from an omphalodiverticular (from the tip of the diverticulum to the abdominal wall) fibrous or a vascular vitelline remnant, which provides a point of fixation for the bowel to twist around. A long diverticulum can even knot on itself, causing obstruction, or it may twist around its base. Giant Meckel diverticula or vitelline cysts may result in volvulus, usually in newborns (Fig. 84-7).[76,77]

Mesodiverticular vitelline remnants (from the mesentery to the tip of the diverticulum) can create an internal hernia under which small bowel becomes entrapped and strangulated. Adhesions due to an inflammatory process may also result in obstruction. A rare cause of obstruction secondary to Meckel diverticulum is an incarcerated Littre hernia.

Preoperative preparation consists of intravenous hydration, correction of electrolytic abnormalities, nasogastric decompression, and antibiotics. Resection of the diverticulum and involved bowel is the treatment of choice. Reanastomosis is usually possible.

## INFLAMMATION

Diverticular inflammation usually occurs in older children and is commonly misdiagnosed as appendicitis. A Meckel diverticulum was found to be the source of the symptoms in 0.76% of 8385 operations performed for presumed appendicitis.[28] A search for a Meckel diverticulum should be undertaken in children suspected of having appendicitis, but in whom the appendix is normal at operation.

Although inflammatory changes are usually due to the presence of gastric or pancreatic tissue in the diverticulum, other mechanisms include stasis of contents in the diverticulum (kinking, narrow neck), enterolith, foreign body, and parasitic or other infection. An obstructive pattern from adhesions or ileus may be the presenting feature, or perforation may occur. The correct preoperative diagnosis is uncommon in Meckel diverticulum with inflammatory complications. Occasionally a CT scan will show a midline mass with a normal appendix, suggesting the diagnosis (Fig. 84-8).

Inflammatory complications are treated by resection, either of the diverticulum alone or including the involved bowel. Primary reanastomosis is usually possible. On rare occasions, the child is so ill that exteriorization or a temporary stoma is necessary.

## NEOPLASIA

Overall, neoplasia is found in 0.5% to 4% of Meckel diverticula,[78–82] and malignant tumors predominate. Benign tumors include leiomyomas, lipomas, angiomas, and neurofibromas. A variety of malignancies have been reported (leiomyosarcoma, carcinoids, adenocarcinoma, villous adenoma, gastrointestinal stromal tumors, and others). Overall, carcinoid is the most common tumor arising in the diverticulum. More carcinoids occur in a Meckel diverticulum per centimeter than in any other area of the gastrointestinal tract (due to the small mucosal area).[83]

Neis and colleagues performed a comprehensive review of carcinoid tumors arising in a Meckel diverticulum.[84] There were 104 cases, with a mean age of 56.6 years and a male predominance; less than 5% of their patients were younger than 20 years of age. Approximately three fourths of the tumors were found at the tip of the diverticulum. Tumors larger than 5 mm were more likely to metastasize, but only 24% had metastasized at the time of diagnosis, with a significantly higher incidence of metastases in women. Slightly more than half were asymptomatic. The classic carcinoid syndrome was present in 8% at diagnosis.[84] Clinically, the biologic behavior of carcinoids in a Meckel diverticulum is closer to that of an ileal rather than an appendiceal carcinoid.[84,85] Excision of a segment of ileum and mesentery containing the diverticulum is recommended.

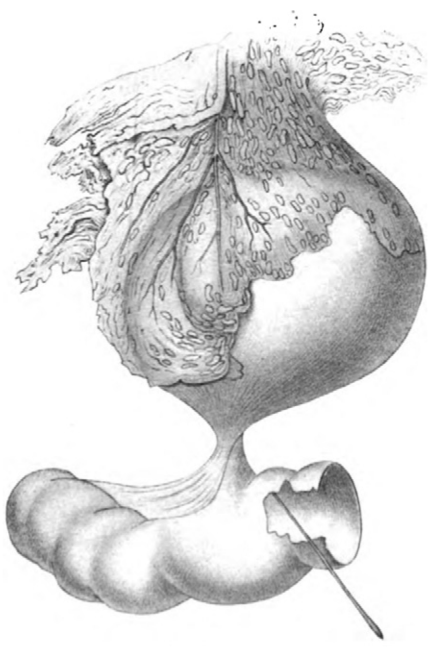

**FIGURE 84-7** Giant cystic Meckel diverticulum. These are rare; the largest reported was 56 cm in diameter. (From Cullen TS: Embryology, Anatomy, and Diseases of the Umbilicus. Philadelphia and London, WB Saunders, 1916.)

**FIGURE 84-8** Computed tomography scan in a 5-year-old boy with symptoms of appendicitis. The appendix (not shown) was normal, but a tubular edematous mass in the pelvis (*arrow*) suggested the diagnosis of Meckel diverticulum.

### OTHER

Enteroliths are a relatively uncommon occurrence in Meckel diverticula. However, in one large series, 10 of 84 patients (12%) had an enterolith.[86] The median age was 45 years, and all were symptomatic (most chronically). The mean stone diameter was 3 cm, and more than half had multiple stones. None had heterotopic mucosa. In another report of 1476 Meckel diverticula, 6% of those resected had an enterolith.[38]

Up to 8% of resected diverticula are due to a foreign body in adult series.[66] Fish and chicken bones, toothpicks, coins, and many other objects have been identified.[87,88] Even wireless video capsules have been lodged in a diverticulum.[89,90]

Parasitic infections in Meckel diverticula can occur, more commonly in underdeveloped countries. *Schistosomiasis mansoni, Ascaris* (roundworm), *Taenia saginata* (tapeworm), and others have been identified.[91,92]

A neonatal presentation of Meckel diverticula is quite unusual; most of the few reported cases have been of perforation or bowel obstruction in this age group.[93]

## Treatment

The treatment of a symptomatic Meckel diverticulum is resection. This can be done with open or laparoscopic techniques. There are several large series of laparoscopic or laparoscopically assisted Meckel diverticulectomies.[94] The procedure is often diagnostic and therapeutic, and some have argued forgoing the Meckel scan entirely because their algorithm for bleeding children with otherwise negative evaluations is to perform laparoscopy if a Meckel scan is positive and to do the same if the study is negative.[44,63,94] The diverticulum is often laparoscopically identified and grasped but removed extracorporeally, particularly if a segmental bowel resection is performed.

A Meckel diverticulum can be removed by either simple resection of the diverticulum and transverse closure across the base, or resection of a short segment of ileum containing the diverticulum with reanastomosis. In patients with bleeding or inflammatory symptoms, ulceration may be present on the mesenteric border or at the margin of the diverticulum, and resection of the ileal segment with the diverticulum is the safest option. The feeding (diverticular) artery should be clearly identified and ligated.

## Outcome

Most series report a short-term complication rate (wound infection, leak, bowel obstruction) after diverticulectomy of about 5% to 10%, lower (1% to 2%) for incidental resection.[31,38,51,65]

In the extensive meta-analysis of 244 articles in the literature since 1950, the historical mortality rate for resection of Meckel diverticula was 0.01% and the current mortality was 0.001%.[31]

# CHAPTER 85

# Intussusception

Paul M. Columbani and Stefan Scholz

## History

Intussusception was recognized as a disease in the late 1600s in Europe (Barbette, Peyer), but Hunter provided the first detailed description of intussusception in 1793.[1–3] Treatment of intussusception at that time included bleeding and quicksilver, to which Hunter added emetics followed by purgatives. Hand bellows to attempt pneumatic reduction per anus were possibly tried as early as Hippocrates' time.[4] In the early 1800s, the first documented descriptions of pneumatic reduction for intussusception appeared in the medical literature.[5] In 1864 the Scottish surgeon Greig[5,6] was the first to lay down strict criteria for the clinical diagnosis of intussusception. He claimed that he successfully reduced four of five actual pediatric intussusceptions with hand bellows: "Contrary to our expectations the air passed readily into the bowel and seemed to give the child great relief." Despite this report of success, there were many competing methods to treat intussusception (effervescent powder, cold water, hypertonic saline, long bougies per rectum, electricity, belladonna, opium). Most were not successful. As a result, the condition remained fatal in most infants and children.

Wilson (1831) reported the first successful operative reduction in an adult, and Hutchinson reported it in an infant 40 years later (1871).[7,8]

Any operative intervention in children at that time was quite hazardous. Treves (1885) reported a 73% mortality rate for his first 33 operative cases.[9,10] In 1876 Hirschsprung published the first of a series of reports on hydrostatic reduction with much decreased mortality (23%) than operation.[11] In the late 1800s various devices for hydrostatic or pneumatic reduction were developed. Forest (1886) calculated that 6 lb of pressure per square inch was acceptable for reduction,[12] and Mortimer (1891) discussed the danger of this new method.[13] Hydrostatic reduction gained wide acceptance as primary treatment around 1900, when both Clubbe and Peterson reported the successful resection of pediatric intussusception.[14,15] Despite Hirschsprung's much lower (23%) mortality rate (in 84 patients, 1905) for hydrostatic reduction, surgical treatment predominated.[5,16] As operative technique evolved, results improved.

In 1913 Ladd reported the use of diagnostic imaging with bismuth enemas and published the first photographs of roentgenologic pictures of an intussusception.[17] Ladd, however, saw this as a good diagnostic technique but did not recognize its therapeutic value. Fourteen years later (1927), Olsson and Pallin,[18] Poulquien,[19] and Retan[20] used hydrostatic reduction of intussusception with barium-guided fluoroscopy.

By this time, hydrostatic reduction was accepted as the preferred method in Australia, Scandinavia, and South America.[5] Hipsley in Australia (1926) published a series of 62 cases treated by hydrostatic saline enema with only 1 death.[21] Despite its inferior results, operation had become the primary method of choice in the United States. Attention only shifted to nonoperative reduction after Ravitch and McCune reported a surgical mortality of 32% in 1948.[22] Reduction via hydrostatic barium enema (BE) and fluoroscopy (contrast enema) was popularized by Ravitch and supported by both his laboratory research and clinical confirmation. In 1953 Gross, much like his predecessor Ladd,[17] acknowledged nonoperative treatment as possibly being effective but opposed it in favor of definite operative treatment.[23] By 1958, nonoperative reduction rates of up to 75% were achieved with a mortality rate close to zero.

Proponents of the hydrostatic method persisted in the United States, and eventually this technique became the primary, safest, and successful means of treating intussusception.

Radiologists began to report on clinical results. Fiorito and colleagues (1959) performed pneumatic reduction with air as the contrast medium.[24] Burke and Clarke (1977) used only ultrasonography (US) for screening, diagnosis, and monitoring the reduction of intussusception.[25] Guo and colleagues (1986) successfully tried delayed repeat enema reduction attempts.[26]

Today, operation is the accepted norm for failed radiologic-guided reduction of intussusception.

## Introduction

The word *intussusception* is derived from the Latin words *intus* (within) and *suscipere* (to receive).[27] Intussusception is the invagination of one part of the intestine into another (Fig. 85-1).

Three cylinders of intestinal wall are involved. The inner and middle cylinders are the invaginated bowel (intussusceptum), and the outer cylinder is the recipient of the invaginated bowel (intussuscipiens).[28]

Intussusception is one of the most frequent causes of acute bowel obstruction in infants and toddlers (Fig. 85-2). It is

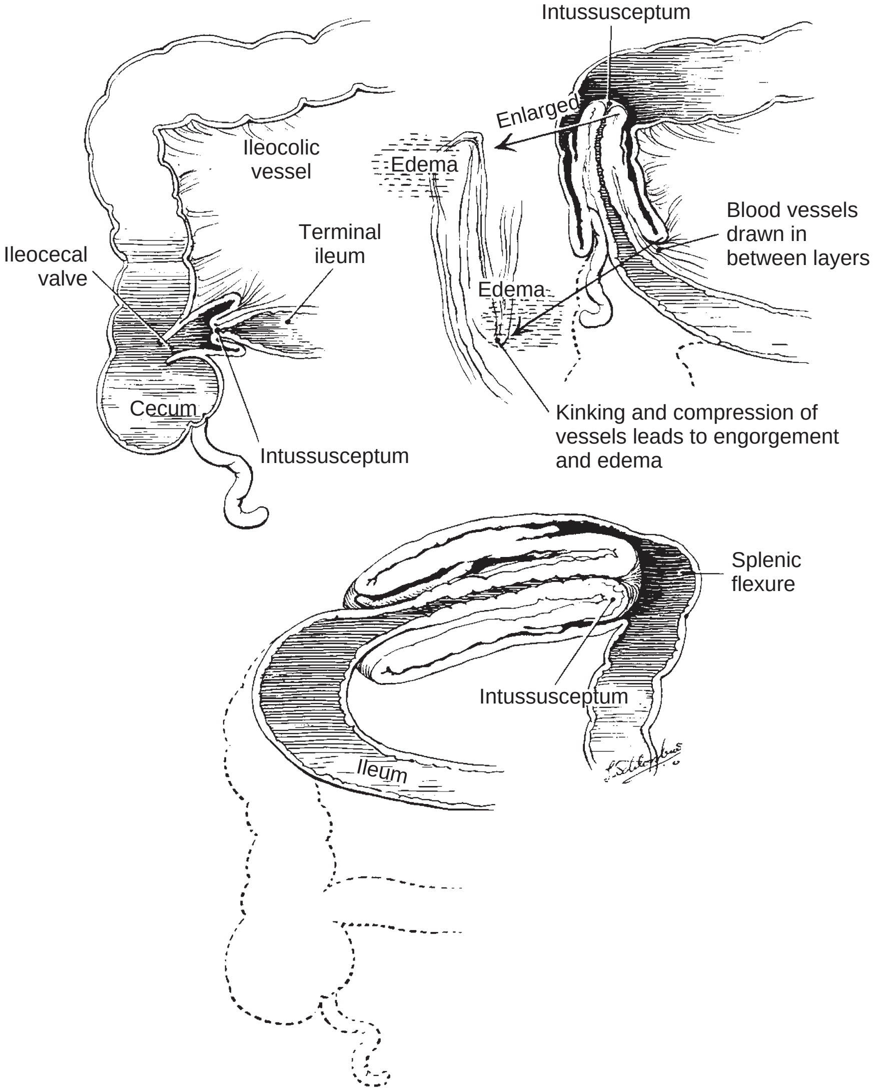

**FIGURE 85-1** Diagram of the most common (idiopathic, ileocolic) type of intussusception. As it develops in the terminal ileum with its prograde bowel peristalsis, the proximal invaginated bowel (intussusceptum) carries its mesentery into the recipient bowel (intussuscipiens) and the mesenteric vessels are angulated, squeezed, and compressed between the layers of the intussusceptum. This causes intense local edema of the intussusceptum, which produces venous compression, stasis, and congestion leading to an outpouring of mucus and blood from the engorged intussusceptum, often producing stool with the appearance of currant jelly. If this vicious cycle continues, ischemic changes will lead to bowel gangrene. The outermost layer of the intussusceptum becomes devitalized first, the innermost layer of the intussusceptum becomes gangrenous much later, and the outermost layer of bowel (intussuscipiens) loses its viability last. Most perforations, however, are located in the colon near the intussusceptum.

probably the second most common cause of acute abdominal pain in infants and preschool children after constipation.

In 1953 Gross stated: "There are few illnesses in which the clinical history and physical findings are more suggestive of the correct diagnosis."[23]

At present, diagnosis and treatment is a combined effort among the pediatrician, the pediatric radiologist, and the pediatric surgeon.

## Incidence and Demographics

Intussusception occurs throughout the world with an incidence of approximately 1 to 4 in 2000 infants and children.

Most series report more males than females with intussusception, usually at a 2:1 or 3:2 ratio (Fig. 85-3), which may be more evident (78% males) after 9 months of age than before (55%).[29,30] Intussusception is reported to occur in greater numbers in Caucasian infants and children.

Although intussusception can be seen in all pediatric ages from prenatal to the late teens (and in adults and animals as well), 75% of cases occur within the first 2 years of life and 90% in children within 3 years of age. More than 40% are seen between 3 and 9 months of age.[31]

In utero, intussusception may lead to intestinal atresia, most commonly ileal atresia.[32–35] Perinatal intussusception in newborns (0.3% of all intussusceptions) is more likely caused by a pathologic lead point like in older patients.[36–38] Sometimes, the disconnected end of the intussusceptum can be found in the distal part of the bowel.[39]

Intussusception has been reported in families and relatives (identical twins, sibling cases, as well as in fathers and sons), but their histories seem to indicate a common viral cause rather than a genetic cause.[15,40] No evidence points to an increased likelihood of intussusception in a sibling once one child of the family has been affected.

The frequency of intussusception displays a seasonal variation that usually correlates with viral infections (respiratory, gastrointestinal, or both), with most cases seen in May, June, and July.[15,29,41] The incidence of a preceding viral illness has been reported as high as 20%.[30,31,42]

Children with intussusception have been described as being generally healthy, sturdy, well developed, and well nourished, supporting Hirschsprung's classic statement: "I never saw a malnourished child with an intussusception."[16,43] Series from South Africa and Chicago[44,45] could not confirm this observation. Children with intussusception exhibited lower weight percentiles irrespective of socioeconomic status.

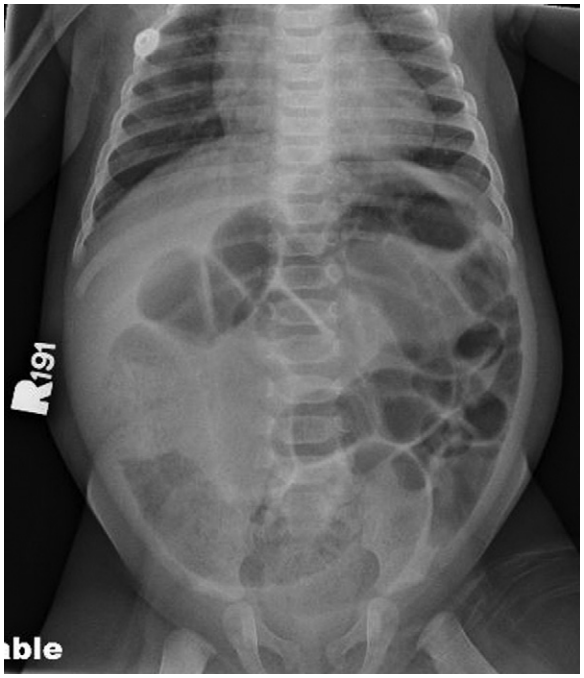

FIGURE 85-2 Radiologic picture of idiopathic intussusception in an infant.

## Pathophysiology

### PATHOLOGIC ANATOMY

Each intussusception has the following pathologic anatomy: as the intussusception develops with its prograde bowel peristalsis, the proximal invaginated bowel (intussusceptum) carries its mesentery into the distal recipient bowel (intussuscipiens). The mesenteric vessels are angulated, squeezed, and compressed between the layers of the intussusceptum. This causes intense local edema of the intussusceptum, which in turn produces venous compression, congestion, and stasis leading to an outpouring of mucus and blood from the engorged intussusceptum, the classic red currant jelly stool (Fig. 85-4). If this process continues unabated, bowel congestion and pressure increase and ultimately produce ischemic changes leading to bowel necrosis in the intussusceptum. In his classic experiments about intussusception, Ravitch[17] already noted in 1959 that the outermost layer of bowel containing the intussusceptum becomes devitalized first, the innermost layer of the intussusceptum becomes gangrenous much later, and the outer layer of the intussuscipiens rarely, if ever, loses its viability.

In most cases, ischemic necrosis needs more than 72 hours to develop.[46]

Karnak and colleagues[47] noticed a weakened longitudinal whitish line in resected intussusception bowel segments. Microscopically the authors found mucosal necrosis, disruption of the muscularis mucosa, and loss of some of its muscular tissue. This location on the antimesenteric border and under the taenia libera can be explained by local vascular compromise as a result of the distribution of the terminal arteries of the colon. After manual reduction, this area should be checked carefully for a longitudinal weakened pressure line. Recognition of such a potentially dangerous weak line on the bowel wall may be an indication for resection.

If the ischemic process goes undiagnosed, bowel obstruction, perforation, or sepsis leads to death within 5 days. In rare cases, the intussusceptum can become gangrenous, and slough and the bowel may fuse. No free perforation occurs, and the separated necrotic intussusceptum may pass out of the rectum.

### TYPES

Intussusception can be categorized into four main types: general, specific, anatomic, and other. (1) The two general types are permanent (fixed, 80%) and transient (spontaneous

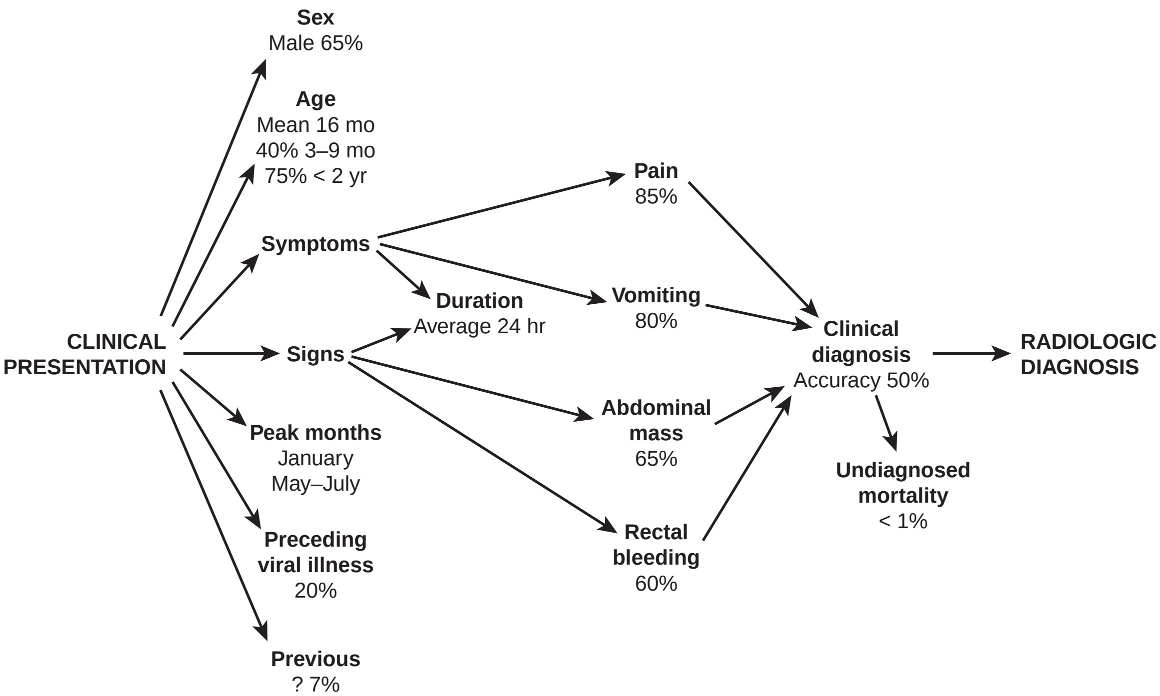

FIGURE 85-3 Algorithm detailing the clinical features and diagnosis of intussusception.

reduction, 20%); (2) the specific types can be described as idiopathic (no pathologic lead point [PLP], 95%), PLP (4%), and postoperative (1%); (3) when classified by anatomic types, their actual occurrence is ileocolic (85%); ileoileocolic (10%); appendicocolic, cecocolic, or colocolic (2.5%); jejunojejunal, ileoileal (2.5%); and those occurring around indwelling tubes; and (4) the fourth type is "other" (Fig. 85-5). Under this category are recurrent (5%) and neonatal (0.3%) intussusception.

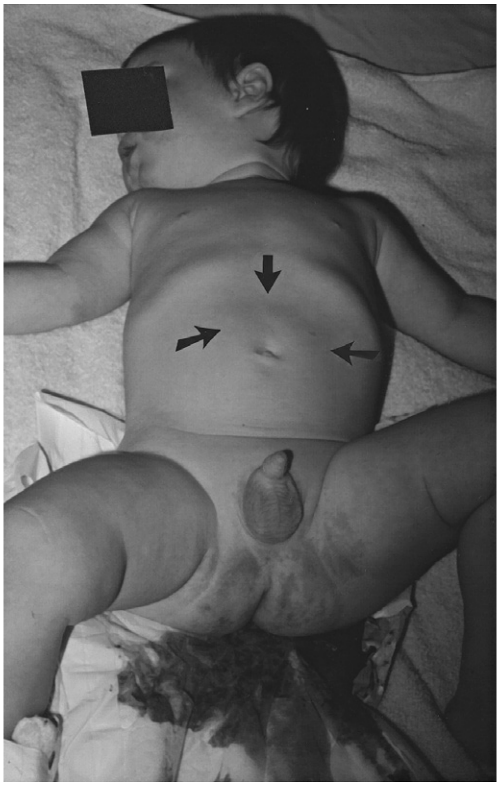

FIGURE 85-4 Pale, lethargic infant with intussusception and the classic currant jelly stool. The *arrows* point to the epigastric mass.

## General

***Permanent (Fixed)*** The vast majority (80%) of intussusceptions are fixed and permanent. They are mostly symptomatic (85%), and all require treatment.

***Transient (Spontaneous Reduction)*** Spontaneous reduction of an intussusception has been reported to occur in almost 20% of intussusceptions.[48,49] During laparotomy, it is a common observation that there are occasional small bowel intussusceptions of a few (<2) centimeters at different sites that spontaneously reduce. Most spontaneously reducing intussusceptions are incidentally seen on abdominal computed tomography (CT) or US performed for other reasons.[48–50] Transient intussusception may also be seen with gastroenteritis, probably because of hyperactivity of the inflamed bowel. Eighty-six percent of these transient intussusceptions involve only the small bowel and are noted in the central and left abdominal regions.[51] Most of these patients are asymptomatic.

Only 6% of symptomatic children with intussusception have gastrointestinal pathology serving as lead point.[48,52,53] The majority of patients with asymptomatic small bowel intussusception can be assumed to reduce and require only clinical observation. No additional imaging is necessary as long as the intussusception remains asymptomatic.

## Specific

***Idiopathic (No Pathologic Lead Point)*** All intussusceptions have some kind of a lead point. In contraindications to cases with pathologic lead points, thickened bowel wall lymphoid tissue (Peyer patches) functions as a lead point in

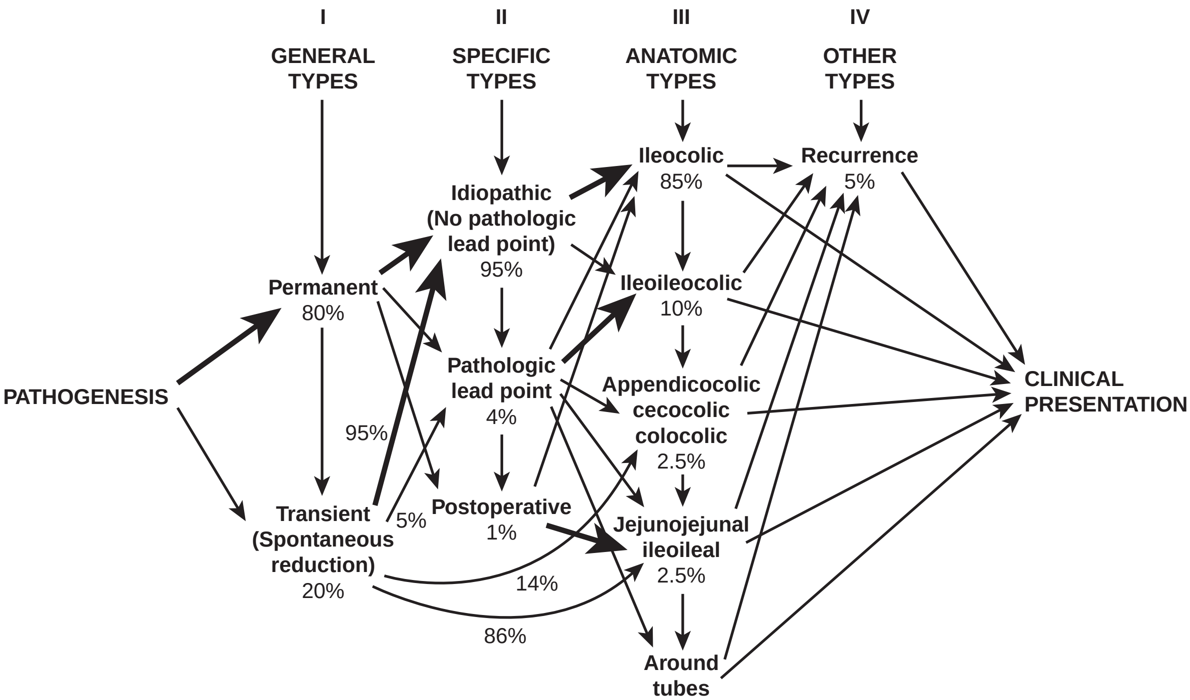

FIGURE 85-5 Algorithm of the pathogenesis of intussusception.

so-called idiopathic intussusception, which forms the majority of all cases (95%).

Infants and children have considerable masses of lymphoid tissue.[54] Peyer patches are usually located in the antimesenteric area of the bowel wall. In the distal ileum, Peyer patches involve the entire circumference of the bowel. With respiratory or gastrointestinal viral infection, the distal ileal wall lymphoid tissues and the nearby mesenteric lymph nodes may enlarge and form a lead point. However, in a mouse model, the Peyer patches did not appear to act as the anatomic lead point for intussusception.[55]

Both adenovirus[56,57] and rotavirus[58,59] infections have been associated with childhood intussusception. No doubt exists about the connection of adenovirus and intussusception.[60] Rotavirus as cause for intussusception has been extensively debated in the literature. Recent large reviews from several countries could not establish an association between rotavirus infection and intussusception.[58,60–63]

In July 1999 the U.S. Food and Drug Administration suspended the tetravalent rhesus-human reassortant rotavirus vaccine (RRV-TV, RotaShield) for a strong association between vaccination with RotaShield and intussusception among otherwise healthy infants.[64]

In 2006 the World Health Organization (WHO) recommended two live oral rotavirus vaccines, RotaTeq (RV5) and Rotarix (RV1), for inclusion into the national immunization programs of countries worldwide.[65] The two new rotavirus vaccines underwent large clinical trials of more than 60,000 infants each to assess safety with regard to intussusception. In 2009 the WHO's Global Advisory Committee on Vaccine Safety recommended its use in children younger than 15 weeks, citing no increased risk for intussusception. Especially in countries with high childhood mortality due to diarrheal illnesses, the benefits of rotavirus vaccination exceed the possibly increased risk of intussusception.

Dietary factors have also been shown to influence the incidence of intussusception. Malnourished children are considered to have a lower risk of intussusception because of less prominent intestinal lymphoid tissue, which may be less suitable to act as a lead point. Johnson and colleagues[66] found that the risk of intussusception among U.S. infants varied on the basis of their feeding patterns. Using breast milk as the reference group, infants who consumed soy milk–based formula had a much lower risk, and infants who consumed cow's milk formula had an increased risk for intussusception.

***Pathologic Lead Point*** The incidence of intussusception caused by a PLP in an infant or child ranges from 1.5% to 12%.[48,67] It increases with age from about 5% in the first year to 44% within the first 5 years of life and 60% in 5- to 14-year-olds. PLPs can be found in 4% of infants and children who have one recurrent intussusception and in up to 19% with multiple recurrences.

The most common focal cause of a PLP is an inverted Meckel diverticulum[68–70] followed by intestinal polyps[71] and duplications (Fig. 85-6).[72] Other less common focal PLPs that have been reported are periappendicitis; appendiceal stump; inversion appendectomy[73]; appendiceal mucocele; local suture line; massive local lymphoid hyperplasia; ectopic pancreas; abdominal trauma; benign tumors (adenoma, leiomyoma, carcinoid, neurofibroma, hemangioma); and malignant tumors (lymphoma, sarcoma, leukemia).[48,74]

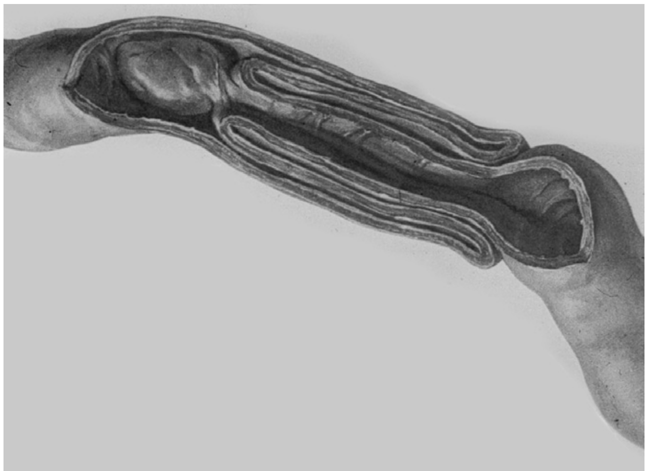

**FIGURE 85-6** Small bowel intussusception caused by a polyp as pathologic lead point.

Other intestinal processes that cause multifocal bowel wall thickening or affect bowel motility include Henoch-Schönlein purpura,[75] cystic fibrosis,[76] celiac disease, disordered coagulation, hemophilia, neutropenic colitis, Hirschsprung enterocolitis, Peutz-Jeghers syndrome, and familial polyposis.[77]

Intussusception caused by a PLP remains a diagnostic challenge[78,79] and has to be differentiated from the more common idiopathic ileocolic intussusception. Most commonly, signs and symptoms are similar but, manifestations can vary and are often nonspecific because of the wide spectrum of lesions or intestinal abnormalities.[48,80]

In 35% of all PLP cases the intussusception is caused by thickened bowel wall, abnormal motility, impaction of secretions, or the presence of multiple polyps. Other important risk factors are ileoileocolic intussusception, an older child, the association of a long duration of symptoms with weight loss, and recurrent intussusception.

Most PLPs manifest as ileoileocolic intussusceptions (40% of all ileoileocolic), with a smaller percentage being jejunojejunal, ileoileal, ileocolic, appendicocolic, cecocolic, and colocolic intussusceptions.

The risk of missing a malignant small bowel tumor is relatively low according to the literature.[81,82] Lymphomas quite commonly present as intussusceptions (17.5%) but are picked up on either US or contrast enema.

No clinical pattern of recurrence is predictive of a PLP, and imaging plays the major role in detection of a PLP. The vast majority of infants and children with recurrent intussusception will not have a PLP. PLP is present in about 5% of patients with one recurrence, as opposed to up to 19% of children with multiple recurrent episodes.[48,83]

Most intussusceptions caused by PLP can be reduced by enema techniques.[84–86] US and reduction enema are the cornerstones of diagnosis of lead points.[87] US is heavily operator dependent, and results vary in different institutions. Diagnosis of 74% of all focal PLPs, 40% of diffuse PLPs, and diagnosis of the exact type of PLP in 32% has been reported. US is most successful for diagnosing a duplication cyst or lymphoma as PLP but less for a Meckel diverticulum.[48]

Other imaging modalities such as CT are of limited value to diagnose PLP.[88,89] Upper contrast studies of the small and

large bowel and colonoscopy may be of value if a polyp is suspected despite negative US results.[90,91]

In suspicious cases, an initially negative US study should never exclude a second repeat US.

***Postoperative*** Postoperative intussusception manifests as a small bowel obstruction (SBO). It is the third most common intussusception (1%) and found most often in the small bowel after prolonged laparotomy with significant bowel handling.[92–96] Typically, there is no lead point present. The risk for SBO after pediatric laparotomy is about 5% (with 80% occurring within the first 2 years after laparotomy). Three to ten percent of those are caused by postoperative intussusceptions.[92,97] They often occur after retroperitoneal dissection (Wilms tumor, neuroblastoma) or an extensive bowel procedure (abdominoperineal pull-through, the Ladd procedure, manual reduction of intussusception).[48,98,99] Recently, several cases of postoperative intussusception were reported after pancreatic surgery.[100]

Postoperative intussusception has been reported after operation outside the abdomen.[67] Abnormal peristalsis from abnormal serum electrolytes, anesthesia, drugs, and neurogenic factors has been implicated.

The key to the diagnosis of a "true" postoperative intussusception is to remember that it can occur, especially after a major laparotomy, and presents as early postoperative obstruction.

Abdominal US is diagnostic, and enema reduction is indicated in case of rare ileocolic intussusception. In all other cases, an operation is required. Further postoperative recurrence is exceedingly rare.[95]

### Anatomic

The most common type of intussusception is ileocolic (85%) (Fig. 85-7). The second most common type (10%) is ileoileocolic and often characterized by complete bowel obstruction. The ileoileal portion invaginates into the cecum and colon and is more difficult to reduce. About 40% are found to have a PLP as its underlying cause.[48]

Appendicocolic, cecocolic, and colocolic intussusceptions are much less common (2.5%) and are usually associated with PLPs.

FIGURE 85-7 Ileocolic intussusception. The hand is milking the most distal intussusceptum retrograde. Note the forceps on the appendix and the pneumatosis of the cecal wall.

Jejunojejunal and ileoileal intussusceptions occur infrequently (2.5%) and usually have a PLP, except when they occur as a postoperative intussusception.

***Around Tubes*** Intussusception is a common complication of the use of indwelling gastrojejunostomy tubes with a reported incidence of 16%.[101–103] Catheters with a distal pigtail appear to have a higher risk and typically cause antegrade jejunal intussusceptions, either along or at the end of the gastrojejunostomy tube. These patients usually present with high SBO and bilious vomiting but without abdominal pain or cramps. Incidental detection in an asymptomatic child is common, and the only treatment may be clinical monitoring.

The diagnosis is often incidentally made on US or CT scan. Removal or conversion to a gastrostomy or nasogastric tube will cure the problem. Many of these intussusceptions are also transient and undergo spontaneous reduction, which suggests that their actual prevalence is probably underestimated. Rarely, there is need for a surgical procedure.[104]

Retrograde jejunoduodenogastric intussusceptions[105–107] occur when gastrostomy tubes migrate through the pylorus by gastric peristalsis.

They develop painlessly in a child with a functioning feeding tube (with the feedings going in distally) and cause high SBO accompanied by bile vomiting without any evidence of the feeding. An operation may be required.

An unusual intussusception is antegrade or retrograde jejunogastric intussusception through a gastroenterostomy causing gastric outlet obstruction. This intussusception almost always requires operative reduction and revision.

### Other

***Recurrent*** Reported recurrence rates range from 8% to 15% following barium enema reduction, 5.2% to 20% following sonography-guided hydrostatic enema reduction, 5.4% to 15.4% following fluoroscopy-guided air enema reduction, and 6.25% to 7% after sonography-guided air enema.[108] Recurrence rates, age and sex distribution, pattern of recurrences (including number of and interval between recurrences), reducibility, documentation of pathologic lead points, operative findings, and long-term follow-up were similar.[109] Recurrence rates are lower after manual operative reduction (3% to 4%) and operative resection and anastomosis of an intussusception (0%).[110]

Most recurrences occur within the first few days after the initial reduction, some within hours. About 70% of children have only one recurrence, but up to eight recurrences have been reported in children without lead points.

Lin and colleagues[111] used intramuscular dexamethasone as premedication before air enema to decrease lymphoid hyperplasia and the rate of early recurrence. The steroid group had only one recurrence in 6 months in 122 children, whereas the control group had 8 in 117 children.

Recurrent intussusceptions have a high reducibility rate (100% for initial recurrence and 95% for multiple recurrences). Perforations are rare.[108] The time between onset of symptoms and arrival in the hospital is shorter because of the awareness of the parents. The earlier the diagnosis, the greater is the chance for successful reduction. Recurrent intussusceptions may be looser and easier to reduce but also have a greater chance of repeat recurrence.

Earlier reports recommended operative reduction in children with one or two recurrences.[112] Reasons were operative exclusion of a PLP (particularly malignancy such as lymphoma) and the reduced recurrence rate after operative intervention.

The presence of a pathologic lead point should always be considered (4% in children with one recurrence and 14% with multiple recurrences), but most children with recurrence will not have one.[48]

Because of the high reduction rate of recurrences, the low perforation rate (<1%), and the favorable long-term follow-up, it is generally recommended that image-guided reduction be undertaken for any and all recurrent intussusceptions.

Operation should only be used for irreducible recurrences after unsuccessful delayed repeat enema attempts, perforation from the enema, clinical evidence to suggest a PLP, or documentation of a PLP by US or enema.

***Neonatal*** Intussusception in neonates is infrequent (0.3% of all cases) and more likely is caused by a pathologic lead point.[36,37] Signs and symptoms resemble those seen in necrotizing enterocolitis such as abdominal distension (17/17), bilious gastric aspirates (13/17), bloody stools (10/17), and rarely a palpable abdominal mass (5/17).[113] Difficulties in establishing the correct diagnosis led to a delay of 7 to 10 days between the onset of symptoms and abdominal surgery, increasing the risk of developing a compromised bowel.[37,114,115] Sometimes, the disconnected end of the intussusceptum can be found in the distal part of the bowel.[39]

Diagnostic features are signs of SBO on the abdominal radiographs. An early diagnosis may be achieved with a high index of suspicion and the use of ultrasound scan. Contrast enema has limited diagnostic and therapeutic capability.

These cases carry a mortality of around 20% in neonates, largely because of sepsis and the delay in diagnosis. If diagnosed in time, it can be treated successfully with resection and primary anastomosis.

## Clinical Findings and Physical Examination

Intussusception should be suspected with any of the two classic symptoms (abdominal pain or vomiting) or two classic signs (abdominal mass or rectal bleeding) (see Fig. 85-3).[30] Most cases are diagnosed within 24 hours of the onset of symptoms. In case of recurrent intussusception the diagnosis is often easier and made in less than 8 hours.[116]

A high level of suspicion is necessary in any infant or toddler with a history of crampy abdominal pain. One, two, or three of the other classic signs or symptoms are often present to help make the diagnosis. All four classic signs and symptoms can only be found late in the disease process and in less than 30% of cases.[117] In about 20% of patients, diarrhea precedes other symptoms and may lead to incorrect diagnosis and triage.

The sudden onset of severe, colicky, intermittent abdominal pain, which makes infants pull up their legs, is the most common classic symptom of pediatric intussusception in about 85% of patients. This pain episode typically lasts only a few minutes. Afterwards, the infant is often quiet, pale, and sweaty and then returns to normal activity for a while. The absence of pain, however, does not rule out intussusception but may delay the diagnosis. It is important to know that about 15% of infants and children present without any obvious pain.[117] These children are often pale and listless and appear quite ill. Infants present more often with vomiting than older children do (up to 45%). Bilious vomiting tends to be found in delayed cases of intussusception with SBO.[15,39,46]

The two classic signs, abdominal mass and rectal bleeding, can be found with about the same frequency (see Fig. 85-4). The often curved, sausage-shaped abdominal mass can be palpated in the right upper quadrant of the abdomen about 65% of the time and usually extends to the left along the transverse colon.[30] The mass may be slightly tender and may be appreciated only when the patient is lying quietly between attacks of pain. Sometimes the mass can be visually appreciated during clinical inspection. The right lower quadrant may be flat or empty, a finding known as the Dance sign.[23] Occasionally, the intussusception passes quite far distally and can be palpated on rectal examination (5%). Prolapse of the intussusceptum out the rectum may be a grave sign and can be mistaken for a rectal prolapse.[15] The longer the symptoms of intussusception persist, the higher the likelihood of occult or gross rectal bleeding. Rectal bleeding is usually the last sign to occur. The blood has a mucus-like texture and, classically, a currant jelly appearance. It is most alarming to parents and physicians. If there has been a delay in seeking medical care before this event, it usually gets the patient to the hospital quickly.

If the delay in diagnosis allows bowel ischemia to occur, fever, tachycardia, and hypotension can be signs of bacteremia and bowel perforation. Rapid diagnosis and emergent operation are essential to prevent a fatal outcome.

## Diagnosis

### LABORATORY STUDIES

No specific laboratory studies aid in the diagnosis of intussusception. As the intussuscepted bowel becomes ischemic, associated leucocytosis, acidosis, and electrolyte abnormalities worsen.

## Radiologic Diagnostic Evaluation

The correct diagnosis of intussusception can only be made clinically about 50% of the time. The diagnostic evaluation relies on radiologic imaging to either confirm or make the correct diagnosis.[118]

### PLAIN RADIOGRAPH OF THE ABDOMEN

The role of abdominal radiographs in pediatric patients with suspected intussusception remains controversial.[78] It was routinely used for the diagnosis or exclusion of intussusception by 73% of the radiologists in a 1999 survey of members of the European Society of Pediatric Radiology.[119]

Few published studies have evaluated the accuracy of this modality in this clinical setting. In two series, intussusception could only be correctly identified on plain radiographs in up to 50% of cases.[120,121]

The abdominal radiograph can confidently exclude intussusception if the bowel is filled with gas throughout or the colon is completely outlined with stool. These findings could also be defined by US or fluoroscopy at the start of the contrast enema. Supine, upright, or cross-table lateral radiographs are often not helpful because their interpretation can be variable and false negatives occur much more frequently than false positives.[122,123]

Characteristic signs of intussusception on a plain radiograph are meniscus sign and target sign.[78] Nonspecific radiographic findings such as a right-sided soft tissue mass combined with an absence of cecal gas are easier to detect (Fig. 85-8). In half of children younger than 5 years, the sigmoid colon filled with gas and stool occupies the right lower quadrant and may be misinterpreted as the cecum.[124] In one report, exclusion of intussusception in three view radiographs of the abdomen was only successful in 25% of patients.[125] These views are obtained to detect air-fluid levels and free air. Air-fluid levels are nonspecific for intussusception, and free air has not been reported in untreated intussusception and perforation before enema reduction.[78] In rare cases the intussusception itself can be clearly visualized on abdominal radiograph (Fig. 85-9).

In most infants and children with suspected intussusception, the abdominal radiograph may be safely omitted. In unclear or delayed cases with concerning physical examination and higher incidence of nonviable bowel, the plain abdominal radiograph may be obtained.[126]

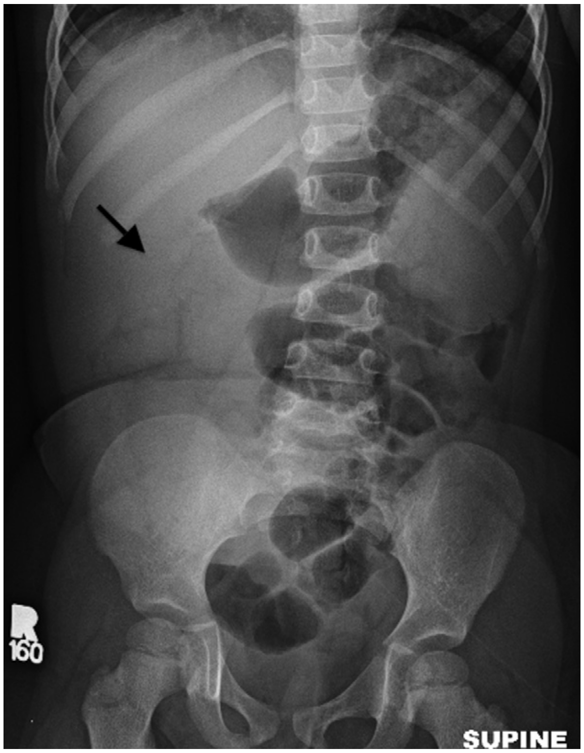

**FIGURE 85-8** Plain radiograph of the abdomen with nonspecific findings suggestive of a right-sided soft tissue mass (*arrow*) combined with an absence of cecal gas.

**FIGURE 85-9** Radiographic finding of ileocolic intussusception seen in Figure 85-7. Note the severe pneumatosis. This patient was later diagnosed with cytomegalovirus colitis likely acting as a lead point.

## ULTRASONOGRAPHY

In the hands of an experienced examiner, ultrasound can have 100% accuracy for the diagnosis of intussusception.[79,127,128] The major advantage of ultrasound for detection of intussusception is that it is portable, noninvasive, and without radiation. With the use of modern high-resolution transducers, the diagnosis of intussusception is straightforward. The characteristic finding is a 3- to 5-cm diameter mass, the typical target or doughnut sign, which is usually found just deep to the anterior abdominal wall on the right side (Figs. 85-10 and 85-11).[80] The viability of the bowel can be evaluated by Duplex ultrasound (Fig. 85-12).

**FIGURE 85-10** Ultrasonography showing intussusception on cross section in the right lower quadrant just deep to the anterior abdominal wall (target or doughnut sign).

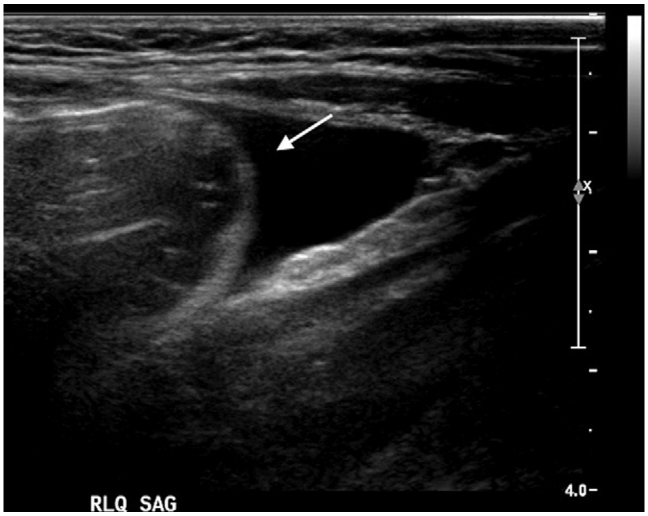

FIGURE 85-11 Ultrasonography showing tip of intussusception (*arrow*) in longitudinal plane just deep to the anterior abdominal wall.

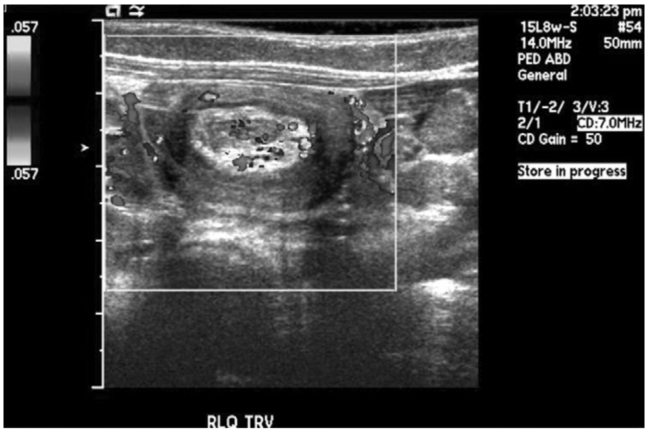

FIGURE 85-12 Duplex ultrasonography showing the target sign of an intussusception and confirming viability of the intussusceptum.

In addition, ultrasound can detect a possible pathologic lead point with higher frequency (66%) than contrast (40%) or air enema (11%).[129]

The role of abdominal ultrasound is not limited to diagnosis or exclusion of intussusception. Other abdominal disease processes such as urinary tract pathology, ovarian torsion, appendicitis, or small bowel volvulus can be detected.[130]

Others oppose the use of ultrasound.[131] The author argues that, if positive, it leads to a second study, the therapeutic enema, and increased health care costs since the US could have been avoided. If negative, the study was likely lengthy and an intussusception may have been missed. If clinical symptoms are very suspicious, a diagnostic contrast enema should be performed.

Ultrasound cannot predict well if the intussusception is already necrotic or amendable to nonoperative reduction and should therefore not preclude reduction by enema. Warning signs of necrosis or possibly unsuccessful enema reduction include, most importantly, the absence of blood flow in the intussusception on Doppler interrogation, a thick peripheral hypoechoic rim, free intraperitoneal fluid, fluid trapped within the intussusceptum, enlarged lymph nodes dragged with the mesentery into the intussusception, or a pathologic lead point.[132]

### COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Most institutions do not routinely use CT and magnetic resonance imaging (MRI) to evaluate intussusception. Intussusception may be found incidentally on imaging performed for another suspected diagnosis.[133] The characteristic finding is a target or doughnut sign. Possible pathologic causes for the intussusception such as lymphoma or masses may be revealed.[88]

Ko and colleagues[89] developed a protocol to detect ileoileal intussusception using immediate CT scanning if the initial abdominal US was suspicious (target sign with a diameter $\leq$ 3 cm and/or atypical location in the left abdomen or at the umbilicus). They were able to avoid unnecessary reduction enemas and facilitate faster operative intervention.

Short transient small bowel intussusceptions can often be seen on CT or MRI and are usually not clinically significant. Repeat imaging usually shows resolution of intussusception.[52,134]

### CONTRAST ENEMA

Before ultrasound became widely available in the mid 1980s, barium contrast study of the colon (BE) was considered the gold standard to diagnose or exclude intussusception. In some institutions it is still the preferred diagnostic modality. It is well known to all radiologists, quick, and considered the most cost-effective method with an accuracy of 100%.[127,135] If positive, the diagnostic procedure may become therapeutic. In addition, an experienced ultrasonographer may not be available during off hours.

In the European survey of pediatric radiologists from 1999, the contrast enema was used as the initial tool for diagnosis by 34% of the respondents.[119]

The clear disadvantages of contrast enema are that it is an invasive procedure and requires radiation. More than 50% of diagnostic contrast enemas in children with suspected intussusception turn out to be negative.[79] In this case, ultrasound is a better modality to diagnose other acute abdominal problems that mimic intussusception.[127,130]

## Treatment

Treatment of an infant or child with an intussusception must start in the emergency department, and the surgeon should be involved from the initial presentation.[136,137] When the clinical history confirms the suspicion of intussusception, the surgeon must evaluate the patient for peritonitis or shock on physical examination to rule out the rare need for emergent operation. It is paramount to promptly fluid resuscitate the patient. If the patient suffers from recurrent vomiting, a nasogastric tube is placed.

A broad-spectrum antibiotic should be given as for any other situation in which the vascular supply of the bowel may be jeopardized, and bowel surgery is a possibility. The patient's blood is cross-matched in case a transfusion is necessary.

While all of this is being done, preparations should be made for radiologic confirmation of the diagnosis, followed by the necessary treatment. The operating room should be notified so that if the nonoperative management is unsuccessful, the patient can go from the radiology suite directly to the operating room.

The treatment options are simple: medical (under occasional and specific situations), radiologic reduction or operative reduction, resection, closure of an enema perforation, or excision of a PLP by laparotomy or laparoscopy.

Currently, virtually all hemodynamically stable infants and children with the absence of peritoneal signs of perforation receive an attempt at nonoperative reduction with water-soluble contrast or pneumatic reduction with air, regardless of the length of the history.[137,138]

## NONOPERATIVE MANAGEMENT

### Medical

In a stable patient, intussusception caused by diffuse thickened bowel wall acting as a pathologic lead point can sometimes be treated with steroids before, along with, and/or after radiologic reduction attempts. Three cases of successfully treated lymphoid hyperplasia[139,140] and three of seven cases of Henoch-Schönlein purpura (HSP) have been reported.[141] The mechanism by which steroid treatment affects lymphoid hyperplasia remains unclear. If steroid treatment is initiated with the intussusception still unreduced, the patient must be observed closely. As Sönmez and colleagues[141] stated: "Conservative therapy is feasible for HSP patients with small bowel intussusception as long as the time of onset is known, an ultrasonographic and x-ray diagnosis is confirmed, emergency operating facilities are available, and an experienced pediatric surgical team follows up the patients."

Most patients with HSP have gastrointestinal symptoms, which are initially treated medically.[142,143] Laparotomy performed for life-threatening complications has to be performed in up to 22% of cases.[144] Intussusception is the most common surgical complication of HSP in childhood, occurring in 0.7% to 13.6% of patients. It is uncommon in children younger than the age of 3. The sites of intussusception are most frequently ileoileal (51%), then ileocolic (39%), and rarely jejunojejunal (7%). There have been only four reported cases of colocolic intussusception.[145] The predominance of small bowel involvement is due to the pathologic lead point being intramural hemorrhage and edema in that area of intestine. Only the ileocolic intussusceptions are amenable to enema reduction attempts.[146] If the ileoileal type does not reduce spontaneously over 24 hours, surgical intervention is probably required.

## RADIOLOGIC REDUCTION

It is important to carefully differentiate those patients who are suitable candidates for attempted image-guided enema reduction from those who will require immediate operative management. Contraindications to attempted enema reduction include clinical evidence of dehydration, shock, peritonitis, or radiographic evidence of perforation with free air. Dehydration should be corrected early, and only then can an enema be performed safely. Immediate operative management is indicated in those patients with peritonitis or free air.

Several factors such as younger age (<6 months), rectal bleeding, radiographic signs of intestinal obstruction, or longer duration of signs and symptoms (>72 hours) have been found in some series to decrease the success rate of reduction.[108] However, successful reduction can be achieved in the presence of any of these factors, and therefore none of them preclude an attempted enema reduction if the patient is well hydrated and clinically stable (Fig. 85-13).

The approach varies from one treatment center to another and in different parts of the world. In the developed world, intussusception is diagnosed early in the vast majority of pediatric patients and medical care provided in timely fashion. Two recent series from Australia and the United States quote the rate of attempted initial enema reductions with 97%[59] and 78%.[147]

Two recent studies reviewed their data for predictors of success of reduction enema and its importance to avoid complications.[148–150] Their conclusion was that hydrostatic or pneumatic enema should be attempted in all children without peritonitis. Predicting the outcome is not crucial because of the high success rate and low complication rate.

In contrast, operative management remains the usual primary treatment in much of the developing world, as has been described in recent reports from Nigeria[151] and Kenya.[152]

In these areas of the world, access to radiographic equipment may be limited. Infants and children have a significantly longer

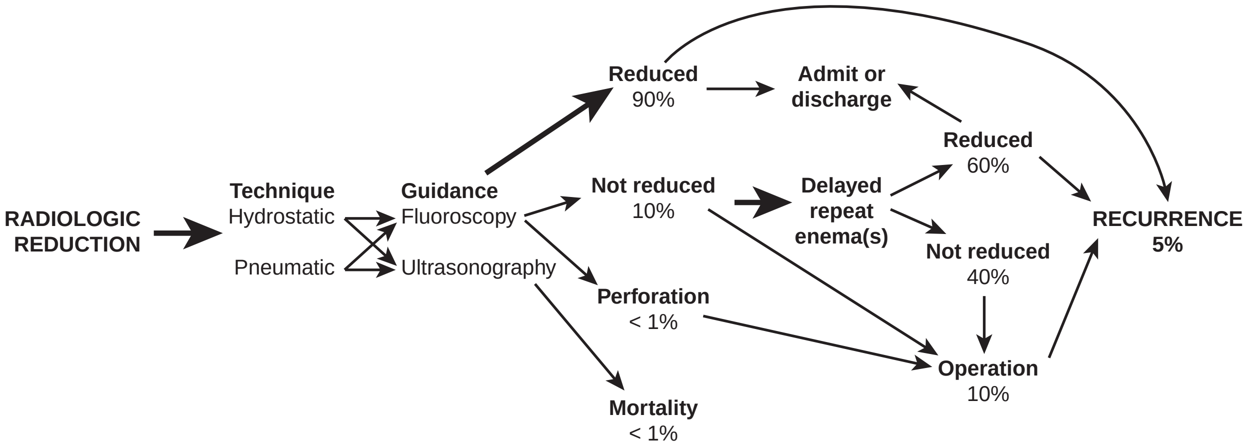

FIGURE 85-13 Algorithm for radiologic reduction of intussusception.

duration of symptoms and signs, an increased incidence of nonviable bowel, and a mortality rate up to 20%.[108,153]

Meier and colleagues[126] suggested that the use of nonoperative enema reduction would not significantly improve the high mortality rate. However, Abantanga and colleagues from Kenya[154] recently reported their use of on-table air reduction under general anesthesia in the operating room in all patients with intussusception without peritonitis (50% of patients). Their success rate was 60% without mortality. The authors' conclusion was that on-table air enema reduction is possible, practical, and reliable in patients without peritonitis and must be tried first before laparotomy, especially in countries with limited resources.

Currently used techniques for nonoperative reduction of intussusception include pneumatic or hydrostatic pressure enemas under fluoroscopy or US.[155] One must be cautious when attempting to make comparisons among the various series, even when they use an apparently similar technique. Reduction rates vary considerably depending on the patient population, the exclusion criteria for enema reduction, and the lack of standardized techniques used by radiologists.

Surveys of pediatric radiology departments in North America[156] and Europe[119] showed that management of intussusception varied greatly with a trend to pneumatic reduction techniques with greater use of ultrasound. Some pediatric radiologists combined fluoroscopy and sonography to a hybrid approach (18%).[119]

The clear advantage of US is that it avoids radiation exposure and provides more information than fluoroscopic techniques do. It has high accuracy and reliability for monitoring the reduction process, visualizes all components of the intussusception, including the postreduction edematous ileocecal valve, and can more easily recognize pathologic lead points. The main disadvantage of US is the need for a radiologist who is comfortable using US for reduction guidance. There is less experience with pneumatic reduction under US guidance, especially recognizing a perforation when using either hydrostatic or pneumatic reduction techniques.[137]

There has been no large, controlled, prospective study comparing the various techniques. Several relatively small series have compared the results of hydrostatic and pneumatic reduction under fluoroscopic control. Most have shown higher reduction rates with the pneumatic techniques.[157–159] Several series have achieved equally high reduction rates using hydrostatic or pneumatic reduction under sonographic guidance.[160–162]

On the basis of these success rates published in the recent literature, one should aim to achieve reduction rates of at least 80% and even as high as 95%.[108,137,162]

In conclusion, successful reductions can be achieved whether one chooses to use the hydrostatic or pneumatic reduction technique under fluoroscopic or sonographic guidance. The choice of technique used will depend largely on the experience, personal preference, and expertise of the radiologist involved, as well as on the local conditions in a particular institution and the type of patient population seen.

### Pneumatic Air Enema

The air enema technique is well described in the literature.[59] The enema tip should be placed within the child's rectum and taped securely in place. The child is placed in a prone position to allow the radiologist or assistant to squeeze the buttocks closed and prevent air from leaking. Air is rapidly insufflated into the colon under fluoroscopic observation. Once the intussusception is encountered, reduction is followed fluoroscopically until it is completely reduced (Fig. 85-14). Air should flow freely from the cecum into the distal small bowel loops to signify complete reduction (Fig. 85-15). One critical safety issue is to keep air pressure below a maximum limit of 120 mm Hg to avoid the risk of perforation.[163,164]

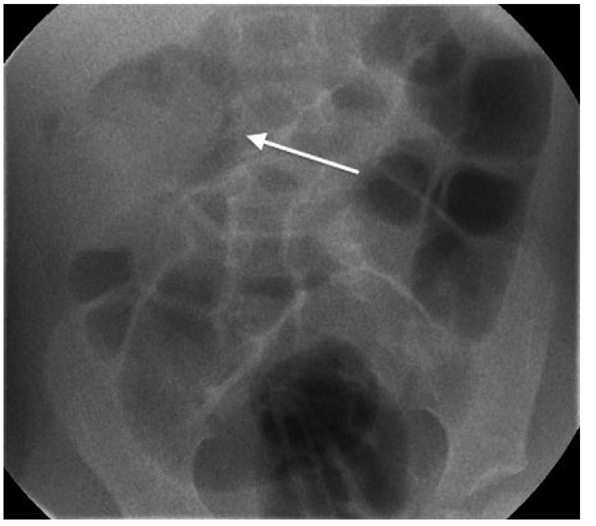

**FIGURE 85-14** Air enema showing the head of the intussusceptum (*arrow*).

The pneumatic reduction technique under fluoroscopy has gained wide acceptance because of several advantages over hydrostatic reduction: it is easy to perform and can be done quickly, is less messy, delivers less radiation exposure, is more comfortable, and results in smaller perforations and less peritoneal contamination.[163] Disadvantages of this technique are the passage of air into the terminal ileum without complete reduction of the ileocolic intussusception[165,166] and a possible tension pneumoperitoneum should a rare perforation occur.

**FIGURE 85-15** Successful reduction of the intussusception by air enema confirmed by sudden reflux of air into the ileum.

### Hydrostatic Barium Enema

Although the air enema may be preferred in experienced hands, the liquid enema is simple, safe, and effective, and most radiologists have experience with its use.[108,162,167] Ultrasound for monitoring of hydrostatic reduction is relatively easy to use and the imaging modality of choice in many centers.[162,168,169]

The disadvantages are that it is messy to use and perforation may occur with larger colonic tears, increased peritoneal contamination, and rapid fluid shifts with hypertonic water-soluble agents.[170,171] Barium is no longer the liquid contrast medium of choice due to the risk of barium peritonitis, infection, and adhesions when perforation occurs during the enema.

The "rule of threes" (three attempts, each of 3 minutes' duration and with enema bags 3 feet above the table) used by many radiologists to guide the liquid enema technique is supported by limited evidence.

Hydrostatic reduction may occur rapidly or stubbornly slowly. There is usually a pause when the barium column meets the intussusception (Fig. 85-16). Typically, the rounded barium column suddenly becomes concave and forms a meniscus around the head of the intussusception. When the intussusception is displaced, the meniscus flattens out.

Because the intussusceptum fits more loosely in the larger-caliber intussuscipiens, barium seeps between the two and produces the characteristic radiologic appearance of a coiled spring. Filling of the cecum is often slow, and it may become quite distended for a while before the sudden rush of barium into the distal ileum indicative of reduction.

If the ileum does not fill freely for several feet (not inches), one should not assume that the reduction is complete (Fig. 85-17).

This process may have to be repeated if the liquid contrast agent leaks out of the rectum or if the tube becomes dislodged or plugged. Once the reduction is successful, the infant or child is relieved of the pain and usually falls asleep.

### Methods to Improve Reduction Rates

Some authors have advocated practices that they believe may improve the rate of enema reduction.

FIGURE 85-16 Hydrostatic contrast enema showing intussusception in the left transverse colon. Note the concave meniscus the contrast forms around the head of the intussusceptum.

***Medications*** Some irreducible intussusceptions are already found reduced after initiation of general anesthesia in the operating room. Either they reduced spontaneously or, more likely, reduction was induced by the sedation and muscle relaxation from general anesthesia.

Smooth muscle relaxants such as glucagon have been tried to improve results of intussusception reduction, with indefinite and variable results.[172–174]

Some hospitals always use sedation for radiologic reduction of intussusception and claim improved results.[175] One third of European pediatric radiologists use sedation for reduction in a 1999 survey.[119] The use of sedation may reduce the intra-abdominal pressure children create by the Valsalva maneuver and therefore reduce success rates.[138]

FIGURE 85-17 Hydrostatic contrast enema showing incomplete reduction of intussusception with only a trickle of contrast into the terminal ileum (*left*). Note the complete reduction with flooding of the terminal ileum with contrast on the right.

Overall, little evidence supports the use of glucagon or sedation in reducing intussusception, and neither is routinely used in most institutions.[137,176]

***Transabdominal Manipulation*** Grasso and colleagues[177] found that transabdominal manipulation improved their reduction rate with air enema from 58% to 76%. The true benefit may be difficult to evaluate because higher rates of reduction than those reported in Grasso's series have been achieved without manipulation. On the other hand, this technique may be more widely used than reported in the literature.[108]

***Delayed Repeat Enema*** In the past it was considered standard practice that immediate operative intervention was required for all patients, in which the intussusception was irreducible by enema techniques. In the operating room about 10% of intussusceptions were found to be already reduced, and another 40% were easily reduced manually.[30] The conclusion was that surgical intervention could possibly have been avoided in half the cases if radiologists used a different or more aggressive approach to their enema technique.

With this rationale, an operation would then be required only for cases that are difficult to reduce manually or have necrotic intussusceptions, enema perforations, or pathologic lead points.

The earliest reports describing the use of delayed repeat enema before proceeding to the operating room were published in the 1980s.[26,178] The time intervals and number of repeat reduction attempts were variable in different studies and ranged between minutes and days and up to three attempts.[179–181] Success rates between 50% and 84% have been reported.[59] Some authors perform delayed attempts only under general anesthesia.[108]

Although delayed repeat enema without anesthesia has only recently received more attention in the literature, it had been used successfully in Toronto institutions for years.[108,182–184]

It has yet to be defined what the optimal time delay between attempted enemas should be and how many attempts should be made. This should probably be tailored to the individual patient and the experience of the radiologist on a case-by-case basis.

Given the initial high success rate of current radiologic enema techniques (close to 90% in some institutions), the need to rely on repeat, delayed enema attempts is only applicable to a minority of children. Therefore the deferral of surgical intervention can be carefully considered in any infant who remains clinically stable, with no evidence of peritonitis and only if the initial enema manages to move the intussusception, achieving at least a partial reduction.[182] Partial reduction and the time interval between attempts may allow the venous congestion and the edema of the bowel wall to decrease, thus facilitating the reduction of the residual, less congested intussusception in a repeated, delayed attempt. Contraindications to a delayed, repeat reduction attempt include failure to move the intussusception at all when it is first encountered at the initial enema or if the patient becomes unstable.

Close cooperation between experienced pediatric radiologists and surgeons and careful clinical monitoring of the patient are essential requirements for this approach. The risks may outweigh the benefits unless staff and equipment are available to observe these patients meticulously between reduction attempts. Widespread acceptance of this approach may require documentation of its success in larger series of children.

### Postreduction Care

After successful enema reduction, the infant or child should be observed closely for at least a few hours, depending on the general condition of the patient.

If the intussusception was recognized early and the enema reduction was relatively easy, the child can be discharged home from the emergency department. Prerequisites are that the parents are reliable and the patient is asymptomatic and tolerates fluids for a short period after the reduction.[185,186] Whitehouse and colleagues[187] reviewing 309 patients with intussusception at Children's Hospital of Wisconsin found that it was safe to discharge 48 (26%) out of 186 patients managed nonoperatively with enema reduction directly from the ED. Recurrence rates did not differ between children observed as inpatients and those discharged home, and there were no missed pathologic lead points.

Most patients, even those with a successful enema reduction, are admitted to a pediatric general surgical unit for observation and further treatment.

If the enema reduction is successful, the child can be started on clear fluids and progressed to a regular diet as tolerated. Intravenous fluids can be decreased and discontinued accordingly. If the patient initially had SBO with vomiting and required insertion of a nasogastric tube, it may take a number of hours for the obstructed small bowel to decompress. It may be preferable to leave the nasogastric tube in place overnight or maintain the child non per os with an intravenous infusion.

The preoperative gram-negative and anaerobic bacterial coverage does not need to be continued unless the patient was febrile before or after reduction and the reduction was difficult.

The presence of fever usually indicates bacteremia, endotoxemia, cytokine (tumor necrosis factor, interleukin) and lysozyme release, and even the production of reactive lymphocytes, in which case antibiotics may be continued for 48 hours.[188–190] In addition, bacterial translocation (the old theory of transmural migration of bacteria) may in part account for the common high fever that accompanies reduction.[191] Animal studies have shown that even when viable intussusceptions are reduced operatively under sterile conditions and tissue for culture is taken from the apparently intact serosal surface, pathogenic bacteria are frequently recovered.[17]

On the other hand, Somekh and colleagues[188] performed serial blood cultures before attempted air enema reduction, immediately after, and 1 hour later to assess the risk for bacteremia. Their results showed that although fever may develop after air enema reduction attempts, the risk for clinically significant bacteremia and sepsis was extremely low.

At discharge, the parents should be aware of the relatively high recurrence rate after an enema reduction.[108,109] Recurrence rates as high as 20% have been described in the literature with an average of about 10%.

A repeat abdominal US study should be performed if any doubt remains about the success of the enema reduction or the abdominal pain recurs.[192] If the intussusception recurs, the enema process can be repeated. After any successful

enema reduction, the ileocecal valve often remains edematous and thickened for a day or more.[108] This appearance can easily be differentiated from a recurrence because it lacks the typical concentric rings. The invaginated mesentery is smaller than the typical target sign of a true intussusception and will disappear with time.[193] The ileocecal thickening can also be appreciated as a filling defect or narrowing if a contrast enema is performed. Recognition of these signs is important when attempting to confirm complete reduction and also to differentiate postreduction edema from pathologic lead point or recurrent intussusception.

Postreduction US[192] becomes essential in the following difficult situations: to confirm the reduction by air enema when the intussusception disappears but there is minimal or no passage of air into the distal end of the small bowel, to delineate an unreduced ileocolic or ileoileal component of an ileoileocolic intussusception even if there is a large amount of air in the large and small bowel,[194] and to rule out a pathologic lead point. If US shows only enlarged mesenteric lymph nodes, marked bowel wall thickening, and hyperemia (on Doppler evaluation), there may be an ongoing inflammatory process (bacterial enteritis with *Yersinia* or *Clostridium*) that originally caused the intussusception.[195,196]

Sonography is an important tool to reevaluate a previous partial reduction and to exclude spontaneous reduction before attempting delayed repeat enema reduction.

## OPERATIVE MANAGEMENT

Operation becomes necessary when radiographic reduction is contraindicated, has failed or is incomplete, peritonitis or pneumoperitoneum is detected, or a pathologic lead point is found (Fig. 85-18). The decision to start laparoscopically or perform immediate laparotomy is decided by the surgeon on a case-to-case basis.

After initiation of fluid resuscitation and application of preoperative broad-spectrum antibiotics, the patient is taken to the operating room and placed in a supine position. Under general anesthesia, the stomach is decompressed with a nasogastric tube. Now, the abdominal mass can generally be palpated, and its position may influence the incision of the surgeon.

### Laparoscopy

Initially, laparoscopy was only used to confirm either a successful radiologic reduction[197] or the correct diagnosis of intussusception before reduction per laparotomy.[198]

Recent studies have reported successful laparoscopic reduction of intussusception in more than 60% of patients.[199–201] A French retrospective study from 2008 including 69 patients from seven centers reported a conversion rate of 31.9% (16% for unsuccessful laparoscopic reduction). The risk for conversion to open surgery was higher with longer duration of symptoms (3.1 vs. 1.6 days in laparoscopic group) and the presence of a pathologic lead point (50% vs. 17%).[202] It was concluded that the optimal candidate for laparoscopic reduction is the child seen early after onset of symptoms (<36 hours) without signs of peritonitis.

A recent retrospective study published in 2009 reviewed 22 patients (average age, 2.9 years) over 10 years whose intussusception could not be radiographically reduced.[203] Twenty patients (91%) could be safely managed laparoscopically or with a small extension of the umbilical incision. Ten patients (46%) had a bowel resection, and nine patients had a pathologic lead point (four with Meckel diverticula, five with lymphoid hyperplasia). The average length of stay was only 2.67 days (median, 2 days). The authors concluded that laparoscopy is a reasonable approach to pediatric intussusception, even when bowel resection becomes necessary.

Most described laparoscopic techniques use three ports (one on the umbilicus and two on the left side of the abdomen). Using atraumatic graspers, gentle pressure is applied distal to the intussusceptum. In difference to the open method, traction must often be applied proximal to the intussuscipiens to succeed with reduction. After reduction, the bowel must be carefully inspected for injury, necrosis, or perforation.

Particular attention, however, must be paid to search for a pathologic lead point because most tactile cues are lost. Postoperative intussusception, adhesions, and obstruction may be reduced with less bowel handling and retraction.

### Laparotomy

The standard incision in infants is a fairly small right-sided transverse incision above or below the umbilicus.

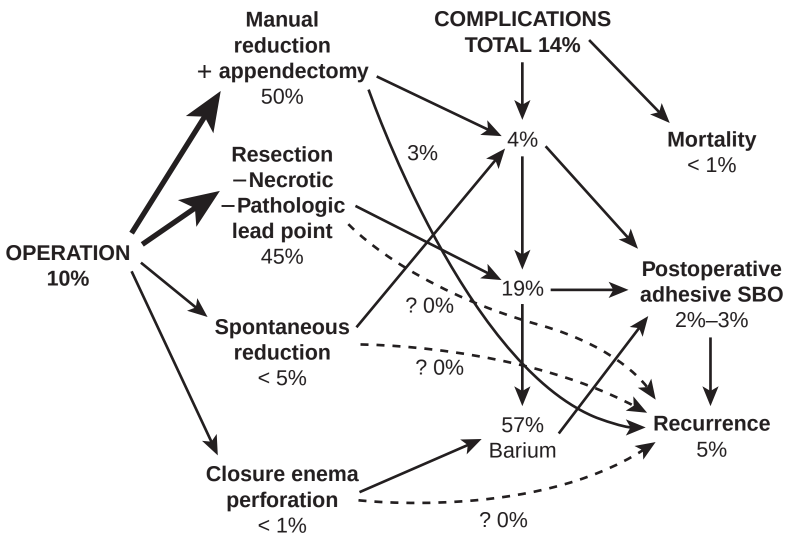

**FIGURE 85-18** Algorithm for surgical intervention for intussusception.

The more distal the intussusception, the more difficult it is to reduce. The cecum in an infant is usually poorly fixed, allowing delivery of most intussusceptions through the incision. If the incision is located lower on the right side resembling an appendectomy incision, the appendix should be removed. Some surgeons remove the appendix after reduction of the intussusception to create local adhesions to decrease the likelihood of recurrence. If serosanguineous peritoneal fluid is encountered on entering the abdomen, bowel necrosis must be suspected.

The key to successful manual reduction is slow constant pinching and squeezing of the most distal part of the intussusceptum, just like squeezing a tube of toothpaste (Fig. 85-19). The intussusceptum is milked in retrograde fashion out of its surrounding intestinal trap. To aid with the reduction, the intussusceptum is gently and slowly pulled out of the intussuscipiens. It is essential to perform both, the retrograde milking and the gentle pulling, slowly and steadily to increase the intraluminal pressure just like the enema does (Fig. 85-20). It should be performed without interruption until the reduction is completed.

The index finger can be used to gently create a wider space between intussuscipiens and intussusceptum (modified Hutchinson maneuver).[204]

The experience of the surgeon plays a significant role in manual reduction. Small serosal tears during reduction are acceptable and can be repaired if necessary. They are warning signs for impending perforation caused by undue pressure. As long as there is progress with the reduction, the operator may press on. If progress stalls during manual reduction and serosal injuries occur, the decision should be made to resect the irreducible intussusception.

In case of ileoileocolic intussusception, the ileocolic component is reduced first and then the remaining ileoileal.

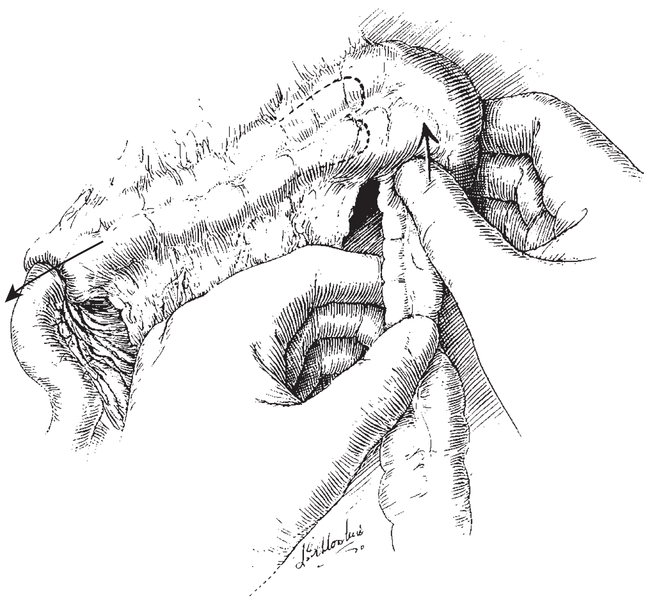

**FIGURE 85-19** The key to successful manual reduction of an intussusception is slow constant squeezing (like a tube of toothpaste) or retrograde milking of the most distal intussusceptum. This can be aided by the assistant gently and slowly pulling the intussusceptum out of the intussuscipiens.

**FIGURE 85-20** Ileocolic intussusception incompletely reduced. Note the partially reduced, congested, but viable terminal ileum.

After successful reduction, the previously intussuscepted bowel may look quite congested, bruised, and possibly not vital (Fig. 85-21). The leading edge of the intussusceptum may look particularly ischemic. In almost all cases the bowel will become pink and vital after application of warm saline towels for less than 10 minutes.

The concept that it is impossible to reduce necrotic bowel anywhere in a pediatric patient may not be always true. In an early study from 1971, Ein and Stephens reported they were able to reduce 50% of all nonviable intussusceptions before resection.[30] After successful manual reduction, a limited bowel resection for ischemia instead of an en mass right hemicolectomy may be performed. Too forceful manipulation of the bowel, however, may cause perforation and contamination. If there is any doubt about the viability of the bowel after reduction, it should be resected. It is rarely feasible to resect or invert a small area of suspected necrosis.

In most patients, a primary end-to-end anastomosis can be fashioned after the ischemic bowel is resected. If the infant is in critical condition or unstable, the ischemic bowel can be quickly resected and both bowel ends exteriorized as temporary stomas.

Perforations during enema reduction usually occur early during the procedure before the intussusception is reduced.[108]

**FIGURE 85-21** Ileoileocolic intussusception after manual reduction. Note the congested and bruised terminal ileum with several serosal tears.

Most will have necrotic bowel. About 50%, however, may be manually reduced in the operating room and require less resection of bowel length.[30] If this is not possible, the intussusception should be resected en mass.

When a perforation is caused, hydrostatic fluid enemas usually result in large colon tears. Hypertonic water-soluble contrast rapidly sequesters fluid into the peritoneal cavity and thereby increases fecal contamination. For radiographic reduction of intussusception, barium is no longer recommended. Colonic perforation with barium causes significant intra-abdominal morbidity and may leave the permanent radiologic picture of a snowstorm (Fig. 85-22).[170,171]

In contrast, perforation after air enema usually leads to a small hole in the colon and much less peritoneal contamination. The free air can easily be recognized during fluoroscopy. Immediately after perforation on the fluoroscopy table, a tension pneumoperitoneum leading to rapid decompensation of the child may occur. Urgent needle decompression may become necessary to stabilize the patient (best done in the midline above the umbilicus with an 18-gauge needle).[205] The enema must be immediately discontinued and the rectum decompressed with the enema tube.

After successful reduction of the intussusception, a pathologic lead point must be manually excluded and, if found, resected. A Meckel diverticulum or ileal polyp is commonly found after ileoileocolonic intussusception.[147,206]

# Complications

## RADIOLOGIC

Bowel perforation is the major complication during enema reduction.[108] Perforation with various techniques is extremely uncommon and quoted less than 1% in most series.[46,207–209]

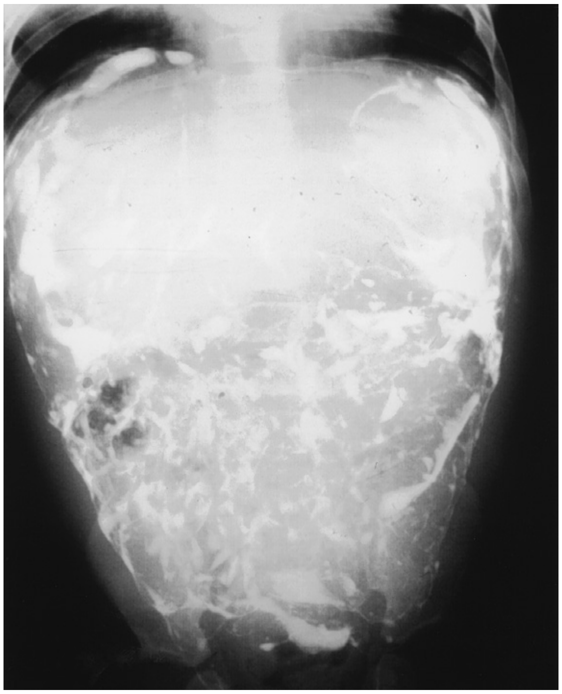

FIGURE 85-22 Postoperative radiograph after perforation caused by hydrostatic barium enema. This snowstorm picture lasts for life.

Perforation rates are comparable with saline or air enema and are rather related to the amount of pressure delivered.

Most perforations occur in the outer intussuscipiens and in the absence of necrosis.[46] Technical factors may play a role such as using too high pressures or too rapid pressure changes. Performing the enema more slowly and keeping the pressure as low as possible may diminish the risk for perforation.

Risk factors for perforation are infants younger than 6 months and a longer duration of symptoms (>36 hours).[210,211] Perforations have been described with low pressures such as 60 mm Hg, suggesting that the perforation was possibly present before enema reduction but covered by the intussuscepted bowel. Partial reduction then uncovered the existing perforation. This may explain why free air is rarely found on plain radiographs in intussusception.[46,209,210]

## SURGICAL

Complications after laparotomy and laparoscopy for intussusception include common postoperative problems such as wound infection, fascial dehiscence, and SBO. Reported complications rates are lower (4%) when no enterotomy or bowel resection had to be performed (26%).[30] The risk of postoperative adhesive SBO after operation for nonperforated intussusception compares with the rate for any pediatric laparotomy. Most cases (80%) occur within the first 2 years.[212] Bowel obstructions caused by stricture after uneventful manual operative reduction of intussusception have been reported.[213] Postoperative complication rates for perforation after barium enema can reach above 50%.

## RECURRENCE

Recurrent intussusception can occur in up to 20% of the cases (average in published series 5%). Most intussusceptions recur within 6 months of the original episode with one third within the first 24 hours.[109,112,214] They are less likely after surgical reduction or resection, and usually there is no lead point.

Parents are more aware of symptoms of recurrent intussusception, which are usually subtle, and present earlier to the hospital. Enema reduction for recurrence is as successful as for the initial episode.

Multiple recurrences can occur in the same child and should prompt a search for a pathologic lead point such as an occult malignancy. The recommended imaging modality is US.[108] Operative exploration is indicated when the ultrasound suggests a pathologic lead point, the reduction enema was unsuccessful, or clinical symptoms persist postreduction.[109]

# Results and Outcome

## CLINICAL

Pediatric intussusception often presents with a wide range of nonspecific symptoms, which can make it challenging to diagnose clinically. The four classic symptoms of pain, emesis, and bloody stools with or without a mass are together present in less than 25% of children. A high index of suspicion is necessary in many cases. It is not surprising that the accuracy of clinical diagnosis is about 50%. Radiographic studies, however, such as abdominal ultrasound and contrast enema

approach 100% accuracy.[137,215] The clinical outcome after treatment of pediatric intussusception continues to be good.

Major improvements over the past 20 years have been made in the success of nonoperative treatment with an average reduction rate of 74% in stable patients.[108] Success rates well above 90% with hydrostatic or pneumatic reduction have been reported, depending on the part of the world.[39] Others report successful initial reduction in 46% and only 36% when symptoms lasted more than 24 hours.[108] Delayed repeat enemas are used to reduce up to 82% of the initial treatment failures.[59,155]

A small number of pediatric patients with intussusception will have to go to the operating room. Reasons for this include an unstable or stable patient with suspected ischemic bowel and peritonitis, unsuccessful enema reduction, suspected pathologic lead point, or, rarely, perforation after pressure enema (<1%). A small number of intussusceptions self-reduced under general anesthesia.[155]

Recurrence occurs in up to 20% of cases.[108,109] Most recur after pressure enema reduction, a small minority after operative manual reduction with or without appendectomy and virtually none after bowel resection.

Most children with recurrence have only one episode (68%), mostly within the first few days after their initial event. About 32% have multiple recurrences that occur as isolated episodes over days, weeks, or years.[108]

The reduction rate for recurrent intussusceptions is higher (95%), possibly because the diagnosis is made earlier by the parents.[109] After recovery, infants and children with intussusception have a normal long-term outcome.

### MORTALITY

Mortalities associated with pediatric intussusception have seen a steady decline. The current overall mortality rate in the pediatric population in developed countries is low (<1%).[216] It is less than 1% for radiologic reduction and less than 1% for surgical intervention.[39]

In 1953 Gross noted that the mortality rate in Boston fell from 59% in 1922 to 2.7% in 1947.[23] His observation remains true to this day: “The interval between onset of symptoms and institution of treatment is of paramount importance and the mortality rates will more nearly approach zero the more frequently treatment is instituted within 24 hours of onset.”

However, deaths continue to be reported occasionally. Stringer and colleagues[77,217] reviewed mortalities after childhood intussusception in England and Wales from the 1980s (overall < 1%) and identified preventable factors in more than 60% of cases. Contributing factors included delay in diagnosis, inadequate intravenous fluid resuscitation and antibiotic therapy, delay in recognizing recurrent or residual intussusception after nonsurgical reduction, and surgical complications.

One of the most recent reviews from the U.S. monitoring trends in intussusception-associated hospitalizations and deaths among U.S. infants until 1997 stated that intussusception-associated infant mortality rates declined from 6.4 per 1 million live births in 1979 to 1981 to 2.3 during 1985 to 1997.[216] Infants whose mothers were younger than 20 years, nonwhite, unmarried, and with an education level below grade 12 were at risk for intussusception-associated death. The authors concluded: “Although intussusception-associated infant deaths in the United States have declined substantially over the past 2 decades, some deaths seem to be related to reduced access to, or delays in seeking, health care and are potentially preventable.”

In a report from 2007, Kaiser and colleagues[147] looked at all 244 children with intussusception admitted to Riley Hospital for Children in Indianapolis from 1990 to 2004. The authors attributed the two deaths (mortality 0.8%) to the delay in diagnosis. Both children presented to the hospital in critical condition and died within 24 hours.

Byard and Simpson[218] reported two intussusception-related deaths at Women’s and Children’s Hospital in Adelaide, Australia, under more than 200 patients between 1975 and 1995. Both infants (5 and 6 months of age) did not appear particularly sick with only nonspecific symptoms until rapid deterioration occurred.[218] A study from Royal Children’s Hospital in Melbourne, Australia, reviewing the 232 patients admitted with intussusception from 1995 to 2001 had no mortality.[59]

In the developing world, intussusception is a common surgical problem with mortality rates as high as 20%.[126] Most infants present later than 3 days after the start of symptoms to medical facilities and even later to a surgeon. Radiologic reduction is often unavailable or not feasible. Recently, tertiary care hospitals in Africa have reduced their mortality rates through increased awareness and education of first-line health care providers and parents. Bode[219] from the University Hospital in Lagos, Nigeria, reported a mortality of 12.1% in 174 consecutive children between 1995 and 2001. At the University of Nigeria Teaching Hospital in Enugu, the routine treatment for intussusception was surgical between 1995 and 2006.[151] Of 71 patients treated, 6 died of sepsis (mortality 8.5%). Kuremu quotes a mortality of 14% after surgical treatment at Moi University in Eldoret, Kenya.[152] Ameh from Zaria, Nigeria, reported 8% mortality rate after operative manual reduction. However, in patients in whom manual reduction was unsuccessful, all six of nine children who underwent right hemicolectomy died from postoperative complications.[220,221] Four of five children (80%) who presented with transanal protrusion of intussusception died. The median onset of symptoms in this group was 21 days (between 6 and 28 days).[222]

Reduction enema has been used successfully in the developing world. Abundanga and colleagues[153] from the tertiary care teaching hospital in Kumasi, Ghana, treated half of their 44 patients with US-confirmed intussusception with air enema reduction in the operation room under general anesthesia. They were successful in 60% of cases and had no mortality.

## Future

Intussusception will continue to occur in children with predominantly gastrointestinal viruses and pathologic lead points. US, not only for diagnosis but also during pneumatic or hydrostatic enema reductions, will play a larger role in the future, predominantly due to evidence of adverse impacts of medical radiation on small children.[223–225] US screening in children with abdominal pain will be routinely performed by pediatric emergency department physicians or pediatric surgeons, therefore reducing the time delay to

diagnosis and treatment.[226–228] Enema reduction rates will increase past 90% as radiologists become more familiar with improved reduction techniques such as pneumatic or delayed enemas, and institutions will aspire to the new standard of care. In the operating room, minimally invasive techniques will be more broadly used by well-trained pediatric surgeons.

## Summary

Intussusception is a common cause of abdominal pain and gastrointestinal obstruction in infants and children. Ninety percent of cases occur between the ages of 3 months and 3 years. A careful history is the mainstay of diagnosis. The classic symptoms of abdominal pain or vomiting and the two classic signs of abdominal mass or rectal bleeding are present in 85% of patients. A high index of suspicion must be maintained for atypical cases, such as the 15% whose intussusception is painless. Abdominal US is the primary adjunct to clinical diagnosis. Idiopathic intussusception is ileocolic in 95% of cases and optimally managed by hydrostatic or pneumatic enema reduction. If these nonoperative methods fail, manual reduction and/or resection in the operating room is performed. If radiographic imaging such as US or contrast enema detects a pathologic lead point, the patient should be taken to the operating room for resection. Delay in diagnosis is the primary avoidable factor that contributes to morbidity and mortality. The mortality rate has steadily declined during the past century to less than 1% in developed nations.

CHAPTER 86

# Disorders of Intestinal Rotation and Fixation

Melvin S. Dassinger and Samuel D. Smith

## History

Information on the failure of rotation and fixation of the intestinal tract has accumulated slowly. Before 1900, only individual cases found at surgery or autopsy were described; these reports could not be placed in context until the embryology was understood.

The first meaningful description of the embryology was written in 1898 by Mall,[1] professor of anatomy at Johns Hopkins University, who had studied in Germany with His, the celebrated embryologist. On the basis of his own studies of reconstructed embryos, as well as those of His, Mall described the process of rotation and then fixation of the bowel. Fraser and Robbins[2] expanded Mall's observations with their own studies of a large group of embryos.

In 1923 Dott[3] published his classic paper on the embryology and surgical aspects of anomalies of intestinal rotation. This was the first clear correlation between clinical and embryologic observations. Dott correlated the findings in 2 of his own cases and 40 collected from the literature with various failures of development. Most subsequent articles described clinical cases in relation to Dott's analysis of the stage of embryologic failure. In 1928 Waugh[4] described two cases of volvulus due to nonrotation. In 1931 Haymond and Dragstedt[5] described the clinical findings and embryology of one type of internal hernia. In the 1930s Gardner and Hart[6] reported 2 cases of their own and classified 104 additional reported cases, Wakefield and Mayo[7] described 13 cases, and McIntosh and Donovan[8] described 20 cases. In 1932 Ladd[9] described 10 cases of malrotation with volvulus and recommended treatment by counterclockwise detorsion. In 1936 Ladd[10] wrote the classic article on the treatment of this condition and described 21 cases. He emphasized the importance of dividing the bands over the duodenum and then placing the cecum in the left upper quadrant. This article shows that Ladd focused his attention on the rarely found bands that go to the right of the duodenum. He did not identify the more frequently encountered bands that enclose the duodenum and cecum. Ladd's procedure of releasing the duodenum and placing the cecum in the left upper quadrant remains the cornerstone of surgical treatment for nonrotation with midgut volvulus. Fixation by sutures has been reported but is no longer advocated because it is not effective.[11,12] In 1953 Gross[13] reported 156 cases in the first comprehensive review of the subject. The Boston Children's Hospital's experience has been updated.[5,14] In 1954 Snyder and Chaffin[15] published a clear and insightful description of anomalies of rotation. In this report, the embryology of malrotation was compared to the twisting of a loop of rope around a central band that represented the superior mesenteric vessels. To date, this remains a useful image.

## Normal Rotation and Fixation

Rotation may be described according to how it affects the two ends of the intestinal tract (i.e., the proximal duodenojejunal loop and the distal cecocolic loop) and the simultaneous rotation of these two components. Most authorities refer to the process as involving the midgut, but it is best to include the entire intestinal tract.[13,16]

### DUODENOJEJUNAL LOOP

The normal adult position of the stomach, duodenum, and first part of the jejunum is well known. Starting at the upper end of the adult intestinal tube and observing its fixed relation to the superior mesenteric artery, it is clear that the stomach is above or anterior to the artery, the second portion of the duodenum is to the right of the artery, the third portion of the duodenum lies beneath the artery, and the fourth portion (the distal duodenum and first part of the jejunum) is to the left of the artery. The duodenojejunal loop starts in the embryo in the same position as that of the stomach in the adult (Fig. 86-1). If the other components of the loop eventually take the position as previously described, the duodenojejunal loop has rotated around the superior mesenteric artery from above (see Fig. 86-1), to the right 90 degrees (Fig. 86-2), and to the bottom another 90 degrees, for a total thus far of 180 degrees (Fig. 86-3), then to its final place to the left of the artery for an additional swing of another 90 degrees, or a total arc of 270 degrees (Fig. 86-4). The direction of the swing is determined by the normal final position of the stomach and all four portions of the duodenum.

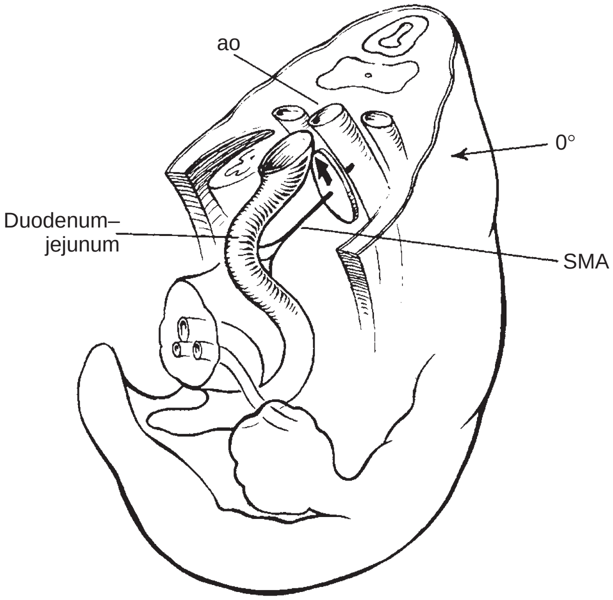

FIGURE 86-1 Schematic ventrolateral view of a 5-mm embryo. The intestinal tract forms a slight curve forward. The superior mesenteric artery (SMA) passes at right angles from the aorta (ao) to the curve of the intestine. A disk has been drawn around the SMA at its base; the arrow points superiorly to the starting position, or 0 degrees rotation, of the duodenojejunal loop. Rotation proceeds around the artery as an axis.

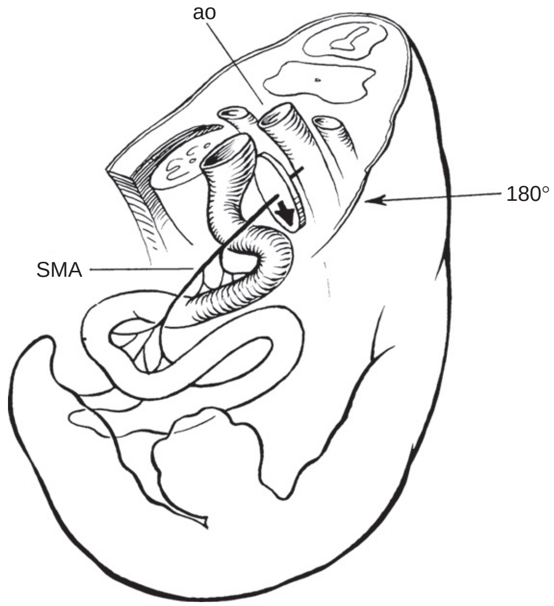

FIGURE 86-3 Schematic ventrolateral view of a 25-mm embryo, indicating further rotation of the duodenojejunal loop to a position below the superior mesenteric artery (SMA), through an arc of 180 degrees. Extension of the remainder of the intestines into the cord is not shown. *ao,* aorta.

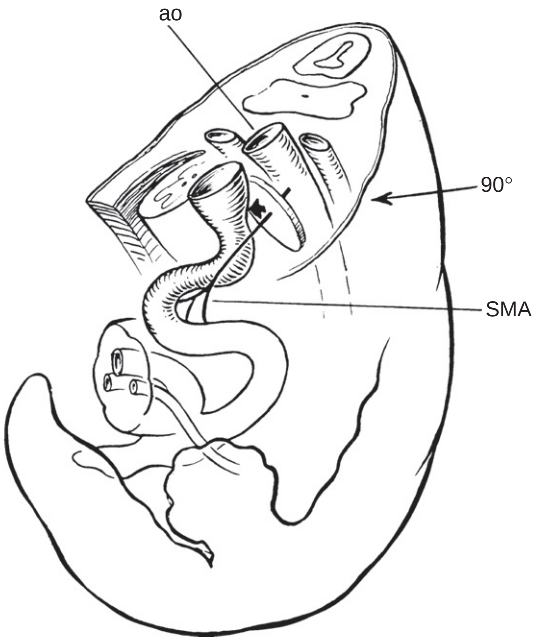

FIGURE 86-2 Schematic ventrolateral view of a 10-mm embryo. The duodenojejunal loop has passed from a position above the superior mesenteric artery (SMA) to the right of the artery and thus has rotated through an arc of 90 degrees from its starting position, as indicated by the arrow in the disk. *ao,* aorta.

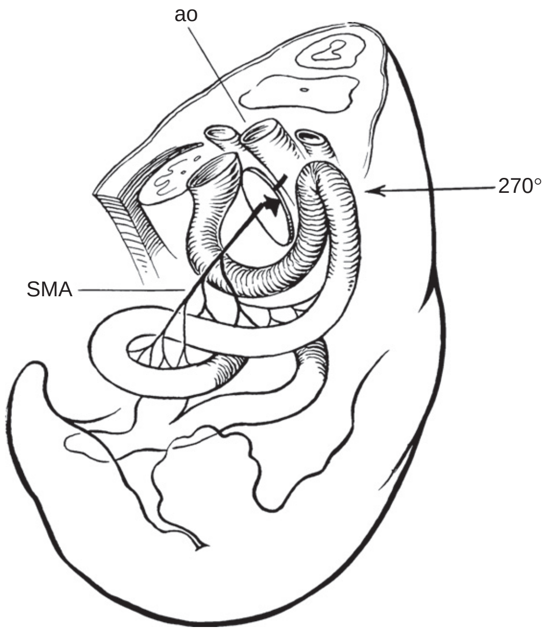

FIGURE 86-4 Schematic ventrolateral view of a 40-mm embryo, indicating final rotation of the duodenojejunal loop to a position immediately to the left of the superior mesenteric artery (SMA). This loop has passed from a position superior, to the right beneath, and to the left, or through an arc of 270 degrees in a counterclockwise direction. This final rotation of the duodenojejunal loop takes place as the intestines return from the cord. *ao,* aorta.

## ORIENTATION FOR SIDE AND DIRECTION OF ROTATION

In the preceding description, the right side is the patient's right, not the right side of the observer facing the patient. However, when the usual direction of rotation is described according to the hands of a clock, the direction noted is from the viewpoint of the observer. If an imaginary clock is placed face up on the posterior wall of the embryo or baby, the pivot point of the hands (i.e., the axis of their rotation) is the superior mesenteric artery. The duodenojejunal loop moves counterclockwise.

## CECOCOLIC LOOP

In the adult, the terminal ileum, cecum, and right colon reside on the right side of the abdomen to the right of the superior mesenteric artery. In the embryo, they lie beneath the artery. This cecocolic loop, like the duodenojejunal loop, passes counterclockwise from its starting point beneath the artery (Fig. 86-5), to the left of the artery 90 degrees (Fig. 86-6), above to 180 degrees (Fig. 86-7), and to the right of the artery, through a total arc of 270 degrees (Fig. 86-8). In this manner, the cecocolic loop normally achieves its adult position.

## SIMULTANEOUS ROTATION OF BOTH ENDS AND OF THE ENTIRE INTESTINAL TRACT

Rotation is best visualized by attaching a loop of rope above and below a metal spoke (wire) on a piece of wood (Fig. 86-9). The loop is grasped in the left hand and turned through three quarters of a turn to the left. The proximal portion of the upper limb of the rope should be watched. This portion turns from its initial position above the wire, to the right of it, beneath it, and to the left of it. At the same time, the lower limb of the rope lies beneath the wire at the start of the turn, then goes to the left, above, and finally to the right of the wire. If the upper limb of the rope represents the duodenojejunal loop, the wire represents the superior mesenteric artery, and the lower limb represents the cecocolic loop, the position of these structures in the process of rotation should be clear. The entire process can be studied in minute detail with a dissecting microscope and a large series of embryos ranging in age from 4 to 12 weeks. In the fourth week of fetal life, or when the embryo has reached the 5-mm stage, the intestinal tract is almost a straight tube, with a slight anterior bulge in the central portion. The superior mesenteric artery comes forward from the posterior wall to the center of the bulge (see Figs. 86-1 to 86-5). Changes occur rapidly as the intestine forms within an extension of the abdominal wall into the umbilical cord. The stomach remains in its original position anterior and above the superior mesenteric artery. The duodenum then begins to curve downward and to the right of the artery. The jejunum and small intestine extend into

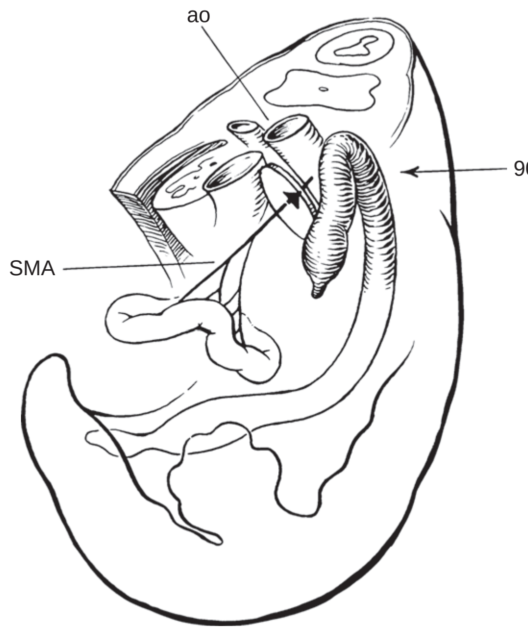

**FIGURE 86-6** Schematic ventrolateral view of a 40-mm embryo, showing the position of the cecocolic loop at the left of the superior mesenteric artery (SMA). The loop has rotated through an arc of 90 degrees from its starting position inferior to the artery (see the disk at the base of the SMA). This phase of rotation is maintained while the intestines are in the cord and at the moment they drop back into the abdomen. *ao,* aorta.

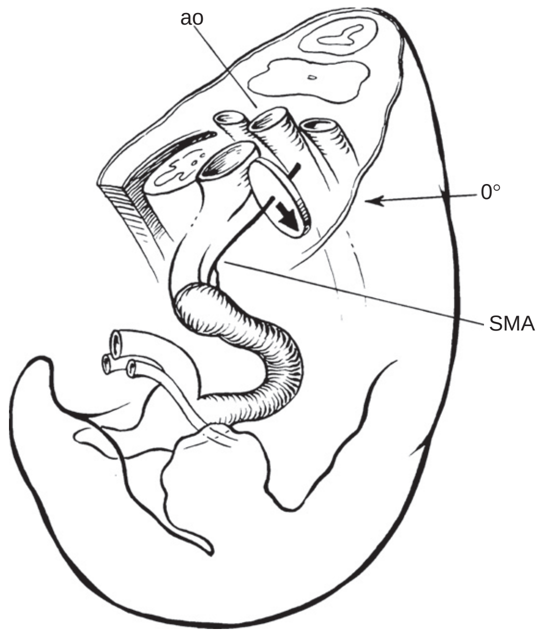

**FIGURE 86-5** Schematic ventrolateral view of a 5-mm embryo, indicating the forward bend of the intestinal tract. The cecocolic loop is emphasized as it lies inferior to the superior mesenteric artery (SMA), or in a position of 0 degrees rotation, indicated on the disk around the base of the SMA. The 0-degree rotation position for this loop is inferior to the SMA, whereas that for the duodenojejunal loop is superior. *ao,* aorta.

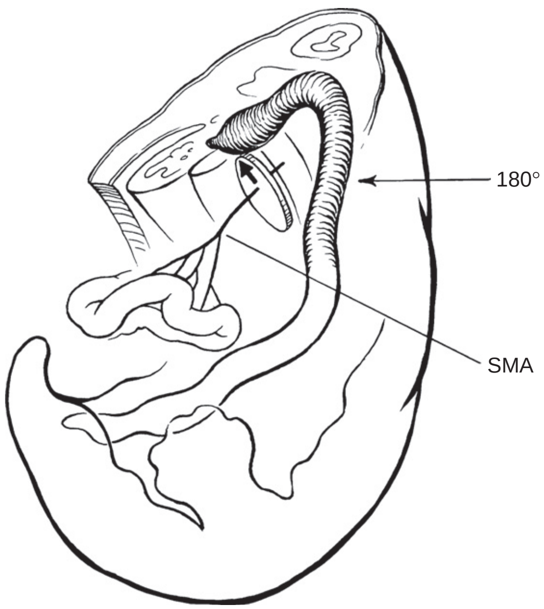

**FIGURE 86-7** Schematic ventrolateral view of a 40-mm embryo, indicating rotation of the cecocolic loop to a position superior to the superior mesenteric artery (SMA), or rotation through an arc of 180 degrees from the starting position inferior to the SMA. This phase takes place immediately after return of the intestines from the cord into the abdomen.

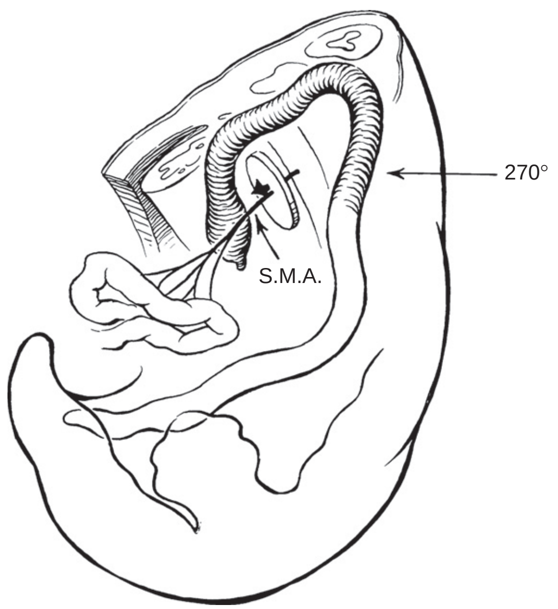

FIGURE 86-8 Schematic ventrolateral view of a 40-mm embryo, showing the final position of the cecocolic loop to the right of the superior mesenteric artery (SMA). This loop has passed from a position beneath, to the left, superior, and finally to the right of the SMA, or through an arc of 270 degrees in a counterclockwise direction.

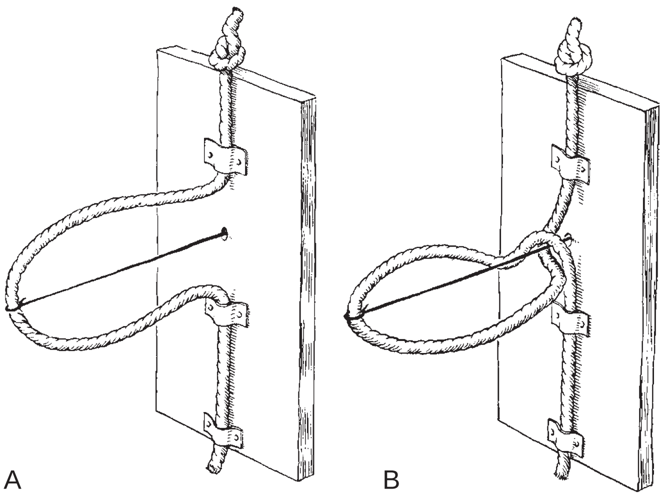

FIGURE 86-9 Mechanical demonstration of intestinal rotation. A rope is attached to a board at both ends, with a wire extending at right angles from the board to the base of the loop. **A,** The top limb of the rope corresponds to the duodenojejunal loop, the wire corresponds to the superior mesenteric artery, and the bottom limb corresponds to the cecocolic segment. **B,** The rope loop has been grasped by the hand and rotated through an arc of 270 degrees, or three quarters of a complete turn around the wire as the axis, in a counterclockwise direction. Thus the top limb has become the bottom one, and the bottom limb the top. By following the movements of the two limbs around the wire close to the board, one can visualize the process of rotation of the intestine in the embryo.

the umbilical cord, along with the cecum, right colon, and part of the transverse colon. Both loops have thus passed from a position in front of the artery to the side of the artery (see Figs. 86-2 and 86-6).

It was previously thought that both loops remained in this position until the intestines returned from the cord into the abdomen.[2,3] However, it was demonstrated by Mall[1] and verified by Snyder and Chaffin[15] that the duodenojejunum continues to rotate during the extracoelomic phase of intestinal development, and at about the eighth week, the third portion of the duodenum comes to lie beneath the artery (see Fig. 86-3). This increases the rotation of this segment to 180 degrees. Finally, at about 10 weeks (or when the embryo is about 40 mm long), the intestines return to the abdomen. This must be a rapid process because few specimens of this stage of development have been described. The small bowel is the first segment of the intestines to return to the abdominal cavity, and it pushes the fourth portion of the duodenum and jejunum to the left of the superior mesenteric artery. This completes the rotation of this segment of the bowel (see Fig. 86-4). The cecum and right colon return to the abdomen last, on the left side (see Fig. 86-6). This loop then passes anterior or above the artery (see Fig. 86-7) and finally to its adult position on the right side of the artery (see Fig. 86-8).

To use another analogy, placing a hand on top of an imaginary automobile steering wheel and making a three-quarter turn to the left executes the process of rotating the duodenojejunal loop around the steering post (superior mesenteric artery). With a hand on the bottom of the steering wheel, a three-quarter turn to the left executes the rotation of the cecocolic loop.

This is the process of normal rotation; the sequence of events has been postulated from bits of evidence contributed by many observers. It does not lend itself to a breakdown into stages I, II, and III, as previously described, because it is a continuing process and is better understood by comparing it to the swing of a twisted rope or the turn of a steering wheel.[2] That description may be an oversimplification, but it is easy to remember in the operating room.

Kluth and Lambrecht[17] proposed a slightly different explanation for intestinal malrotation on the basis of rat embryo studies. They emphasized that rapid growth and lengthening of the duodenum force the tip of the duodenojejunal loop to grow under the mesenteric root. The distal midgut also rapidly lengthens and forces the cecum from a caudal to a cranial position; this may appear to be rotation, but the rest of the colorectum is not involved in the process. These authors view fixation and position of the intestine to be a process of differential growth rather than rotation because they did not find gross changes in the straight midgut in their embryo studies. They postulate that maldevelopment of the embryonic duodenal loop is the major problem involved in the pathogenesis of midgut malformations. Reduced growth of the duodenal loop or abnormal insertion of the mesenteric root, functioning as a barrier to growth of the duodenal loop, may explain the abnormal location of the duodenum and the ligament of Treitz. They believe that cecal and colonic movement plays a more passive or minor role in causing abnormalities of intestinal position and fixation.

## CLASSIFICATION OF ABNORMALITIES OF INTESTINAL ROTATION

Normal fixation of the duodenum and colon is illustrated in Figure 86-10. The normal mesenteric attachment extends from the ligament of Treitz, located at the level of the gastric outlet, to the cecum. Both the ascending and descending colon are fixed retroperitoneally. The abnormalities of intestinal

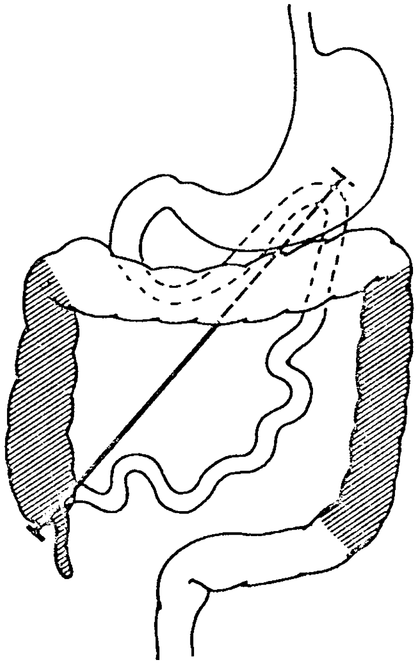

**FIGURE 86-10** Normal fixation of the mesentery of the midgut. The normal broad base extends from the ligament of Treitz to the ileocecal junction and prevents twisting of the intestine. Both the ascending and descending colon are fixed retroperitoneally. (From Filston HC, Kirks DR. Malrotation—the ubiquitous anomaly. J Pediatr Surg 1981;16:614.)

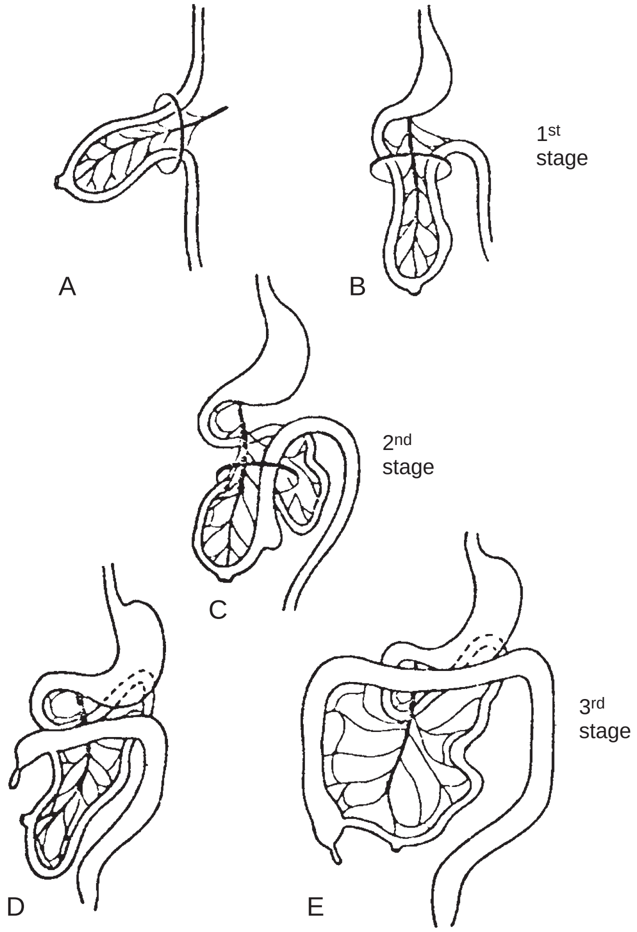

**FIGURE 86-11** Normal intestinal rotation. **A,** Six weeks' gestational age: nonrotation. **B,** Eight weeks' gestational age: incomplete rotation. **C,** Nine weeks' gestational age: incomplete rotation. **D,** Eleven weeks' gestational age. **E,** Twelve weeks' gestational age. (From Filston HC, Kirks DR. Malrotation—the ubiquitous anomaly. J Pediatr Surg 1981;16:614.)

rotation represent a spectrum with many variations. The surgical problems resulting from these abnormalities of rotation are best classified by understanding the errors in growth, rotation, and position of the duodenum and ligament of Treitz. Any defined stages are arbitrary, but referring to Figure 86-11, which shows the stages of normal rotation, may be helpful in determining the maldevelopment that may have occurred in an individual case.[18] The term *malrotation* refers to all abnormalities of intestinal position and attachment[19] and includes the more recent concept of atypical malrotation or malrotation variant. Atypical malrotation results when the ligament of Treitz is to the left of midline, defined by the vertebral body, or below the gastric outlet on upper gastrointestinal (GI) contrast studies. The term nonrotation is used for the first stage (see Fig. 86-10), and the terms incomplete rotation and mixed rotation are used for abnormalities of the second stage.

Reverse rotation is a rare anomaly in which the duodenum and colon rotate clockwise in relation to the superior mesenteric artery and vein. The transverse colon eventually lies behind the vessels, which may result in acute or chronic colonic obstruction.

Rotation and fixation abnormalities are also known to coexist with heterotaxia, but rarely with situs inversus.[20] Heterotaxia, previously known as situs ambiguus, is defined as an abnormal arrangement of body organs or complete situs inversus. Major cardiac anomalies are commonly associated with heterotaxia. GI anomalies include midline liver, malposition of the stomach, anomalies of intestinal rotation and fixation, intraperitoneal pancreas, and either asplenia or polysplenia.[20]

Malrotation is an integral part of congenital diaphragmatic hernia and all abdominal wall defects. In gastroschisis, the midgut is nonrotated and may be suspended and stretched outside the fetal abdominal cavity; this leads to ischemic injury without volvulus. Infants with omphalocele or diaphragmatic hernia have varying degrees of normal rotation and fixation, depending on the extent of intestinal displacement.

Associated anomalies are found in 30% to 60% of patients with malrotation.[7,21–23] Duodenal atresia has been found in conjunction with malrotation and perinatal volvulus. Intrinsic duodenal obstruction from a partially obstructing web must not be overlooked in cases of malrotation. Filston and Kirks[21] found midgut malrotation as an associated malformation in half of jejunal and one third of duodenal atresia cases. Malrotation is rarely associated with Hirschsprung disease and anorectal malformations.[1] Mesenteric cysts have been observed in association with malrotation, but whether this is a primary anomaly or results from lymphatic obstruction due to chronic volvulus is not clear.[24]

## CLINICAL MANIFESTATIONS

Various clinical presentations, ranging from chronic abdominal pain to acute midgut volvulus with ischemic bowel injury, may result from failure of normal intestinal rotation and fixation. In general, it is possible to correlate the various clinical syndromes with the observed anatomic findings, but there are many variables and exceptions.

### Acute Midgut Volvulus

The narrow pedicle formed by the base of the mesentery in malrotation predisposes the midgut to clockwise twisting from the duodenum to the transverse colon (Fig. 86-12). Excessive length of the mesentery or a point of adhesion at the convexity of the loop may act as an axis for a twist.[3] The actual inciting mechanism is unknown, but various possibilities have been suggested including unusual movement of the torso, abnormal intestinal peristalsis, or segmental bowel distention.[25]

Most patients with midgut volvulus present in the first month of life.[26] In a group of 74 patients, 23 were seen in the first 7 days of life; 16 from 7 to 30 days of life, and 24 from 1 to 12 months; only 11 were older than 1 year.[27] Fourteen of 22 patients described by Torres and Ziegler[28] presented during the first month of life.

The primary presenting sign of malrotation is the sudden onset of bilious vomiting in a previously healthy, growing infant.[29] With the onset of proximal intestinal obstruction, the distal colon empties; soon after the onset of vomiting, the lower abdomen may appear scaphoid. As vascular compromise progresses, intraluminal bleeding may occur and blood is often passed per rectum. Crampy abdominal pain is common. Innocent "colic" or hypertrophic pyloric stenosis may be ruled out on the basis of bilious vomiting.

Infants with complete obstruction rapidly develop intestinal ischemia with a firm, distended abdomen; hypovolemia; and shock. Abdominal tenderness varies with the degree of vascular compromise, but signs of peritonitis are invariably present.

A high index of suspicion for midgut volvulus is based on the history, physical examination findings, and presence of metabolic acidosis. The decision whether to confirm the diagnosis by either Doppler ultrasonography or upper GI contrast radiography or to proceed directly to laparotomy or laparoscopy must be based on the condition of the patient and the risk of vascular compromise if there is any delay.

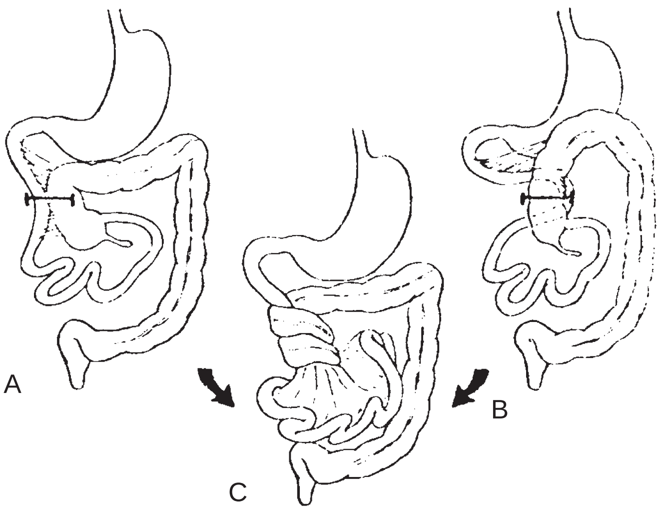

**FIGURE 86-12** Pathophysiology of midgut volvulus with malrotation. **A,** The narrow mesenteric attachment in nonrotation **(B)** or incomplete rotation **(C)** predisposes the patient to midgut volvulus. (From Filston HC, Kirks DR. Malrotation—the ubiquitous anomaly. J Pediatr Surg 1981;16:614.)

## CHRONIC MIDGUT VOLVULUS

Intermittent or partial midgut volvulus results in lymphatic and venous obstruction, with enlargement of the mesenteric lymph nodes. This situation is more commonly encountered in children older than 2 years.[29–33] On the basis of our review of malrotation in children older than 2 years, the most frequent presenting complaints are chronic vomiting (68%), intermittent colicky abdominal pain (55%), diarrhea (9%), hematemesis (5%), and constipation (5%).[34] The average duration of symptoms before an operation was performed was 28 months. Absorption and nutrient transport can be impaired by venous and lymphatic stasis, leading eventually to protein-calorie malnutrition in severe cases of long-standing incomplete rotation with partial obstruction.[31,33] An increased predisposition to infection has also been observed.[31]

Failure to suspect this diagnosis has resulted in dietary manipulation and even psychiatric evaluation in some patients. Bilious vomiting in conjunction with abdominal pain should be considered a surgical problem until proved otherwise.[35] Nonbilious vomiting may also occur as a neurogenic response to gastroduodenal distention.

## TYPICAL MALROTATION IN ASYMPTOMATIC OR MINIMALLY SYMPTOMATIC PATIENTS

The incidental finding of malrotation on radiography or at the time of an operation raises the question of the eventual risk of complications in an asymptomatic patient. In a study of 50 adults with malrotation, Wang and Welch[36] found that 26 actually had symptoms referable to the abnormality. The general consensus is that a corrective surgical procedure is indicated at any age.[21,26,37]

The issue of asymptomatic patients with malrotation was brought into focus by Chang and colleagues,[20] who reported on 34 patients with heterotaxia and complex heart disease. Four of 28 developed acute or chronic signs of midgut volvulus requiring an emergency Ladd procedure. A subsequent group of six patients with heterotaxia had upper GI radiography that detected anomalies of intestinal fixation and rotation in all of them. Each patient underwent an uncomplicated elective Ladd procedure once the cardiac condition stabilized.

The first indication of malrotation may be noted during surgical exploration for an acute abdomen. Locating an acutely inflamed appendix in a patient with malrotation may be anticipated by radiographic absence of a cecal shadow in the right lower quadrant. In Collins's[38] study of 71,000 human appendix specimens, 2849 were in an abnormal position because of incomplete rotation of the large bowel. Further evaluation of such patients by upper GI radiography is indicated after their recovery from emergency operation.

## ACUTE DUODENAL OBSTRUCTION SECONDARY TO CONGENITAL BANDS

Acute duodenal obstruction results from peritoneal bands (Ladd bands) extending across the third portion of the duodenum, causing extrinsic compression of the lumen or kinking of the bowel at the site of fixation. Duodenal obstruction is more common in neonates and infants but can occur later in life as well. Volvulus is not a principal finding in these patients.

An infant or newborn usually presents with forceful, bilious vomiting. Abdominal distention may or may not be present, depending on the degree of gastric emptying achieved by vomiting. Gastric peristaltic waves may occasionally be observed.[39] The obstruction may be complete or incomplete, so meconium or stool may have been passed. Jaundice may be seen.[40] In a newborn, symptomatic malrotation with bands is often associated with intrinsic duodenal obstruction. A "double bubble" due to duodenal obstruction is usually seen on plain abdominal radiographs, but an upper GI contrast study of the duodenum is diagnostic.

### CHRONIC DUODENAL OBSTRUCTION SECONDARY TO CONGENITAL BANDS

Chronic, recurrent, or subacute obstruction of the duodenum results when the prearterial limb does not complete its normal rotation and is fixed by adhesions and peritoneal bands that may twist, angulate, or kink the duodenum.[41] Some degree of volvulus may pull on the bands and contribute to the kinking. The obstruction is usually in the third portion of the duodenum.

Bilious vomiting is the main finding at presentation. Failure to gain weight and intermittent colicky abdominal pain are commonly observed. The age at diagnosis ranges from infancy to preschool age. Transient dilatation of the duodenum without reflux can, by reflex, stimulate gastric regurgitation. Contrast studies, although diagnostic, must be performed carefully because the degree of enlargement may be subtle.

### REVERSE ROTATION WITH COLONIC OBSTRUCTION

In this rare abnormality (Fig. 86-13), the duodenum and jejunum lie anterior to the superior mesenteric vessels and obstruct the posteriorly lying transverse colon. The transverse colon must pass through a tunnel beneath the mesentery, and this produces a chronic incomplete or complete obstruction of the colon. This condition is usually seen in adults and is rarely reported in children.[36]

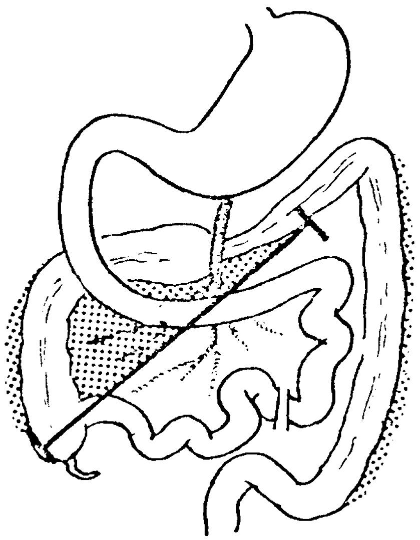

**FIGURE 86-13** Reverse rotation of the duodenum and colon. When the colon rotates beneath the superior mesenteric artery, the midtransverse colon may become partially obstructed. This is caused by pressure of the vessels and by bands from the mesentery to the small bowel.

### INTERNAL HERNIA

Lack of fixation of the mesentery of the right or left colon, or of the duodenum, may result in the formation of potential spaces for hernias. Internal hernias are associated with recurrent entrapment of bowel with partial obstruction, which may eventually progress to complete obstruction and strangulation. The most commonly seen internal hernias are the right and left mesocolic hernias described by Willwerth and colleagues.[42] The term *mesocolic* is preferred to the alternative term *paraduodenal*. A right mesocolic hernia is produced when the prearterial limb fails to rotate around the superior mesenteric artery and the bowel loops are entrapped by the mesentery of the cecum and colon (Fig. 86-14, *A*). A left mesocolic hernia is produced when the unsupported area of the descending mesocolon between the inferior mesenteric vein and the posterior parietal colonic attachment is ballooned out by the small intestine as it migrates to the left superior portion of the abdominal cavity. Usually, the cecum has completely rotated and lies in a normal position in the right lower quadrant. The ileum exits from the sac, but at a variable distance from the ileocecal valve (Fig. 86-14, *B* and *C*).

Signs and symptoms of an internal hernia are related to recurrent, intermittent bouts of intestinal obstruction characterized by recurrent colic. The latter may lead to constant abdominal pain, vomiting, and, sometimes, constipation. The symptoms are often mild and are occasionally thought to be psychologic. Radiographs obtained during an attack of colic may suggest obstruction of the small intestine.

### VOLVULUS OF THE CECUM

Cecal volvulus, seen most often in patients older than 60 years, is caused by lack of fixation of the cecum, terminal ileum, and proximal ascending colon. The main symptoms are acute, severe abdominal pain and nausea associated with right-sided abdominal distention. Complete obstruction frequently develops. The characteristic abdominal radiograph shows a large air-filled loop of colon occupying the left upper quadrant (the convex surface faces the left lower quadrant), associated with small bowel obstruction.[43]

## Radiologic Diagnosis of Abnormalities of Rotation and Fixation

Contrast radiography is essential for the clinical evaluation and diagnosis of disorders of intestinal rotation and fixation. The normal relations of the stomach, duodenum, ligament of Treitz, and ileocecal area are shown schematically in Figure 86-11 and radiographically in Figure 86-15. The extent of normal mesenteric attachment is largely predictive of the radiographic findings.[18,44–46]

Plain abdominal radiography is often nondiagnostic because differentiation between gas-filled small intestine and large intestine may be difficult in neonates and small infants.[47] However,

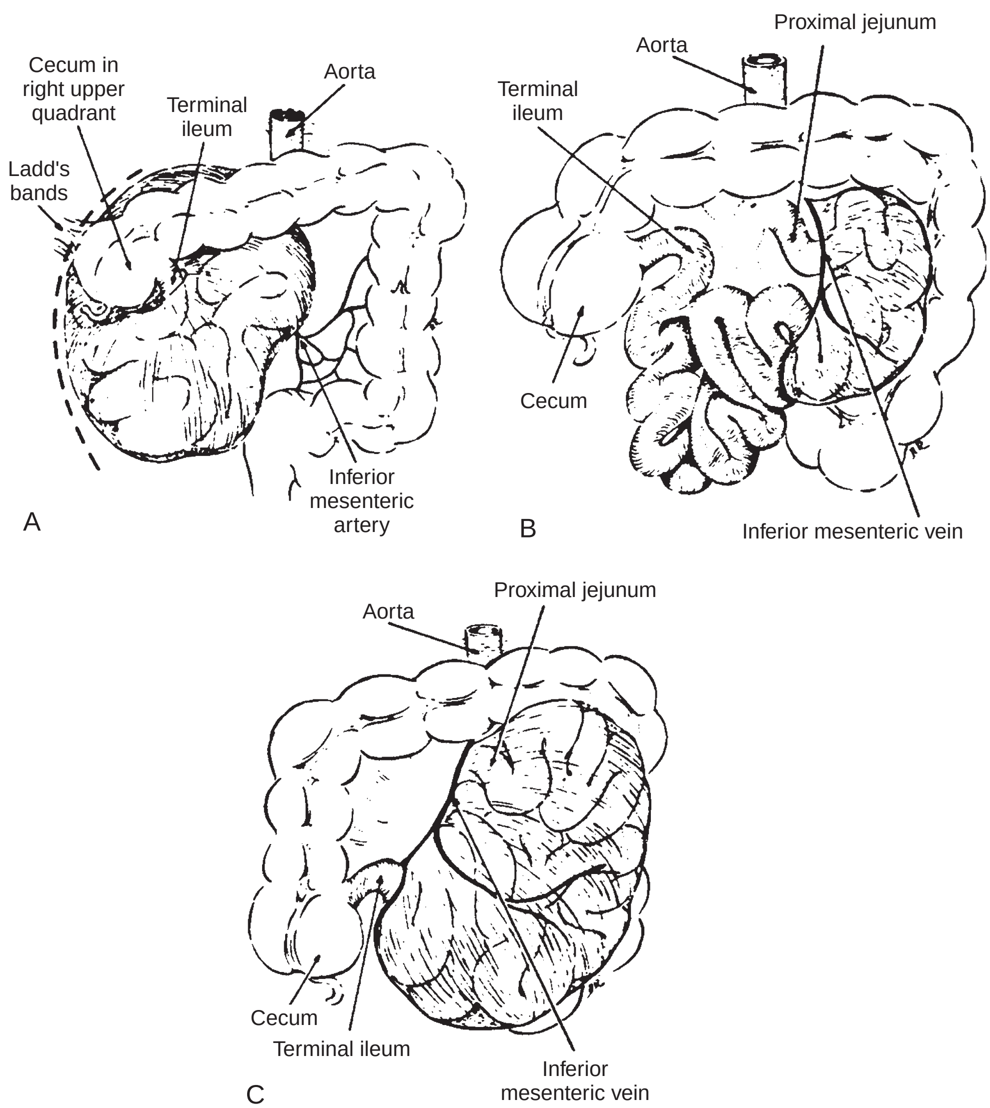

**FIGURE 86-14** Mesocolic hernias. **A,** Right mesocolic hernia. The prearterial segment of the midgut has failed to rotate. The postarterial segment does not rotate and traps most of the small bowel behind the right mesocolon. The hatched line indicates the surgical incision used to reduce the hernia. **B,** Left mesocolic hernia. Initial rotation of the small intestine is normal. During migration to the left superior portion of the abdomen, the bowel invaginates an avascular portion of the left mesocolon posterior to the inferior mesenteric vein. **C,** Left mesocolic hernia. The small intestine, except for portions of the distal ileum, is trapped beneath the left mesocolon. Note that the inferior mesenteric vein delineates the right margin of the sac and is an integral part of the neck of the sac. (From Willwerth BM, Zollinger RM, Izant RJ. Congenital mesocolic [paraduodenal] hernia: Embryologic basis of repair. Am J Surg 1974;128:358. **B** and **C,** Based on Callander CL, Rusk GY, Nemir A. Mechanism, symptoms and treatment of hernia into the descending mesocolon (left duodenal hernia). Surg Gynecol Obstet 1935;60:1052-1071.)

some useful signs are occasionally seen including the "double bubble" of acute duodenal obstruction (Fig. 86-16, *A*) or the absence of a normal colonic gas pattern in an older patient with a displaced cecum. Volvulus of the midgut is often characterized by a "gasless" abdomen, but distal intestinal obstruction may also be found.[47] In these instances the intestine may be thickened and edematous (Fig. 86-16, *B*).

Ultrasonography has become a useful study for the detection of many intra-abdominal conditions. It is a good screening device for infants suspected of having midgut volvulus because it can define vascular flow through the superior mesenteric vessels. Pracros and colleagues[48] reported an ultrasonographic "whirlpool" flow pattern of the superior mesenteric vein and mesentery around the superior mesenteric artery in 15 of 18 patients with midgut volvulus; this pattern was best seen using color Doppler imaging (Fig. 86-17). Additional ultrasonographic findings are a fluid-filled, distended duodenum and dilated, thick-walled bowel loops located mainly to the right of the spine. Computed tomography may also demonstrate a "whirlpool" flow pattern with intravenous and oral contrast (Fig. 86-18). More recently, Yousefzadeh has proposed that ultrasound be used to diagnose malrotation without volvulus on the basis of the position of the duodenum and the superior mesenteric artery. As mentioned in the embryology section, the third portion of the duodenum assumes a retroperitoneal position anterior to the aorta and posterior to the superior mesenteric artery in individuals with normal intestinal rotation. Verification of this position by ultrasound potentially obviates the need for further imaging. Application of this technique prospectively in multiple institutions is likely needed before widespread acceptance.[49]

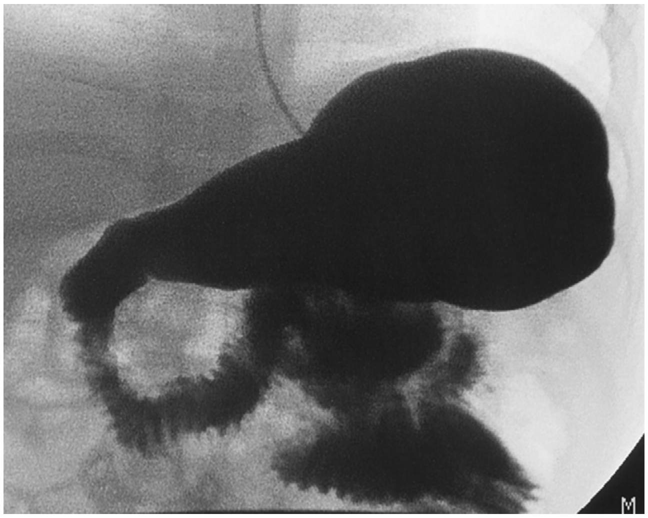

FIGURE 86-15 Normal duodenal rotation and duodenojejunal fixation. The duodenum descends to the right of midline, courses transversely to the left, and ascends to the left of midline to the level of the duodenal bulb before becoming intraperitoneal beyond the duodenojejunal junction. (Courtesy Marc S. Keller, MD, Yale University School of Medicine.)

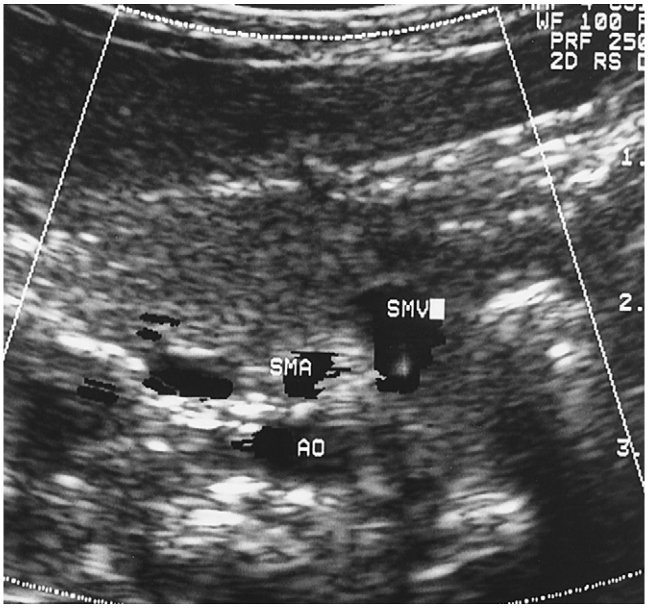

FIGURE 86-17 Color Doppler image of malrotation of a transverse upper abdomen. The abnormal position of the superior mesenteric vein (SMV) to the left of the superior mesenteric artery (SMA) can be seen just anterior to the abdominal aorta (AO). (Courtesy Marc S. Keller, MD, Yale University School of Medicine.)

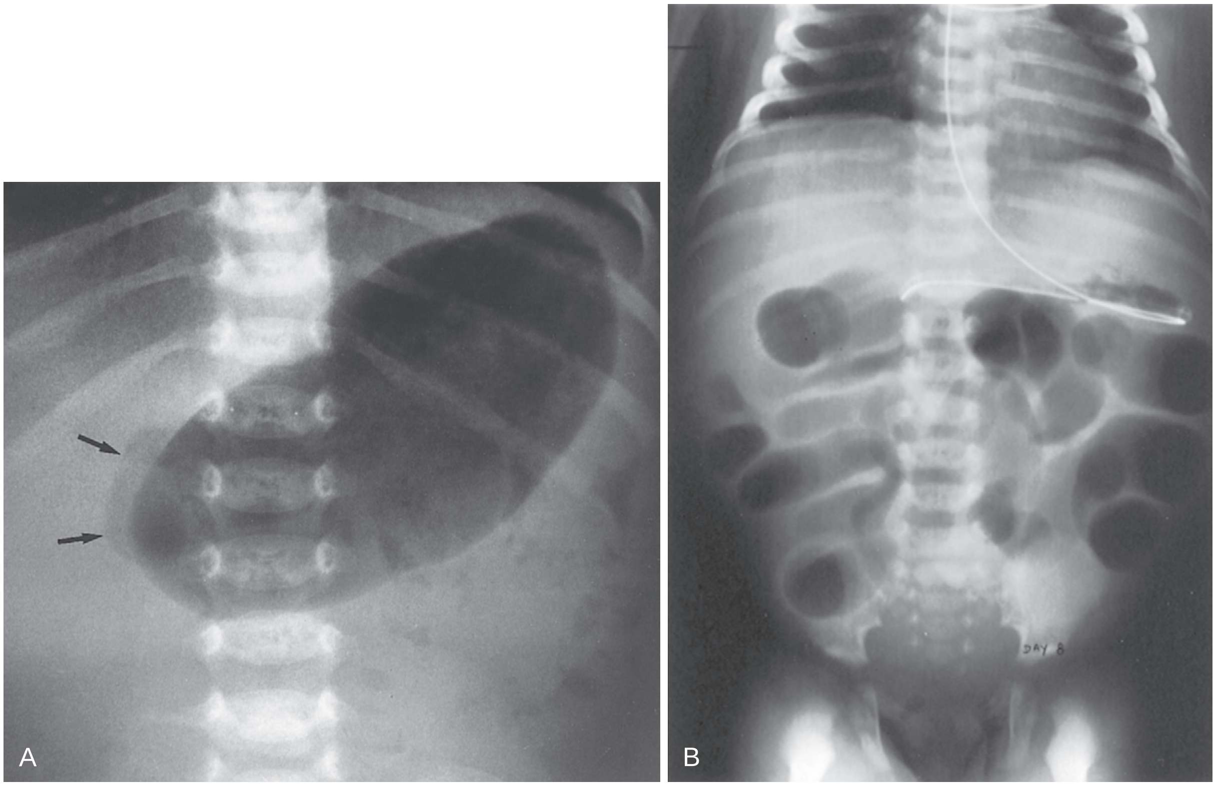

FIGURE 86-16 **A,** Plain radiograph of an infant with midgut volvulus. Obstruction of the descending duodenum may result in the pattern of gaseous distention of the stomach and duodenum (*arrows*) seen here, with a paucity of gas noted distally. **B,** Eight-day-old infant with midgut volvulus. This pattern of distal intestinal obstruction with thickened walls is much less common than that of proximal duodenal obstruction, but it is associated with more severe vascular compromise and clinical illness. (**A,** Courtesy Marc S. Keller, MD, Yale University School of Medicine.)

**FIGURE 86-18** Computed tomography scan of malrotation with volvulus (note the spiral configuration of the mesenteric vessels [*arrow*]).

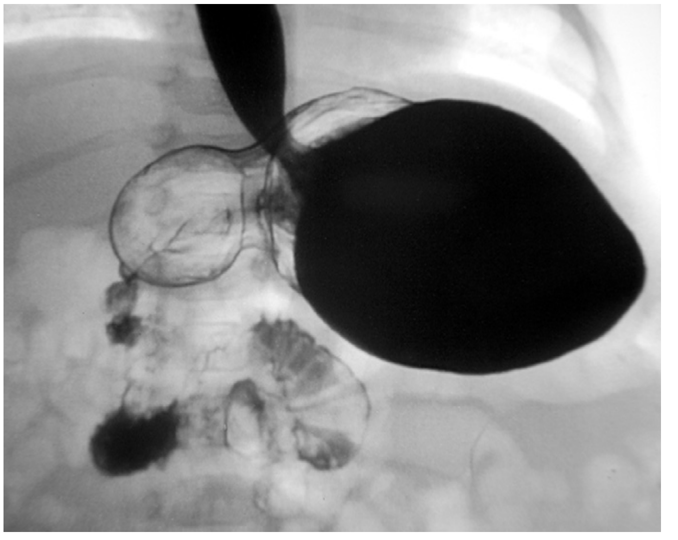

**FIGURE 86-20** Contrast study of atypical malrotation or malrotation variant. The ligament of Treitz fails to reach its normal position left of midline and at the level of gastric outlet.

An upper GI contrast study with careful delineation of the duodenojejunal course is now the preferred study for evaluating a patient with a possible abnormality of intestinal rotation. The position of the ligament of Treitz is assessed relative to the midline or center of the vertebral body and the level of gastric outlet. A normal finding is defined as the ligament of Treitz to the left of the vertebral body and at the level of the gastric outlet (Fig. 86-19). Malrotation is described by many pediatric radiologists as "typical" if the ligament is to the right of midline or absent, and "atypical" if the ligament of Treitz is midline or to the left and below the gastric outlet (Fig. 86-20). Cecal position is classified as either right lower quadrant (normal) or somewhere other than right lower quadrant (abnormal). The surgical dilemma of managing patients with atypical malrotation is discussed later.

The radiographic distinction between midgut volvulus and obstruction from peritoneal bands may be subtle. Ablow and colleagues[50] described a Z-shaped duodenojejunal loop in older children with intermittent abdominal pain and vomiting. Upper GI contrast radiography reveals a sharply angulated, to-and-fro course of the distal duodenum and jejunum, which may cross to the left of the midline, rather than the usual smooth duodenojejunal loop at the ligament of Treitz (Fig. 86-21, *B*).

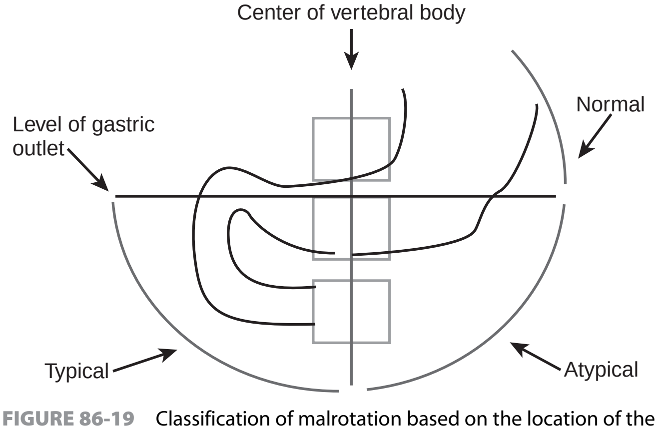

**FIGURE 86-19** Classification of malrotation based on the location of the ligament of Treitz in comparison with the midline of the vertebral body and the level of gastric outlet.

The Z sign is diagnostic of incomplete rotation and broad peritoneal bands extending across and fixing the involved small intestine without an accompanying volvulus. These Z-band findings can be distinguished from the corkscrew appearance of midgut volvulus.

Radiographic examination of an infant with heterotaxia is particularly challenging because of the ambiguous location of the stomach, liver, and spleen. In our experience,[20] most patients have a fixation abnormality of the duodenum and jejunum that is recognized by contrast radiography regardless of whether the stomach is right or left sided (Fig. 86-22).

Thickening of the mucous membrane of the small intestine, often seen in malabsorption syndromes, is an additional sign of chronic obstruction and volvulus.[19] With a right mesocolic hernia, the relation of the ascending and transverse colon may be abnormal, and contrast studies may show entrapment of the small intestine.

# Treatment

## PREOPERATIVE MANAGEMENT

Infants with suspected midgut volvulus and vomiting may be dehydrated and show signs of hypovolemia and hypochloremia. They require rapid intravenous resuscitation with a physiologic salt solution. Prolonged resuscitation efforts are not warranted, however, because expeditious laparotomy is essential to preserve intestinal viability. Additional measures including placement of a nasogastric tube, satisfactory intravenous access, and administration of parenteral antibiotics should be accomplished as quickly as possible.

## OPERATIVE TECHNIQUE

The Ladd procedure corrects the fundamental abnormalities associated with malrotation with or without midgut volvulus. This procedure consists of the following important steps, which must be carried out in the proper sequence: (1) evisceration of the bowel and inspection of the mesenteric

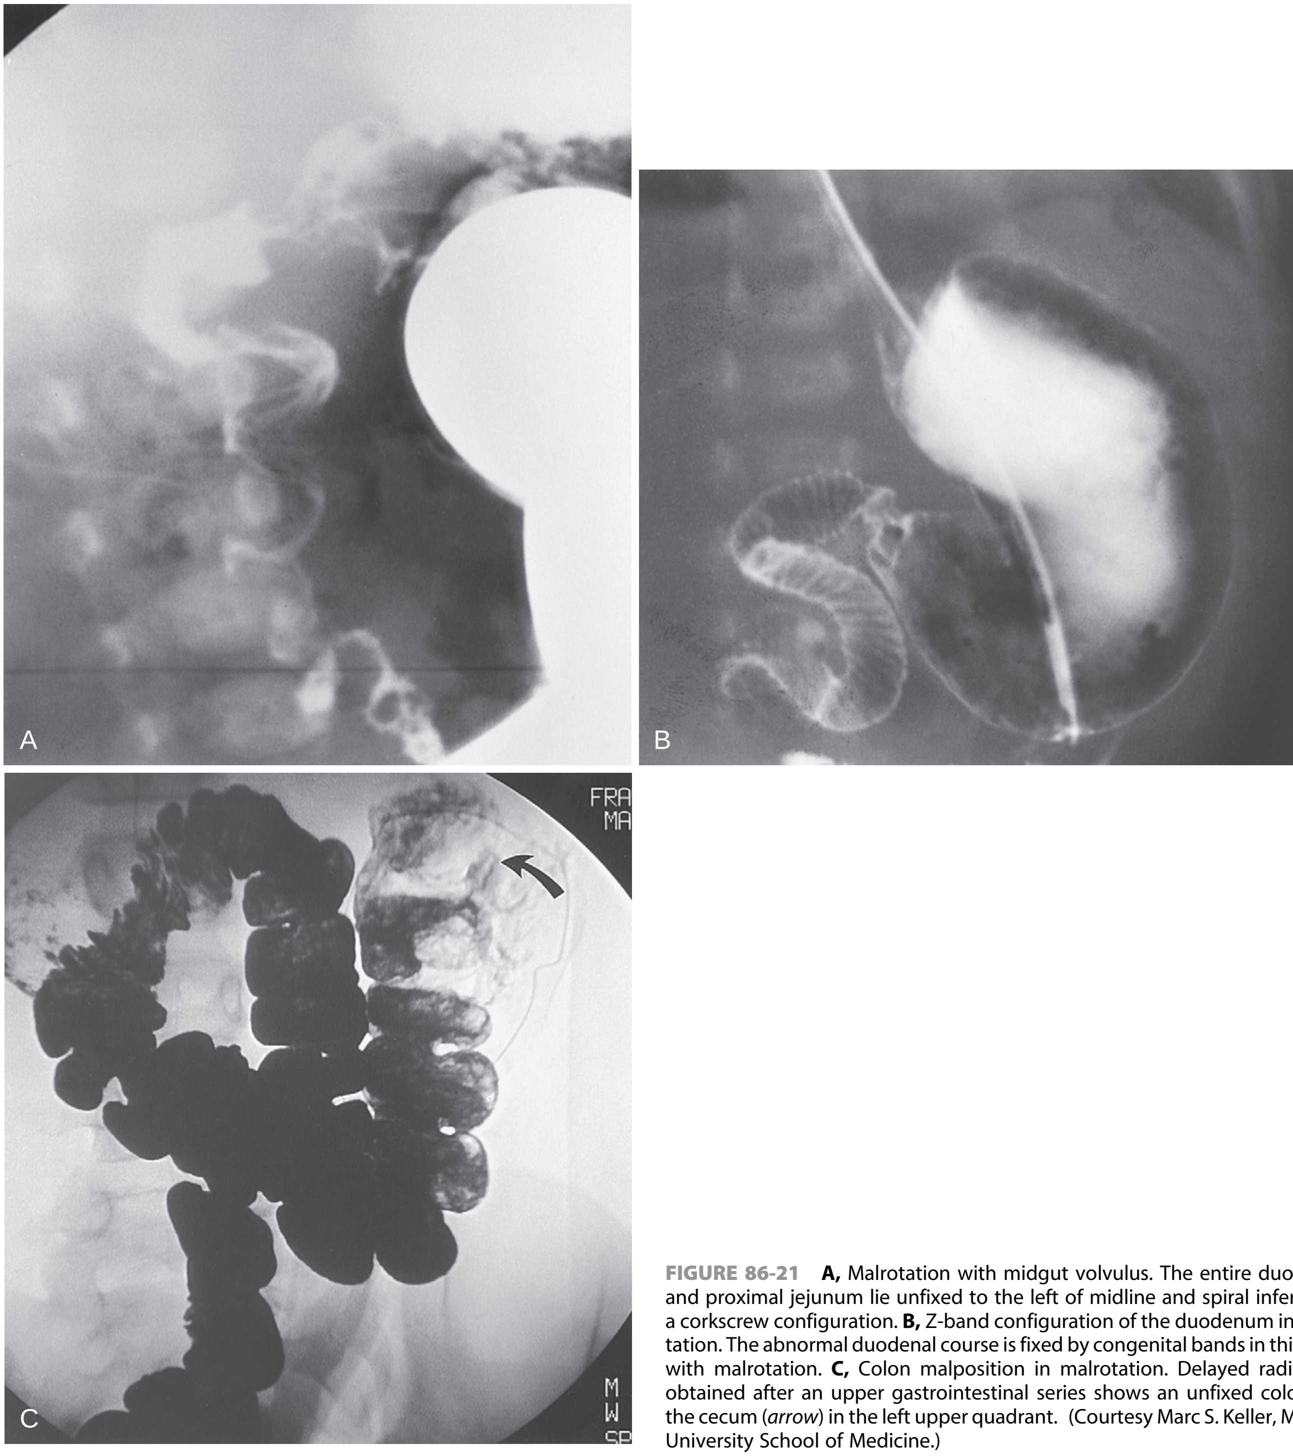

**FIGURE 86-21** **A,** Malrotation with midgut volvulus. The entire duodenum and proximal jejunum lie unfixed to the left of midline and spiral inferiorly in a corkscrew configuration. **B,** Z-band configuration of the duodenum in malrotation. The abnormal duodenal course is fixed by congenital bands in this infant with malrotation. **C,** Colon malposition in malrotation. Delayed radiograph obtained after an upper gastrointestinal series shows an unfixed colon with the cecum (*arrow*) in the left upper quadrant. (Courtesy Marc S. Keller, MD, Yale University School of Medicine.)

root; (2) counterclockwise derotation of the midgut volvulus; (3) lysis of Ladd peritoneal bands, with straightening of the duodenum along the right abdominal gutter; (4) appendectomy; and (5) placement of the cecum in the left lower quadrant.

### Recognition of Abnormalities of Rotation and Fixation

The peritoneal cavity should be entered through a supraumbilical right transverse incision extending from the midline laterally. The incision must be long enough to permit adequate inspection of the entire midgut. The entire bowel should be removed from the abdomen so that its orientation and fixation can be examined completely.

The two most constant anatomic points in the abdomen are the pylorus and the splenic flexure; their positions are not altered in patients with malrotation. A seemingly normal position of the cecum in the right middle or lower abdomen and a partial leftward course of the duodenum neither prove normal rotation nor rule out malrotation.

Several signs suggest a rotational anomaly: (1) abnormal peritoneal bands extending from the ileum or right colon

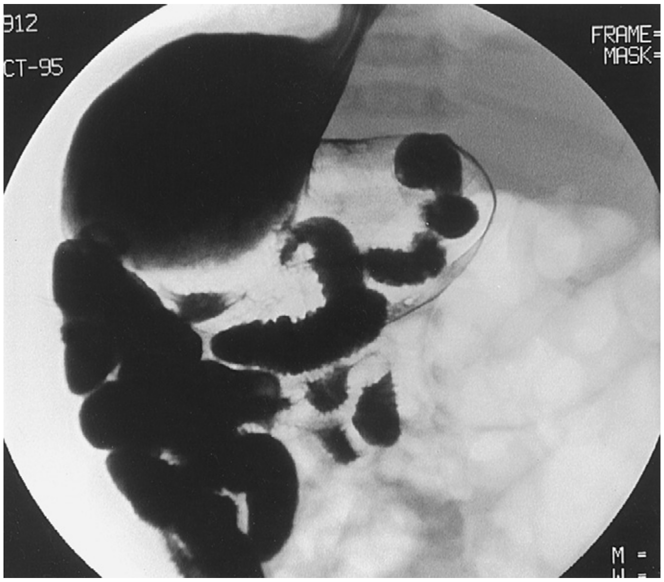

**FIGURE 86-22** Malrotation with heterotaxy. Note the horizontal liver margin and the right upper quadrant stomach in this neonate with congenital heart disease. The duodenum descends left of midline and courses transversely to the right but does not ascend to a point of duodenojejunal junction fixation. (Courtesy Marc S. Keller, MD, Yale University School of Medicine.)

to the parietal peritoneum over or to the duodenum; (2) fixation of the duodenum or upper jejunum to the cecum or right colon; (3) visualization of the entire duodenum, particularly the third and fourth portions at the base of the transverse colon mesentery; and (4) abnormal position and mobility of the cecum or of the duodenum along the right gutter.

It is helpful to locate the ileocecal region and orient the ileal mesentery so that it lies flat on the surgeon's palm. If normal, the cecum lies to the right of the ileum. In many cases, the location of the mesentery is uncertain, but a narrow mesenteric attachment is usually apparent. Sometimes, only after the cecum and right colon separate at the duodenocolic isthmus, a malrotation is clearly evident.

### Reduction of Volvulus

With midgut volvulus, the colon is not evident as the abdomen is opened because it lies posteriorly. In addition, the small bowel may appear congested and blue, with dilated mesenteric veins (Fig. 86-23, *A*).

The entire mass of small and large intestine should be delivered from the peritoneal cavity, avoiding traction on the mesentery. With this maneuver, the twist at the base of the mesentery may be visualized (Fig. 86-23, *B*). The bowel should then be cradled between the surgeon's hands and the volvulus derotated in a counterclockwise fashion (Fig. 86-23, *C*). The author prefers to reduce the bowel in steps of 180-degree turns until the transverse colon and cecum are brought into view anterior to the mesenteric pedicle (Fig. 86-23, *D*). Improvement in the color of the intestine usually accompanies the reduction unless the bowel is already severely compromised or necrotic. Generally, two to three full rotations of the bowel are required to completely reduce the volvulus.

### Relief of Duodenal Obstruction and Division of Ladd Bands

After reduction of the volvulus, any duodenal bands causing obstruction should be identified; division is then begun at either the pyloric or the duodenojejunal end (see Fig. 86-23, *D*). The bands usually attach the duodenum to the cecum or the right colon near the superior mesenteric vessels, the so-called *duodenocolic isthmus*. Dissection is carried out close to the serosa of the duodenum (with careful attention to the superior mesenteric vessels) and to the hepatoduodenal ligament superiorly and medially. Obstructing bands may also involve the ileum or progress down onto the jejunum. Houston and Wittenborg[45] pointed out that these bands may also extend superiorly to the gallbladder and the liver. Sharp dissection is used in most cases. Fairly vascular attachments can be anticipated in older children with chronic duodenal obstruction.

In all cases, it is imperative to prove that no associated intrinsic obstruction exists. This can be tested by passing a nasogastric tube of adequate size or, alternatively, a catheter through a gastrotomy, through the duodenum, into the jejunum (Fig. 86-23, *E*). Demonstrating that air passes through the duodenum is not sufficient to rule out a duodenal diaphragm or "windsock" web, a condition that may be totally unsuspected in a neonate.

Once Ladd bands have been dissected, the duodenum should have a relatively straight downward course along the right abdominal gutter (see Fig. 86-23, *E*). Failure to lyse all the bands may cause recurring duodenal obstruction or midgut volvulus. Any temptation to "stabilize" the mesentery by fixation of the duodenum or colon should be resisted, because this procedure may actually increase the risk for recurrent obstruction from adhesions or internal hernia.[14,22,27,51]

The Ladd procedure is completed by performing an appendectomy. Some authors[28] have advised an inversion-ligation appendectomy to avoid the unlikely possibility of fecal contamination in an otherwise clean case. The cecum is then placed into the left lower quadrant to maximally widen the mesentery.

## LAPAROSCOPIC VERSUS OPEN REDUCTION

Minimally invasive techniques have been used to both diagnose and correct malrotation.[52–54] However, because laparoscopy is believed to cause fewer postoperative adhesions, theoretically, an increased risk of future volvulus may exist. The largest series to date is a single-institution, retrospective comparison of open and laparoscopic techniques used to correct malrotation.[55] The 29 patients who underwent a laparoscopic Ladd procedure had a shorter hospital stay and an earlier return to full enteral feeds. This cohort had no episodes of postoperative volvulus at a mean follow-up period of approximately 2 years. However, the authors readily acknowledge that the nature of the study and the relatively short follow-up period does not allow for definitive recommendations to be made. Therefore although laparoscopy may have benefits, until prospective trials are published comparing the open and minimally invasive approaches, no clear statement can be made regarding optimal operative management. At the authors' institution, they find laparoscopy helpful in diagnosing malrotation when imaging studies are equivocal; the Ladd procedure is typically performed via laparotomy.

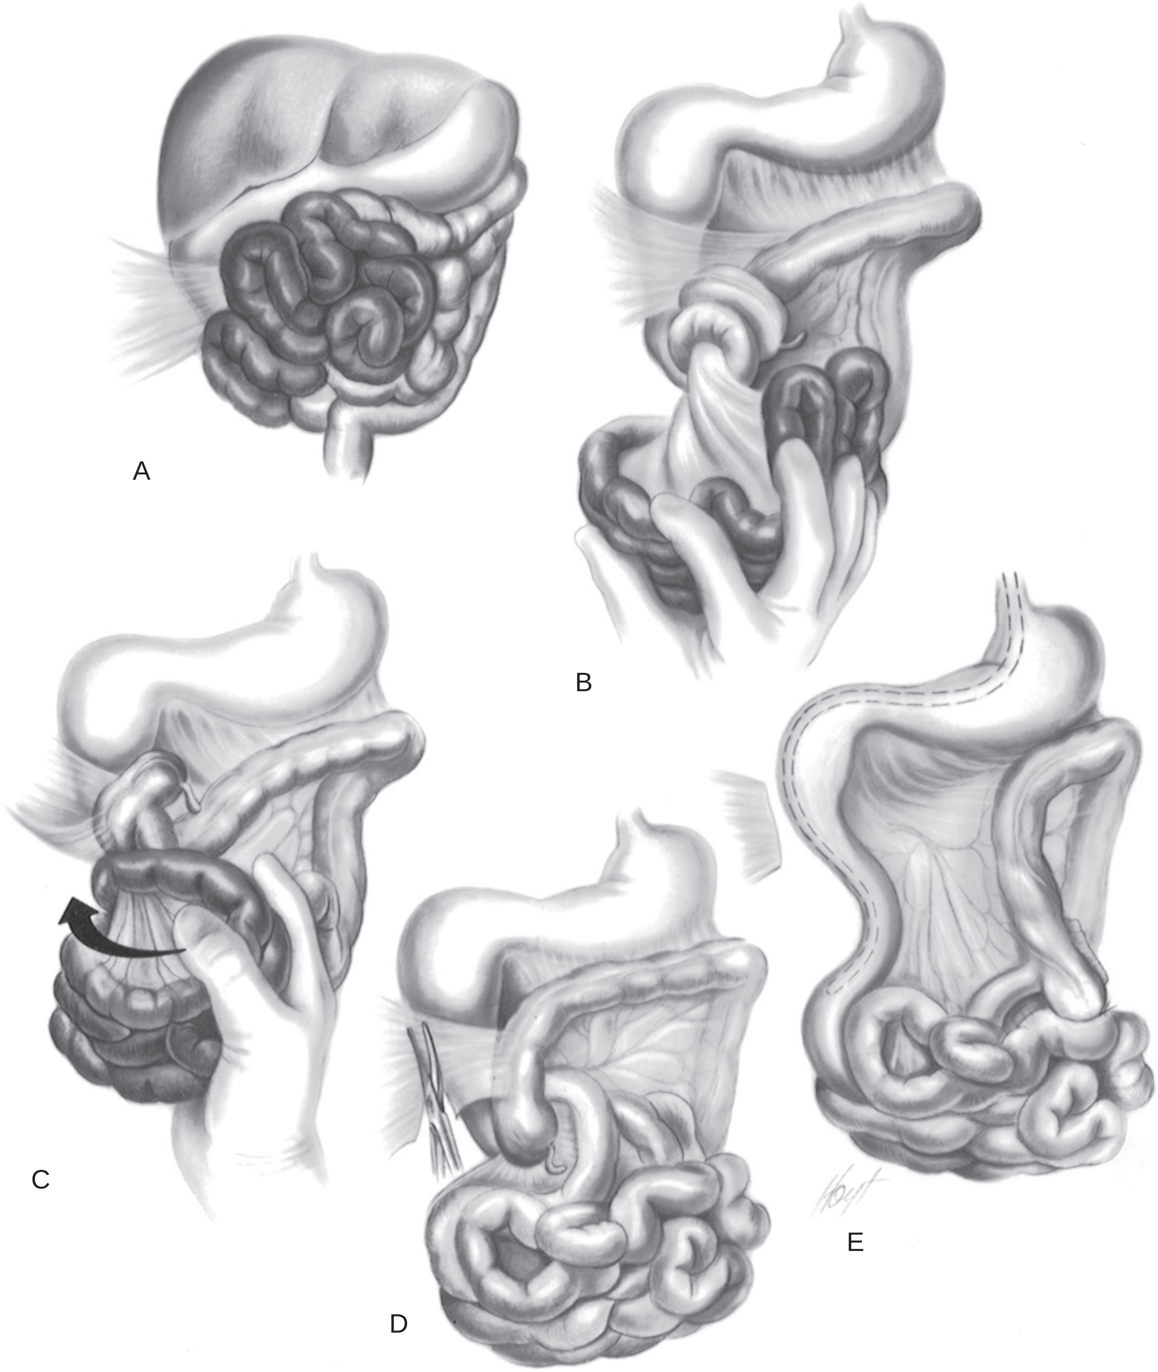

FIGURE 86-23 Malrotation of the intestine. **A,** Appearance of viscera as the abdominal cavity is opened. The small intestine is seen at once and seems to hide the colon. Vascular compromise of the intestine may be obvious. **B,** The entire intestinal mass is delivered out of the wound and drawn downward, showing the base of the mesentery. Coils of intestine or ascending colon are wrapped around the root of an incompletely anchored mesentery. The volvulus has taken place in a clockwise direction. The descending duodenum is dilated because of extrinsic pressure from Ladd bands or peritoneal folds that cross it. **C,** The volvulus is reduced by taking the entire intestinal mass in the hand and rotating it counterclockwise (in most cases). **D,** With reduction of the volvulus, the cecum lies in the right paravertebral gutter. The peritoneal folds from the cecum obstruct the duodenum. The folds are incised close to the lateral serosal border of the duodenum. The underlying superior mesenteric pedicle is identified and carefully preserved. **E,** Appearance of the intestines and ascending colon at the end of surgery. The duodenum descends along the right gutter. The small intestine lies on the right side of the abdomen, and the cecum and ascending colon are in the midline or on the left side of the abdomen. The superior mesenteric artery and its branches are left exposed, as shown. A nasogastric tube has been passed into the jejunum to rule out intrinsic obstruction. (Modified from Ladd WE, Gross RE: Abdominal Surgery of Infancy and Childhood. Philadelphia, WB Saunders, 1941.)

### INTESTINAL RESECTION AND SECOND-LOOK PROCEDURES

When the intestine appears viable, simple enterolysis and a Ladd procedure suffice. A localized gangrenous segment may be resected and a primary anastomosis performed if there is ample remaining bowel that is viable. The incidence of ischemic injury requiring resection varies with the duration of symptoms. Thirty percent of Torres and Ziegler's patients had intestinal necrosis,[28] but only 3 of 40 patients (7.5%) required resection in Seashore and Touloukian's series.[26]

Second-look laparotomy is usually performed when there are multiple areas of bowel of questionable viability, when the entire midgut appears nonviable, or when clinical signs and symptoms suggest progressive loss of intestine. At 12 to 24 hours, recovery of questionable bowel or demarcation of the areas of frankly necrotic bowel requiring resection is usually obvious.

Although the management of patients with frankly necrotic or marginally viable intestine must be individualized, three principles should be considered: (1) preserving the minimum length of intestine required for survival has the highest priority; the surgeon should err on the side of preserving intestine, particularly the terminal ileum and ileocecal valve, for a second-look procedure; (2) anastomoses between ends of intestine of questionable viability should be avoided; and (3) resection of the entire midgut will necessitate lifelong parenteral nutrition or small intestinal transplantation.

### ATYPICAL MALROTATION OR MALROTATION VARIANT

The diagnosis of malrotation variant is increasingly made by radiologists on upper GI contrast studies.[56] Patients with this finding are frequently referred to pediatric surgeons for evaluation and possible surgical treatment. These patients present a dilemma for surgeons because the risks of operation versus nonoperative treatment are not clear in this subgroup of patients, many of whom were diagnosed during a workup for presumed gastroesophageal reflux. The authors and their colleagues reviewed their experience with the surgical treatment of malrotation variant over a 5-year period,[39] during which 201 patients underwent operation for malrotation (excluding infants with diaphragmatic hernia and abdominal wall defects). Typical malrotation was present in 75 patients, and malrotation variant in 101. Volvulus and internal hernia were more common in typical malrotation (16% vs. 2% and 21% vs. 7%, respectively). Persistent symptoms and complications such as postoperative obstruction were more common in the malrotation variant group (21% vs. 12% and 12% vs. 0%, respectively). The only patients who presented with ischemic volvulus were those with typical malrotation. These data reaffirm the importance of operative correction of typical malrotation. However, because patients with malrotation variant were less likely to have volvulus or internal hernias, and because of the higher rate of postoperative complications in those patients, the authors questioned the need for operative correction in asymptomatic atypical malrotation patients or those with only gastroesophageal reflux symptoms.

### COLONIC OBSTRUCTION SECONDARY TO REVERSED ROTATION

In the past, division of the colon with anastomosis anterior to the duodenum was recommended for treating colonic obstruction secondary to reversed rotation. It is now recognized that this form of obstruction can be relieved by freeing the duodenum and the underlying mesenteric vessels anteriorly and laterally off the transverse colon.[36]

### MESOCOLIC HERNIA

Right mesocolic hernia is best treated by incising the lateral peritoneal reflection of the right colon and rotating the colon to the left, thereby freeing the small intestine.[42] Treatment of left mesocolic hernia is more technically challenging. The small intestine can sometimes be reduced through the neck of the sac. The key to repair and reduction is mobilization of the inferior mesenteric vein; this vein, which runs along the anterior margin of the neck of the sac, should be spared (see Fig. 86-14, *B* and *C*). The bowel can be reduced if an incision is made to the right of the vein. The peritoneum adjacent to the vein is sutured to the posterior peritoneum to close the neck of the sac.

### CECAL VOLVULUS

Reduction of cecal volvulus is followed by fixation or cecostomy when the bowel is viable. Resection is advised if the bowel is compromised.

## Postoperative Management and Complications

Return of intestinal function depends on the duration of obstruction and the extent of bowel compromise. In an uncomplicated extrinsic obstruction caused by duodenal bands, peristalsis returns in 1 to 5 days, at which point feedings may be initiated.[22] In patients without evidence of volvulus or obstruction, the authors no longer routinely decompress the stomach with a nasogastric tube. Older patients with chronic malrotation or those with evidence of chronic obstruction frequently have a prolonged ileus that requires nasogastric drainage and parenteral support.

Patients who have marginally viable bowel with mucosal injury and short-bowel syndrome pose special problems. Total parenteral nutrition is essential to sustain infants with massive loss of intestine until adaptation and compensatory growth of the residual bowel can occur.[57] Small amounts of enteral nutrition are recommended to encourage adaptation and provide nutrition for the intestinal mucosa. The need for gastrostomy tube insertion to assist in nutrition must be assessed individually; a gastrostomy tube does facilitate "drip" feeds.

Coombs and colleagues[25] described a group of children with malrotation who were older than 1 year and had recurrent and often long-standing symptoms suggestive of intestinal dysmotility. Such children did not seem to benefit from a Ladd procedure. These findings of pseudo-obstruction may be incidental or may be related to a neurogenic bowel injury from long-standing partial obstruction.

Complications encountered (aside from those related to malnutrition, diarrhea, and dehydration in short-bowel syndrome) are similar to those associated with any type of abdominal operation. Postoperative intussusception was noted in 3.1% of all patients who underwent a Ladd procedure, compared with 0.05% of other laparotomies.[58] The typical presentation was distention and bilious emesis between 5 and 8 days after the procedure. The incidence of postoperative adhesive bowel obstruction was 4%.

The incidence of recurrent volvulus is low. In the Boston series of 441 patients, only 2 had recurrent obstruction; in the Los Angeles series, no patients had recurrence.[27] Only 2 of our 159 patients who underwent a Ladd procedure had recurrent midgut volvulus.[39]

Death is associated primarily with peritonitis from extensive intestinal necrosis in midgut volvulus, late nutritional complications, or catheter sepsis, particularly in infants younger than 1 year. The mortality rate is at least 65% when more than 75% of the bowel is necrotic.[39]

CHAPTER 87

# Other Causes of Intestinal Obstruction

Wolfgang Stehr and Cynthia A. Gingalewski

Intestinal obstruction can occur at any age from newborn infants to adults. The etiology of the obstruction varies greatly, depending on the age and past surgical history of the patient. Common congenital causes including atresia, stenosis, malrotation, Hirschsprung disease, imperforate anus, and meconium diseases of the newborn are discussed in detail in other chapters of this text. In this chapter, other common and uncommon causes of intestinal obstruction are reviewed.

## Embryology

With a few exceptions, the etiology of bowel obstruction in infants younger than 1 year is embryologic in origin. These entities are discussed in detail in other chapters. Where relevant, the embryologic basis of obstruction is discussed in this chapter.

## Spectrum of Disorders

Small bowel obstruction in infants and children is more common than large bowel obstruction. By far the most common of these is adhesive small bowel obstruction, which accounts for up to 60% of small bowel obstructions. Adhesions are followed by tumors (20%), hernias (10%), inflammatory bowel disease (5%), volvulus (3%), and various intramural and extramural causes of intestinal obstruction.[1]

## Postoperative Adhesions

Differentiating a prolonged postoperative ileus from an early postoperative bowel obstruction can be difficult. Radiographic demonstration of dilated bowel loops may not distinguish between the two entities. Adhesive small bowel obstruction most commonly develops after pelvic surgery including appendectomy, gynecologic procedures, and colorectal surgery. The obstruction is thought to be secondary to adhesive band formation in the pelvis, where the bowel is more mobile and likely to twist and obstruct around the adhesions.

The incidence of postoperative small bowel obstruction in children ranges from 2% to 30% and is greater in neonates. Festen[2] documented a 2.2% incidence of adhesive small bowel obstruction in 1476 abdominal operations. Eighty percent of obstructions occurred within 3 months of the initial operation, and 70% were secondary to a single adhesive band. The incidence was 57% greater in neonates than in infants and children and was more common after procedures for gastroschisis and atresias. Eighteen percent of children born with an abdominal wall defect developed a small bowel obstruction in a recent 30-year review.[3]

In children the most common inciting operation was appendectomy, and there was no difference in occurrence after perforated, nonperforated, or negative appendectomies. A 2007 review out of Kansas City comparing laparoscopic with open appendectomies showed an advantage of laparoscopic over open appendectomy, when comparing postoperative bowel obstruction from adhesions.[4]

A review of 1581 patients from the Scottish National Health Service Medical Record Linkage database showed that patients undergoing surgery on the ileum had the highest risk of readmission because of adhesions in the subsequent 5 years after surgery (9.2%). Formation/closure of ileostomy had the greatest risk (25%). In addition, 6.5% of children were readmitted after general laparotomy, 4.7% after duodenal surgery, and 2.1% after colonic surgery.[5]

### DIAGNOSIS

The key to the diagnosis of adhesive bowel obstruction is abdominal distention and emesis in a patient with previous abdominal surgery. In the early stages of intestinal obstruction, it may be difficult to discern obstruction from infectious gastroenteritis. Initially, the emesis may be nonbilious, but with time it progresses to bilious or "feculent" emesis. The child complains of crampy abdominal pain and has anorexia. With

a partial obstruction there continues to be passage of flatus or small stools. In children with complete obstruction, both cease. As the obstruction progresses, the child becomes increasingly lethargic. The presence of a fever or pain should make one suspect bowel compromise.

Physical findings may not be initially obvious, but abdominal distention with either high-pitched or hypoactive bowel sounds evolves over time. Eventual progression of the obstruction leads to continuous, localized pain that is not relieved by nasogastric decompression. This ominous sign is the only reliable predictor of ischemic intestine. In a series of 131 obstructions reported by Janik and colleagues,[6] persistent pain after nasogastric decompression was a 100% predictor of intestinal gangrene.

Radiographs can help to differentiate obstruction from infectious causes. All children should have at least two view radiographs of the abdomen (Fig. 87-1). Obstruction is manifested by dilated bowel loops with air-fluid levels. The presence of air in the colon and rectum may signify an early or partial bowel obstruction. Free intraperitoneal air is indicative of bowel perforation and requires urgent operative treatment. The diagnosis of intestinal obstruction can be confirmed with computed tomography (CT) or a contrast-enhanced upper gastrointestinal series with small bowel follow-through (UGISBFT) (Fig. 87-2). The advantage of a CT scan is that it can rule out other diagnoses and identify an abnormal vascular course or a transition zone of the obstruction.[7]

## TREATMENT

There continues to be debate whether immediate operation is warranted in all cases of small bowel obstruction as opposed to nonoperative management with nasogastric decompression. All children with suspected obstruction should receive aggressive intravenous fluid and electrolyte replacement and placement of a nasogastric tube to decompress the stomach. A complete blood count should be obtained because the presence of leukocytosis with a left shift in the differential count should raise suspicion of compromised intestine. The decision to proceed to the operating room should be based on the child's physical condition. If there is complete obstruction with fever, pain, and no passage of flatus or stool, the child needs immediate exploration.

Observation is warranted, however, if there is a partial bowel obstruction in the absence of fever, leukocytosis, and localized abdominal pain. Observation should include frequent abdominal examinations, serial abdominal radiographs, and frequent measurement of serum electrolytes. Nonoperative treatment was successful in 74% of patients in a retrospective review of 230 adhesive obstructions.[8] However, patients treated this way had a 36% incidence of recurrent episodes of obstruction as compared with a 5% to 19% incidence in those treated by lysis of adhesions.

Laparoscopic lysis of adhesions can be performed in instances of obstruction despite the presence of dilated intestinal loops. The more proximal the obstruction, the easier it is to accomplish adhesiolysis with laparoscopic techniques. The reported rate of bowel injury during open laparotomy for adhesive obstruction is 11%,[6] and there was a 32% conversion rate from laparoscopic to open technique because of an inability to find the transition point, inability to achieve pneumoperitoneum, dense adhesions, and gangrenous intestine.[9] Morbidity was higher in the open group and included pneumonia, prolonged ileus, and wound infection. A conversion rate of greater than 50% was found in another retrospective study in adults.[10] A higher incidence of complications was observed in the laparoscopically treated group including bowel injury and anastomotic leak. No such studies have been performed in children.

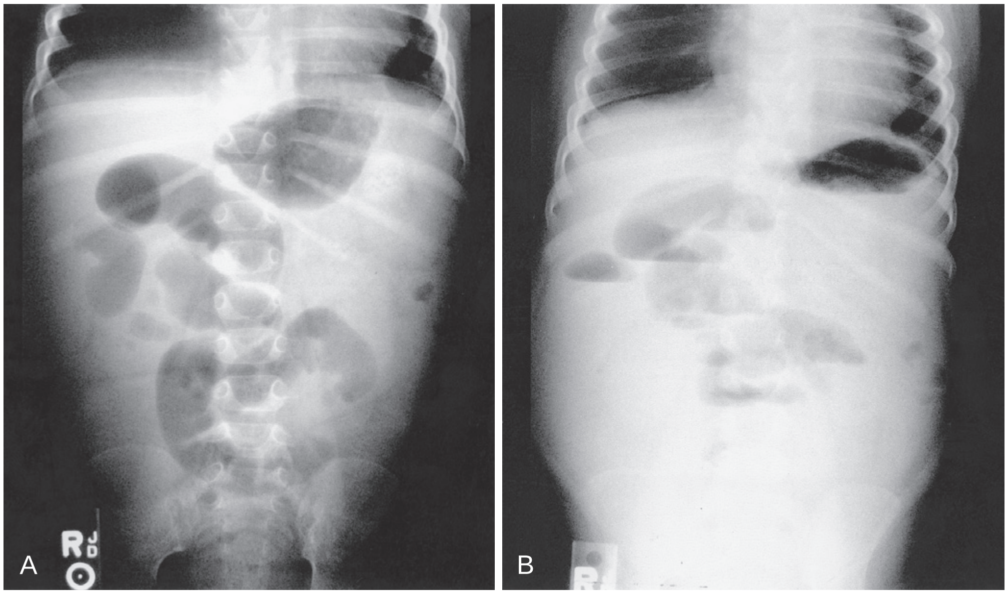

FIGURE 87-1 Complete intestinal obstruction. **A**, Supine plain abdominal radiograph demonstrating dilated small bowel loops and absence of air in the colon in a child who had previously undergone a Ladd procedure for malrotation. **B**, Upright abdominal radiograph from the same patient illustrating air-fluid levels in the dilated small bowel loops and absence of gas in the large intestine.

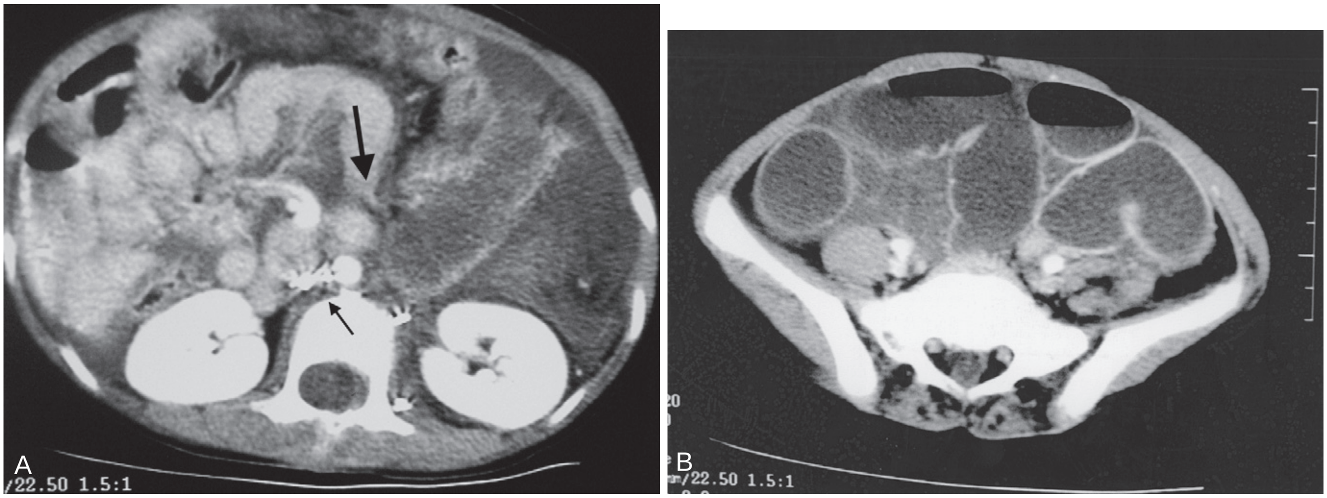

**FIGURE 87-2** Incomplete small bowel obstruction. **A**, Contrast computed tomography (CT) scan of child with a partial small bowel obstruction after resection of a ganglioneuroma. The *small arrowhead* points to surgical clips from the previous resection. The *large arrowhead* demonstrates the transition zone of the obstruction. Note the dilution effect of the contrast in the dilated bowel. Partial obstruction is noted with passage of contrast past the transition point. **B**, Contrast CT scan from the same patient demonstrating proximal dilated fluid-filled bowel loops in the pelvis with air-fluid levels present.

### PREVENTION

A multitude of reports have described the prevention of intra-abdominal adhesions; however, a "magic bullet" to prevent adhesion formation has yet to be found. General principles of gentle bowel handling, careful hemostasis, irrigation of the abdominal cavity, and prevention of prolonged bowel exposure to air have not eliminated the occurrence of adhesions. Commercially available adhesion barriers such as Seprafilm, a hyaluronic acid and carboxymethylcellulose membrane, have been widely used and publicized. Several clinical trials using Seprafilm have demonstrated a decreased incidence of postoperative adhesions in adults[11–13] and a decreased incidence and severity of postsurgical adhesions with Seprafilm in pediatric patients.[14]

However, one should avoid wrapping Seprafilm around an anastomosis because it may lead to an increased risk for anastomotic leaks. The only other substance that has shown a consistent reduction in adhesions in clinical trials has been Interceed.[15]

## Postoperative Ileus

In the majority of patients, postoperative ileus resolves within 5 to 7 days. Passage of flatus signifies the return of colonic function and usually indicates that the ileus has resolved. The duration of postoperative ileus is prolonged by use of narcotics in a dose-dependent manner. Anesthetic agents, excessive trauma to the bowel, intra-abdominal bleeding, and preoperative gastric obstruction also prolong the return of normal bowel function.

Opiates have an inhibitory effect on gastric motility, increase tone in the antrum and the first portion of the duodenum, and have a biphasic effect on the small intestine.[16] Morphine is initially stimulatory to phase II of the migrating motor complex (MMC), but this stimulation is followed by atony and slowing of gastrointestinal transit time.[17] Treatment with morphine antagonists such as naloxone have not proved beneficial in shortening the duration of postoperative ileus.[17,18]

Anesthetic agents exert their greatest antimotility effect on the large intestine because of the lack of intercellular gap junctions.[18] The anesthetic agents halothane and enflurane also cause decreased gastric emptying. Thoracic epidural anesthesia with local anesthetics increases splanchnic blood flow, impedes afferent and efferent inhibitory reflexes, and when administered in the thoracic region, has demonstrated a significant reduction in the duration of postoperative ileus.[19,20] Interestingly, lumbar epidural administration failed to have a similar effect on postoperative ileus.[21,22]

Laparoscopic surgery, early enteral feeding, and various pharmacologic agents have been used in an attempt to shorten postoperative ileus; early feeding has not shortened the duration of postoperative ileus.[23] On the other hand, both animal and human studies have demonstrated a reduction in ileus duration when the surgical procedure was performed laparoscopically.[24,25] Of the numerous pharmacologic agents tested, the only benefit in humans was achieved with cisapride (now unavailable except for compassionate use). The somatostatin analogue octreotide, known to inhibit several gastrointestinal hormones, shortened the duration of postoperative ileus in dogs.[26–28] Nonsteroidal antiinflammatory drugs (NSAIDs) help lessen the duration of ileus by reducing the dose of narcotic analgesia required. Metoclopramide hydrochloride (Reglan), a prokinetic agent that is a cholinergic agonist and a dopamine antagonist, stimulates phase II of the MMC. Repeated studies, however, have failed to demonstrate any benefit from postoperative administration. Erythromycin, a motilin receptor agonist, also failed to shorten the duration of postoperative ileus in prospective, randomized trials.[29] Recent attempts to postoperatively stimulate the cephalic-vagal axis through sham-feedings (chewing of gum) have been associated with improved outcomes but require further investigation.[30]

## Postoperative Intussusception

Children are more prone to the development of postoperative intussusception, especially after operative procedures for retroperitoneal tumors, Hirschsprung disease, and other neurocristopathies. The sudden occurrence of bilious emesis after a normal postoperative return of bowel function should make one suspect small bowel intussusception. The diagnosis can be made by a contrast-enhanced upper gastrointestinal series or an abdominal ultrasound. Because the majority of postoperative intussusceptions occur in the small bowel, they require surgical exploration for correction.

## Inflammatory Adhesions

Episodes of intra-abdominal inflammation including, but not limited to, ovarian torsion, ventriculoperitoneal shunt infection, Crohn disease, acquired immunodeficiency syndrome, and pelvic inflammatory disease can lead to adhesion formation and subsequent intestinal obstruction in the absence of previous surgical procedures.

## Hernias

Although hernias account for only 10% of small bowel obstructions, they are more likely to be associated with strangulation of the bowel. Such hernias include inguinal, ventral, and internal hernias. Internal hernias, caused by internal bands or defects in the mesentery after bowel resection, are likely to cause a "closed-loop" bowel obstruction. This condition can rapidly progress to bowel ischemia and is characterized by pain often out of proportion to an unimpressive abdominal examination.

Congenital hernias include paraduodenal hernias, inguinal hernias, internal hernias secondary to omphalomesenteric duct remnants, congenital bands of nonembryonic origin, and nonfixation of the falciform ligament. Postsurgical causes of hernia include incomplete closure of the mesentery and parastomal hernias.

### PARADUODENAL HERNIAS

Paraduodenal (mesocolic) hernias are rare congenital lesions that result from abnormal rotation of the gut. The name "paraduodenal" is a misnomer but implies herniation of the small intestine posterior to the mesocolon. A right mesocolic hernia occurs when the prearterial limb of the midgut fails to properly rotate around the superior mesenteric artery. The majority of the small bowel then remains to the right of this artery (Fig. 87-3, *A*). The etiology of a left mesocolic hernia is less clear. The rotation of the intestine is normal, and the intestine is introduced into an avascular area between the ligament of Treitz and the transverse colon, below the inferior mesenteric vein (Fig. 87-3, *B*). Fusion of the mesocolon and the mesentery of the duodenum is incomplete, thus resulting in a defect.[31] It may lead to incarceration of the jejunum and varying lengths of ileum in the left upper quadrant. Despite their congenital origin, mesocolic hernias are most frequently diagnosed in adults. Left mesocolic hernias are three times more common than those on the right. They are the most frequent cause of internal hernias and account for 50% of cases.

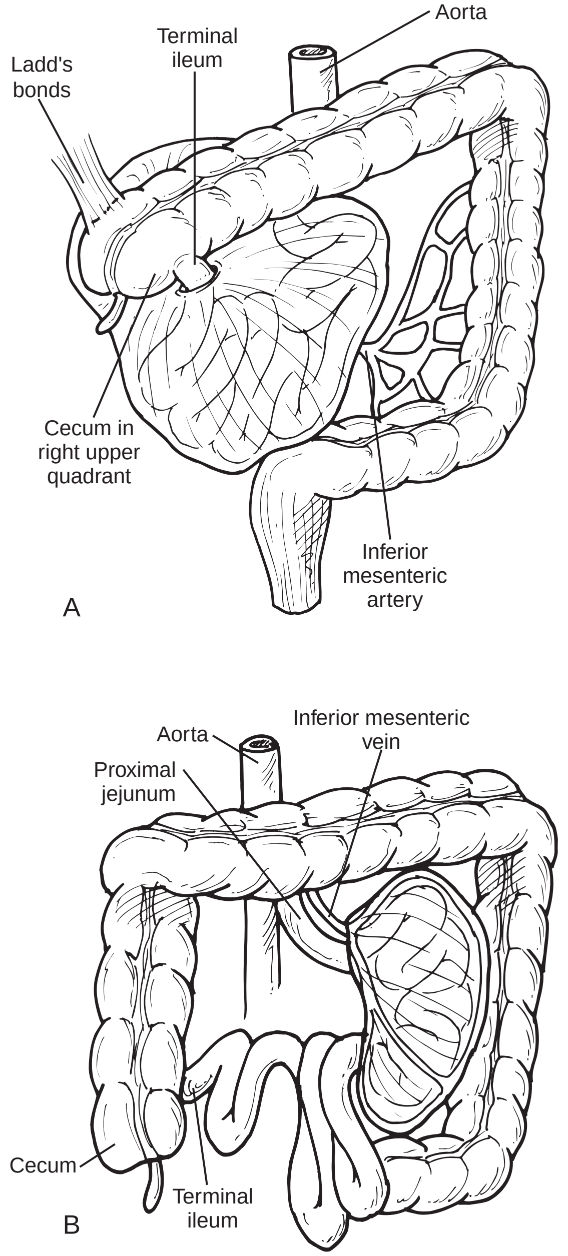

**FIGURE 87-3** Paraduodenal (mesocolic) hernias. **A**, Right paraduodenal hernia. Note the abnormal bowel rotation with the cecum in the right upper quadrant and the presence of Ladd bands. The majority of the small bowel is trapped behind the right mesocolon. **B**, Left paraduodenal hernia. The bowel rotation is normal in a left paraduodenal hernia. The small bowel becomes trapped behind the left mesocolon, posterior to the inferior mesenteric vein. (Modified from Willwerth BM, Zollinger RM Jr, Izant RJ Jr, et al: Congenital mesocolic (paraduodenal) hernia. Embryologic basis of repair. Am J Surg 1974;128:358-361.)

A high index of suspicion is necessary to make the diagnosis of a paraduodenal hernia. These internal hernias cause vague symptoms including recurrent bouts of abdominal pain, vomiting, abdominal distention, and melena.[32] Imaging techniques including an upper gastrointestinal series or CT scan are the only means of accurate preoperative diagnosis.

Surgical treatment of both right and left paraduodenal hernia consists of opening the sac, reduction of the small intestine, and repair of the defect. Sac removal should not be attempted. Laparoscopic repair of a paraduodenal hernia has also been reported.[33]

## OMPHALOMESENTERIC DUCT REMNANTS

The omphalomesenteric (vitelline) duct is a normal component of fetal development. It connects the fetal intestine to the yolk sac. When these structures persist in a newborn, they are called omphalomesenteric duct remnants. They vary in appearance from a fistula to the umbilicus, a fibrous band between the ileum and umbilicus, and a Meckel diverticulum. Though one of the most common congenital anomalies (2% prevalence in the population), they are least likely (2%) to cause symptoms. In a review of 46 cases, 28% of symptomatic omphalomesenteric remnants were associated with intestinal obstruction (intussusception, internal hernia, volvulus).[34] Treatment is surgical, and there have been reported cases of laparoscopic excision.[35]

## CONGENITAL BANDS OF NONEMBRYONIC OR INFLAMMATORY ORIGIN

The presence of intestinal obstruction as a result of congenital bands has been described sparingly in the literature. The etiology of these bands is unknown, but they are not secondary to known embryologic remnants such as omphalomesenteric duct or vitelline vessel remnants. A review of eight patients with anomalous bands demonstrated them to occur between the ascending colon and the terminal ileum (50%), the ligament of Treitz and the terminal ileum (25%), the right lobe of the liver and the terminal ileum (12.5%), and the right lobe of the liver and the ascending colon (12.5%).[36]

Patients may have chronic abdominal pain or an acute bowel obstruction. A high index of suspicion is required to make the diagnosis. Division of the band is therapeutic.

## NONFIXATION OF THE FALCIFORM LIGAMENT

The falciform ligament normally consists of two closely applied layers of peritoneum and attaches the liver to the anterior abdominal wall. It has three borders: the diaphragm, the anterior abdominal wall to the level of the umbilicus, and the free inferior edge of the liver, in which runs the obliterated umbilical vein. Failure of the peritoneum to fuse around the umbilical vein would lead to this unusual "nonfixation" of the falciform ligament and allow the small bowel to herniate around it like a congenital band (Fig. 87-4). The defect appears to be of congenital origin inasmuch as internal hernias around the falciform ligament have been reported in newborn infants.[37–39]

Such hernias commonly contain small intestine, but they can contain omentum or large intestine.[40]

The diagnosis is usually made in the operating room during exploration for an acute small bowel obstruction in the absence of external hernias or previous surgery. A preoperative CT scan showing intestine above the liver that is centered on the falciform ligament can be suggestive (Fig. 87-5). The presence of ascites is an ominous sign indicative of compromised bowel. Release of the obstruction by dividing the falciform ligament is therapeutic.

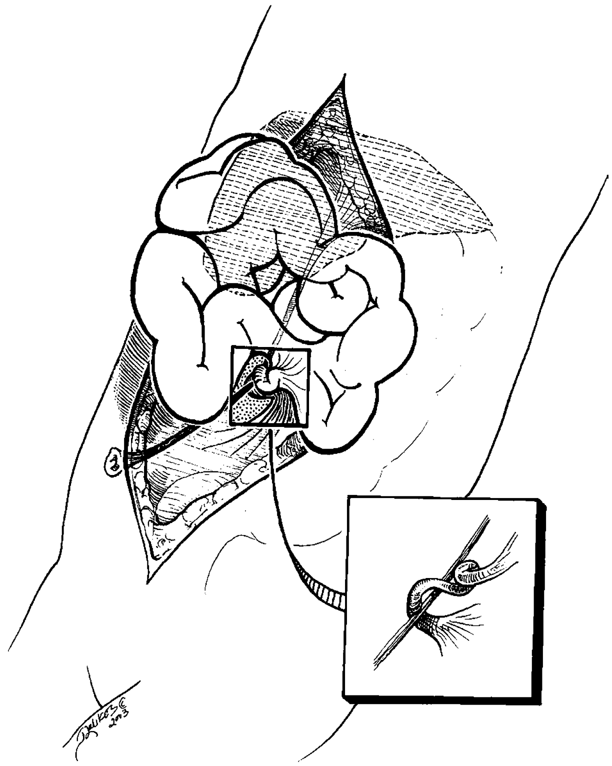

**FIGURE 87-4** Internal hernia secondary to nonperitonealization of the falciform ligament. The falciform ligament acts like a congenital band when it is not fixed to the anterior abdominal wall by the double layer of peritoneum. This allows the small bowel to herniate around the falciform ligament, thereby causing an internal hernia.

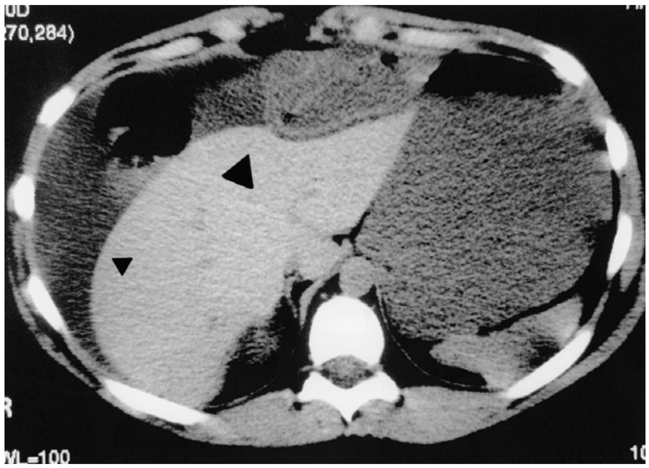

**FIGURE 87-5** Preoperative contrast-enhanced computed tomography scan of a patient with an internal hernia around the falciform ligament. The patient had feculent emesis and no past surgical history. The *large arrowhead* demonstrates small bowel loops around the falciform ligament, above the liver edge. The right colon is also noted to be above the liver in the right upper quadrant. The *small arrowhead* demonstrates the presence of ascites. The patient was found to have gangrenous small bowel loops present. The falciform ligament was divided, the gangrenous bowel resected, and primary anastomosis performed.

### MESENTERIC DEFECTS

During any surgical procedure involving bowel resection, great care must be taken to close all defects created in the mesentery. Closure can be performed with absorbable or nonabsorbable suture and in running or interrupted fashion. The advantage of interrupted suture is that unraveling of a single stitch is unlikely to make a large enough defect in the mesentery for an internal hernia to occur.

The risk for mesenteric hernias is particularly high in laparoscopic procedures with bowel anastomoses, specifically in gastric bypass procedures, because the closure of the mesenteric defect can be quite difficult in the laparoscopic setting, and a high index of suspicion and low threshold for reoperation should be applied in these patients.[41]

### PARASTOMAL HERNIAS

Parastomal hernias are a common problem after a colostomy. The incidence of parastomal hernia ranges from 2% to 35%. Most hernias appear within 2 years after creation of an ostomy and are more common in patients who are obese or malnourished. The use of steroids and postoperative wound infection also increase the risk. To minimize the risk for development of a parastomal hernia, the colon should be brought through the rectus muscle, the subcutaneous fat should be left in place, and the fascial defect created should not be excessive. Suture fixation of the bowel serosa to the stomal defect may reduce the risk for hernia in infants.

For repair, the colostomy should be taken down, if possible. In cases in which the colostomy is permanent, a small, asymptomatic parastomal hernia can be observed. Surgical repair should be offered when the hernia is large, interferes with appliance fitting, causes pain, or becomes incarcerated. Options include relocation, fascial closure, and mesh repair. The results of surgical repair in adults are dismal, with a recurrence rate of 33% to 50% after relocation, 50% to 100% after fascial repair, and 50% after mesh repair. A second recurrence of a parastomal hernia after initial attempts at repair is associated with even more dismal surgical outcomes approaching a 90% to 100% recurrence rate.

## Large Bowel Obstruction

### VOLVULUS

Though not an uncommon etiology of large bowel obstruction in adults, colonic volvulus is a rare entity in children. Several case reports, however, have described cecal, sigmoid, and transverse colon volvulus in children.[42–45] Associated medical problems include mental retardation, Hirschsprung disease, intestinal dysmotility, and chronic constipation. These children have an acute onset of abdominal pain and obstruction. Abdominal radiographs demonstrate dilated loops proximal to the obstruction, and barium enema is diagnostic by demonstrating the characteristic "bird's beak" appearance in the involved bowel segment.

Treatment options are sigmoidoscopy or colonoscopy, laparoscopy, or primary laparotomy with distorsion as the goal. Cecal volvulus should be managed by primary resection and anastomosis or cecopexy.[46] Volvulus of the transverse colon is the only bowel reported to twist in a counterclockwise direction. Resection plus end-to-end anastomosis is the treatment of choice for volvulus occurring in the transverse colon, splenic flexure, and sigmoid colon. In all cases, nonoperative reduction alone is not recommended because of the high risk of recurrence.

### CANCER

Only 1% of all colonic malignancies occur in patients younger than 30 years. Very few cases have been reported in children younger than 10 years. The mucinous adenocarcinoma, signet-ring variety, accounts for 48% of all tumors. In children, colon cancer is associated with rapid progression of disease and a poor prognosis. The overall 5-year survival rate is 2.5%.[4]

Treatment consists of surgical resection for cure or palliation. Unlike adult patients, chemotherapeutic regimens and radiotherapy provide little palliative or curative value.[47]

### COLONIC STRICTURE

Acquired colonic strictures can cause partial bowel obstruction, which may be high grade. Strictures may be the sequelae of necrotizing enterocolitis, inflammatory bowel disease, trauma, or cystic fibrosis (cystic fibrosis colonopathy). Treatment is similar for all and includes segmental resection and anastomosis.

## Miscellaneous Causes of Small and Large Intestinal Obstruction

### INTRAMURAL AND EXTRAMURAL LESIONS

Numerous causes of intramural and extramural lesions throughout the gastrointestinal tract can lead to intestinal obstruction. The obstruction can be a consequence of the lesion itself, secondary to intussusception with the lesion as a lead point, or due to volvulus around the lesion.

Various cancerous lesions occur both intramurally and extramurally including lymphoma (in particular Burkitt) and leiomyosarcoma. Any child older than 3 years with intussusception should have these diagnoses entertained as the culprit lead point. A detailed small bowel follow-through with specific attention paid to the right lower quadrant by a pediatric radiologist is helpful in identifying intraluminal lead points in this population.

Noncancerous causes include juvenile polyps of the colon, inflammatory polyps, submucosal hemorrhage, hemangiomas, and foreign body ingestion. Juvenile polyps are the most frequent type of polyp encountered in pediatric patients and are seen in 1% to 2% of children.[48] Their peak incidence is between 2 and 5 years. They are manifested as painless rectal bleeding. Initial complaints may also include a prolapsing rectal mass, mucopurulent stools, abdominal pain, and colocolonic intussusception. These polyps are hamartomas, and the etiology is unknown. Colonoscopy can be diagnostic and therapeutic with endoscopic removal at the time of diagnosis.

Inflammatory polyps, composed of chronic inflammatory cells such as eosinophils, are frequently found in the stomach

and small bowel, rarely in the colon, and are nonneoplastic. They can cause intussusception and obstruction at the level of the small bowel. They are frequently manifested as abdominal pain, and surgical excision is the treatment of choice. Because of their location in the small bowel, the diagnosis can be difficult to make. Endoscopy with a wireless capsule endoscope, as well as intraoperative endoscopy, may be helpful in locating the polyp.[49]

Submucosal hemorrhage can occur throughout the gastrointestinal tract. Causes include Henoch-Schönlein purpura, platelet disorders, anticoagulant therapy, and a complication of chemotherapy. They can also serve as a lead point for small bowel intussusception.

## FOREIGN BODIES

Ingestion of various foreign bodies including peanuts, phytobezoars, trichobezoars, and pica in the mentally disabled can cause partial or complete bowel obstruction in children. Common locations of intestinal obstruction caused by foreign bodies include the gastric outlet and terminal ileum. The ingestion of multiple magnets harbors its own set of risks for bowel obstruction, volvulus, and intestinal fistulas and usually requires operative exploration.[50]

## INFLAMMATORY PSEUDOTUMOR

Inflammatory pseudotumor (IPT) is synonymous with inflammatory myofibroblastic tumor (IMT) and plasma cell granuloma. IPTs represent a group of tumors that have been found throughout the gastrointestinal tract, thorax, head, and neck. The etiology of these lesions remains obscure. Histologically, these tumors consist of plasma cells, histiocytes, and lymphocytes in a matrix of myofibroblasts. Although they can be locally invasive, as a whole these tumors are benign.

Alimentary tract IMTs can cause obstructive symptoms, weight loss, and abdominal pain. Laboratory evaluation reveals anemia and elevation in the erythrocyte sedimentation rate. Typical abdominal locations include the appendix and stomach, but lesions have been reported to arise from the small intestine, colon, and Meckel diverticulum.

Treatment is complete surgical excision. The recurrence rate of this tumor ranges from 18% to 40%.[51] The risk of recurrence is greater with incomplete resection, and malignant degeneration has been associated with multiple recurrences of these tumors. There has been variable success with preoperative and postoperative treatment with NSAIDs in these patients.

## ASCARIASIS

A common tropical infection is infestation with the nematode *Ascaris lumbricoides*. The estimated worldwide prevalence of *Ascaris* infection is over 1 billion cases, and death primarily results from intestinal obstruction. Human transmission is hand to mouth. The infection is generally asymptomatic; however, heavy infestation (>60 worms) can cause partial or complete obstruction of the gastrointestinal tract or biliary tree.[52] The diagnosis is made by ultrasonographic demonstration of worms in the biliary tree, pancreas, or intestine. Treatment consists of antihelmintic chemotherapy with mebendazole, albendazole, levamisole, or pyrantel. If medical treatment fails, endoscopic retrograde cholangiopancreatography can be used to extract worms from the biliary tree, and surgical enterotomy can accomplish worm removal from the intestinal tract.

## POSTTRAUMATIC INTESTINAL STRICTURE

Acute perforations of the gastrointestinal tract are the most common intestinal injury after automobile accidents.[53] They are secondary to seat-belt trauma and are usually detected shortly after injury has occurred. A late sequela of a seat-belt injury is an intestinal stricture manifested as intestinal obstruction.

Abdominal pain and bilious vomiting 10 days to 3 weeks after blunt traumatic injury should lead one to suspect posttraumatic intestinal stricture.

## LYMPHATIC MALFORMATION

Cystic lymphatic malformations are rare causes of abdominal masses in infants and children. They are also known as *mesenteric* or *omental cysts* and can be manifested as an asymptomatic abdominal mass, with or without abdominal pain, intestinal obstruction, and volvulus. These are true cysts in that they are lined with endothelium, and it is postulated that they are secondary to ectopic proliferation of lymphatic structures that lack communication with the normal lymphatic system.[54] Mesenteric cysts may be found throughout the gastrointestinal tract and are most common in the ileum. They are best diagnosed by ultrasonography and appear as a well-circumscribed cystic structure with thin walls and septae. The diagnosis can be complemented by CT scan, which shows the extent of disease and rules out pancreatic, renal, and ovarian cysts. Treatment is complete surgical excision, which may require simultaneous bowel resection. The cyst can be marsupialized if complete enucleation is not possible. There has been a recent report of laparoscopic cyst excision in a young adult.[55]

## DUPLICATION CYSTS

Duplications of the gastrointestinal tract are uncommon congenital anomalies. They lie within the wall of a segment of intestine or within the mesentery. Duplications are diagnosed pathologically by the presence of smooth muscle in the wall of the cyst. They can exist anywhere in the gastrointestinal tract and are usually symptomatic early in life. Symptoms include an abdominal mass, pain, intestinal obstruction as a result of volvulus or intussusception, and free air secondary to perforation. The diagnosis can be made preoperatively with ultrasound and CT. Surgical excision is the treatment of choice.

## PSEUDOOBSTRUCTION

Intestinal pseudoobstruction is a syndrome in which there are signs or symptoms of intestinal obstruction without a mechanical lesion obstructing the intestinal lumen. Though typically associated with an older patient, pseudoobstruction can occur as a primary phenomenon in neonates, as well as be due to secondary causes in an adolescent patient (Table 87-1). The disorder is not confined to the small intestine. It is generally agreed that motility of the intestine is abnormal, the etiology of which is either myopathic or neuropathic.

Patients have recurrent attacks of variable length and frequency consisting of nausea, vomiting, abdominal distention, and diarrhea or constipation. They frequently have steatorrhea

secondary to slow transit time and bacterial overgrowth in the small intestine. Radiographic studies demonstrate the slow gastrointestinal transit time with dilation of both small and large bowel loops.

Satisfactory treatment of this group of patients is difficult to achieve. After mechanical lesions are ruled out with a barium contrast study, the mainstay of therapy is medical. Erythromycin (50 to 100 mg) stimulates motilin receptors and enhances gastric emptying. At low doses it stimulates intestinal contractions, yet more is not better. At high doses it inhibits intestinal motility. Octreotide (50 μg, parenterally) has been used to stimulate rhythmic contractions of the small intestine. New treatment regimens aimed at serotonin receptors in the intestinal tract are now available (alosetron, 1 mg orally) or are currently in clinical trials. Surgical therapy is limited to patients who have a short segment of dysmotile intestine. Operation should be avoided in patients with diffuse dysmotility because recurrent symptoms and radiographic abnormalities are practically impossible to distinguish from adhesive small bowel obstruction in a previously operated patient.

CHAPTER 88

# Short Bowel Syndrome

Tom Jaksic, Ivan M. Gutierrez, and Kuang Horng Kang

The management of pediatric short bowel syndrome (SBS) remains a major clinical challenge. However, nutritional, medical, and surgical advances, in conjunction with the evolution of specialized multidisciplinary intestinal failure centers, have been associated with a significant improvement in patient outcome. Over the past 4 decades the mortality from pediatric SBS has decreased from almost 50% to approximately 10%.[1–3] The advent of promising new therapies suggests that further reductions in SBS morbidity and mortality are possible.

## Definitions

Pediatric intestinal failure may be defined as intrinsic bowel disease resulting in an inability to sustain growth, hydration, or electrolyte homeostasis. Classically SBS is a subset of intestinal failure consequent to actual small intestinal loss or resection. Mucosal enteropathies (i.e., microvillus inclusion disease, tufting enteropathy) and motility disorders (i.e., chronic intestinal pseudoobstruction [CIPO]) are other causes of intestinal failure that do not involve bowel loss. At times these etiologies coexist in a single patient. For example, a neonate with surgical necrotizing enterocolitis may have intestinal failure secondary to small intestinal loss, compounded by malabsorption and disordered motility due to damaged bowel that has remained in situ. In practice the terms *intestinal failure* and *SBS* are often used interchangeably.

Animal models of SBS are defined by a small intestinal resection of 80% or greater.[4] No such convention exists in patients, although the length of the remaining small intestine is highly correlated with parenteral nutrition (PN) dependence (Fig. 88-1). In the absence of any surgical bowel lengthening and tapering procedure, 35 cm of neonatal small bowel are associated with a 50% probability of weaning from PN.[5] However, a relatively wide variability is evident in Figure 88-1 and patients with much longer bowel lengths sometimes do not wean from PN. Poor motility and/or residual malabsorption in the injured remaining bowel may contribute to this finding. Conversely, neonates with as little as 10 cm of residual small intestine can sometimes be weaned from PN (Fig. 88-1).

The more premature the neonate, the more likely the intestine will subsequently grow in length, thus resulting in a greater capacity for adaptation. Some additional inaccuracies in small bowel length interpretation are introduced by different measurement techniques. The convention is to record the antimesenteric length with no tension applied to the intestine. Residual small intestinal length remains the major positive clinical predictor of ultimate enteral feeding tolerance.[5,6]

Although studies are somewhat conflicting, the presence of an ileocecal valve has historically been deemed a secondary favorable prognostic factor in SBS.[1,5] Conceptually it is important to realize that the presence of an ileocecal valve is a marker for remaining ileum, and this may in fact be the underlying important determinant for weaning from PN. The loss of colonic length has a relatively modest effect on nutrient transport because the colon's prime function is fluid and electrolyte absorption. The colon is also the site for some short chain fatty acid transfer. Reestablishing bowel continuity surgically sometimes significantly reduces intravenous (IV) hydration requirements, and the prompt closure of stomas is associated with improved SBS patient outcome.[5]

An alternate method of assessing intestinal mucosal mass is the serum citrulline concentration. This may be particularly useful if an accurate small intestine length measurement is unavailable. Citrulline is a nonstructural amino acid that is primarily synthesized in the intestinal mucosa, and serum citrulline levels are highly positively correlated with intestinal length and the ability to wean from PN.[7] Retrospective data indicate that SBS patients with a serum citrulline level persistently less than 12 μmol/L are usually unable to wean from PN.[7]

A purely functional definition of neonatal SBS may also be used. The simplest and most frequently applied is PN dependence for greater than 3 months.[5,6] More complex definitions based on amalgams of functional and anatomic considerations have also been suggested.[8]

## Etiology

The causes of pediatric SBS vary according to the specific clinical setting surveyed. The Center for Advanced Intestinal Rehabilitation (CAIR) at Children's Hospital Boston manages

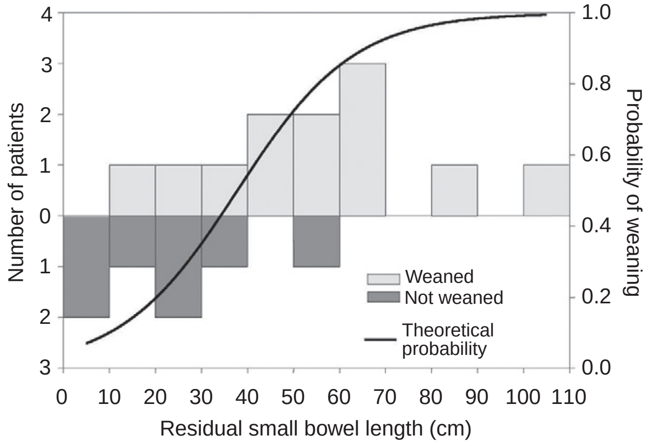

**FIGURE 88-1** This demonstrates the correlation between small intestinal length and parenteral nutrition dependence in neonates with short bowel syndrome. The *lightly shaded bars* represent those individuals weaned to full enteral nutrition while the *darkly shaded bars* reflect patients failing to attain enteral autonomy. The sigmoid-shaped *dark line* plots the theoretic probability of weaning from parenteral nutrition on the basis of the remaining small bowel length. It may be seen that 35 cm of residual small intestine is associated with an approximately 50% probability of weaning from parenteral nutrition. (Reproduced with permission from Andorsky DJ, Lund DP, Lillehei CW, et al: Nutritional and other postoperative management of neonates with short bowel syndrome correlates with clinical outcomes. J Pediatr 2001;139:27-33.)

more than 200 children with SBS, approximately 60 of whom are on home parenteral nutrition (HPN) at any one time. The primary etiologies of SBS in this cohort are necrotizing enterocolitis (35%), intestinal atresia (25%), gastroschisis (18%), and malrotation with volvulus (14%), with the remainder comprising a compendium of rarer diagnoses such as Hirschsprung disease extending into the small bowel (2%). When comparing the causes of intestinal failure among different centers it is important to note that the incidence of necrotizing enterocolitis (NEC) is highly dependent on birth weight (BW). Neonates between 500 and 750 gm have a 12% incidence of NEC and there is a symmetric 3% decrease in NEC occurrence for each 250 gm increment in BW over 750 gm.[9] It follows that centers with large numbers of extremely low-birth-weight infants (especially at the lower ranges) will have a greater preponderance of patients with SBS secondary to NEC. As noted for SBS in general, the prime predictor of eventual enteral tolerance in NEC is residual small bowel length.[6]

## Incidence, Morbidity, and Mortality

A large group of hospitalized neonates, encompassing 16 tertiary care centers in the United States, was found to have an incidence of SBS between 0.7% and 1.1% depending upon birth weight.[10] These estimates, however, did not include term infants. A study from the Province of Ontario, Canada, calculated the incidence of SBS to be 24.5 per 100,000 live births. The occurrence of SBS was much higher in infants born at less than 37 weeks estimated gestational age as compared to term newborns (353.7/100,000 live births vs. 3.5/100,000 live births, respectively). In this investigation the mortality was three times higher for SBS patients than a control group matched by underlying diagnoses.[11]

In 2002 it was estimated that 39,000 patients in the United States received HPN. Unfortunately, accurate data regarding underlying diagnoses and long-term outcomes remain unavailable. The American Society of Parenteral and Enteral Nutrition (ASPEN) in 2011 established the SUSTAIN cohort study registry for patients on HPN (www.nutritioncare.org). This should allow for more reliable future benchmarking of SBS morbidity and mortality.

Patients with SBS die from their underlying disease, as well as delayed complications such as intestinal failure–associated liver disease (IFALD), and sepsis. It is also of concern that approximately 1 out of 10 SBS patients successfully transitioned to full enteral nutrition has hepatic cirrhosis.[12] Despite this, recent reports indicate that long-term survival rates of 89% to 93% can be achieved in pediatric SBS patients.[1,3]

## Clinical Presentation

Patients with severe SBS tend to be intolerant of full enteral feeding, with resultant vomiting, diarrhea, or both. The clinical presentation of a young patient with SBS is reflected by the radiograph in Figure 88-2. It shows a typical bowel gas pattern, a central venous line for PN, and a gastrostomy tube (G-tube) for decompression and/or supplemental feeding. Even in the absence of mechanical obstruction, the residual small intestine may appear dilated. Although following small intestinal loss the bowel will lengthen with age, there is no compensatory acceleration in this process beyond the patient's genetic potential. This tendency of the bowel to dilate rather than lengthen is likely related to the fact that its blood supply is at a right angle to its longitudinal axis. The dilation of the bowel does tend to increase absorptive surface area, yet deleterious consequences such as dysmotility and bacterial overgrowth may follow.

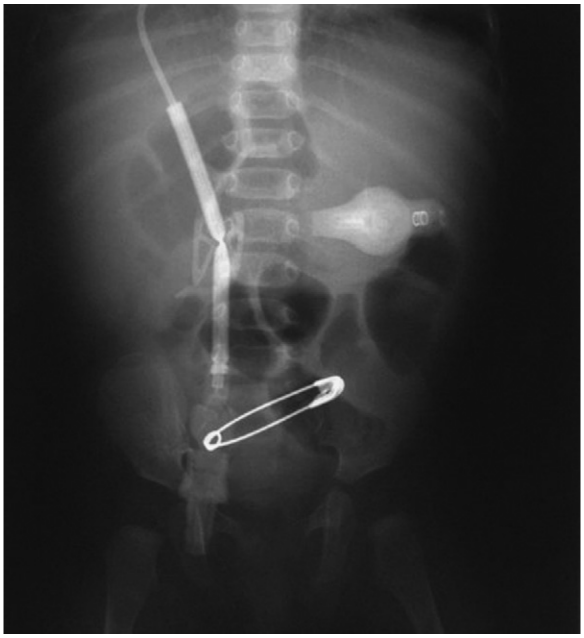

**FIGURE 88-2** This abdominal radiograph is stereotypical of a young child with short bowel syndrome. There are a few moderately dilated intestinal loops with no clear evidence of mechanical obstruction. A G-button and central line may be noted.

It is important to note that bowel adaptation is a prolonged process and may occur for years. Further, on a per-kilogram body weight basis, pediatric caloric and protein requirements drop dramatically over time.[13] Data from intestinal failure centers suggest that more than 80% of patients with SBS will eventually transition to full enteral nutrition. This conversion is not only more cost effective and desirable from a quality-of-life perspective but is also associated with a formidable improvement in morbidity and mortality.[5,14,15]

## Clinical Assessment

The first phase of successful SBS management is an accurate clinical assessment. As noted earlier in the definition of SBS, small intestinal length (or its proxy serum citrulline) is a key prognostic factor for determining the likelihood of attaining full enteral tolerance. Understanding the exact residual intestinal anatomy is also beneficial in identifying potential nutrient deficiencies. Patients without an ileum have reduced absorptive capacity for long chain fatty acids and are at risk for deficiencies of the fat-soluble vitamins A, D, E, K, the trace mineral zinc, and the water-soluble vitamin $B_{12}$.

An upper gastrointestinal series, with small bowel follow-through, should be done during the course of therapy if mechanical obstruction is suspected. This study will additionally evaluate the degree of intestinal dilation and estimate transit time. A contrast enema may be of utility in helping to rule out strictures and identifying atonic bowel segments. If Hirschsprung disease is suspected, a rectal biopsy or anal manometry is necessary. In the presence of chronic intestinal motility disorders, colonic and antro-duodenal manometry is useful in planning therapy. The specific underlying etiology of SBS is also pertinent. Because necrotizing enterocolitis patients frequently have remaining bowel that is functioning suboptimally, length considerations alone may underestimate potential problems. Neonates with gastroschisis may have disordered motility that precludes enteral feeding even if adequate bowel length is present.

Precise weight, length, weight for length, body mass index, and head circumference measurements should be followed longitudinally and compared with standardized growth charts. Overfeeding is usually evidenced by an increase in weight out of proportion to length and underfeeding by a plateau in weight gain. Body composition assessment reflected by anthropometry (i.e., triceps skin fold thickness and midarm circumference) is also important because alterations in fluid status or organ mass may affect weight without a change in lean body mass. Adequately calibrated PN maintains linear growth in pediatric SBS patients, and once they are weaned from artificial enteral and parenteral supplementation normal anthropometrics are usually attained.[16]

Micronutrient and vitamin deficiencies are frequent in patients with SBS and tend to be unmasked when PN is halted. A recent review of children with SBS noted a respective 70% and 77% incidence of vitamin and trace mineral deficiency.[17] An inadequacy may be present even if normal somatic growth is evident.[18] Trace elements that should be assayed are zinc, iron, copper, magnesium, manganese, and selenium. Aluminum is a contaminant that may be elevated in PN-dependent patients.

Metabolic bone disease has been widely noted in SBS patients.[19] It is related to an inability to provide adequate parenteral calcium and phosphate, calcium malabsorption, reduced physical activity, and inappropriate provision of vitamin D. Vitamin D status is best assessed by serum levels of 25-hydroxy vitamin $D_3$ because this form more accurately reflects hepatic stores. Dual-energy x-ray absorptiometry (DEXA) is used to follow bone density in older SBS children. In neonates a sudden spike in serum alkaline phosphatase may be the harbinger of pathologic fractures. These can be confirmed by plain radiographs.

The complete measurement of stomal, stool, and urine output is mandatory and aids appropriate fluid and electrolyte management. SBS patients are susceptible to diarrheal losses in the presence of viral (i.e., rotavirus) or bacterial (i.e., *Clostridium difficile*) infections. The presence of a nonanion gap acidosis with low bicarbonate is usually due to excessive small intestinal losses. Diarrhea and high stoma output will also cause loss of zinc. Zinc deficiency is evident clinically by acrodermatitis enteropathica, consisting of a rash of the face, hands, feet, and genitalia. Although zinc status is notoriously hard to determine because of stores present in bone, adequacy is estimated by serum levels. Gastrointestinal sodium losses are also frequently seen in SBS, and a urinary sodium concentration of less than 10 mEq/L is a better indicator of diminished total body sodium stores than serum sodium.[20] Low sodium reserves result in growth failure.[21]

At times the presence of variant quantities of red blood per rectum may be noted in children with SBS. The common causes are bacterial overgrowth, allergic enteritis, and anastomotic ulcers. Endoscopy with biopsy and quantitative culture is informative in such patients.[22] Less frequently global ischemia is the etiology of intestinal blood loss, and plain abdominal films may show pneumatosis.

The timely diagnosis of the SBS-engendered complications, IFALD, bacterial overgrowth, and catheter-associated blood stream infection (CABSI) is also extremely important and is discussed later in “Medical Management.”

## Nutritional Management

The nutritional management of intestinal failure patients is predicated on an appropriate provision of proteins, carbohydrates, lipids, electrolytes, vitamins, and trace minerals. Adequacy is judged by attaining optimal growth and development while minimizing the problems linked with intestinal failure.

It has been shown that both breast milk and amino acid (elemental) formulas are associated with a more rapid transition to full enteral nutrition in SBS neonates.[5] Interestingly, allergic (cell mediated) enteritis is not uncommon in young SBS patients because the mucosal barrier to proteins is compromised.[22] If allergic enteritis is suspected, amino acid formulas are used preferentially because they eliminate the possibility of peptide-mediated allergic responses. With time allergies tend to improve, and in infants the consumption of solid food can actually decrease diarrheal output. As soon as it is safe, oral intake is encouraged because oral aversion develops in SBS children and is difficult to overcome. Successfully orally fed patients tend to exhibit “hyperphagia,” a food requirement that seems excessive and is secondary to the obligate malabsorption of nutrients caused by SBS.

The benefits of enteral nutrition in SBS include decreased complications, higher survival, improved adaptation, and lower cost.[5,14,15,23] In the presence of inadequate oral intake, supplementation by direct enteral access is required. The placement of a gastrostomy allows for continuous or bolus enteral nutrition. The advantage of continuous feeds is that a relatively lower volume of nutrients is provided per unit time and intestinal transport mechanisms are less likely to be overwhelmed. Hence fluid and nutrient absorption tends to be improved.[24] Supplemental continuous feeds are usually given at night, whereas oral feeds are encouraged during the day.

No consensus exists regarding the optimal rate at which enteral feeds may be safely advanced, but initial increases of 10 mL/kg/day are reasonable. A common reason for limiting enteral nutrition is a stool or stoma output of greater than 2 mL/kg/hr. Although fluid/electrolyte problems and perianal skin irritation may ensue, clinical judgment is warranted and liberalization of this criterion may be feasible in stable patients. The provision of soluble fiber such as pectin may transiently worsen stool output before improving it, and its benefits are primarily associated with its effect on the colon.[25]

If upper gastrointestinal motility is problematic, a G-tube can be changed to a gastrojejunal tube (GJ) tube. The gastric portion of the GJ tube is used for decompression while feeds are undertaken distally. Disadvantages of GJ tubes are that radiologic replacement is necessary if they dislodge and that in severe SBS a portion of the potential absorptive surface is bypassed. GJ tubes are particularly useful if one of the reasons for the lack of enteral feeding advancement is refractory vomiting.

The enteral administration of prebiotics (substances that promote the "good" bacteria in the intestine) and probiotics (the "good" bacteria themselves) is highly controversial in SBS. No clear benefit has yet been established. In SBS patients who still have central lines, catheter-associated bloodstream infections have been reported with both bacterial and yeast probiotics.[25,26] It is unclear if the mechanism for these infections is translocation across the intestinal mucosal barrier or aerosolization of the organisms and resultant contamination of the line hub.

If appropriate growth cannot be obtained enterally, then PN is started. PN is a life-saving therapy for pediatric SBS that was first reported in 1968 and has become the standard of care.[27] PN formulations consist of amino acids, glucose, electrolytes, lipids, trace minerals, and vitamins. There is little compelling evidence that patients with SBS in the convalescent phase require parenteral amino acid and caloric allotments different from comparable healthy individuals. Both overfeeding (causing fatty liver, hyperglycemia, and increased $CO_2$ production) and underfeeding (resulting in poor growth) should be avoided.

Cycling of PN involves the provision of total fluid and nutrient allotments in less than 24 hours. From a practical standpoint it allows the patient and family to be free from PN for a portion of the day. It also tends to avoid persistent hyperinsulinism and theoretically decreases the likelihood of hepatic steatosis. Cycling is precluded if the serum glucose level decreases to below 60 mg/dL. The provision of enteral nutrition during the time of cycling off PN counteracts the tendency toward hypoglycemia. In an effort to maintain glucose stores, neonates are not left off PN for more than 6 hours.[28] In older children a minimum 12-hour period completely off PN is the therapeutic target.

The transition from parenteral to enteral nutrition is initiated in individuals who are growing and are tolerating a substantial allotment of enteral calories. The patient's parenteral intake is weaned (usually by reducing the amount of PN and then finally skipping a day of PN) while growth parameters are followed closely. If growth remains adequate, further nonconsecutive days of PN are eliminated until complete weaning has transpired. Hydration fluid may still be necessary to maintain fluid homeostasis.

Because bowel rehabilitation is a protracted process, the home provision of parenteral and enteral nutrition is often a necessary and desirable component of therapy. This is a feasible option throughout the United States, but meticulous physician monitoring is necessary. Peer support for HPN patients and their families is available through the Oley Foundation (www.oley.org).

# Medical Management

The medical management of pediatric patients with SBS focuses on the amelioration of complications induced by intestinal failure and the promotion of bowel adaptation.

## INTESTINAL FAILURE–ASSOCIATED LIVER DISEASE

The exact cause of IFALD remains to be determined. Known risk factors include low birth weight, prematurity, duration of PN, and number of septic episodes.[5,29,30] IFALD is reflected biochemically by elevations of serum transaminases and direct bilirubin, followed later by increases in the PT and INR. Once splenic enlargement occurs, thrombocytopenia may evolve. Hypoalbuminemia is usually an even later finding. Clinically one may note persistent jaundice, scleral icterus, and an enlarged liver and spleen. A large spleen may also portend thrombocytopenia. Routine liver function assessment is mandated in PN-dependent patients with SBS, and any signs consistent with portal hypertension require further Doppler ultrasound evaluation of the liver, spleen, hepatic arteries, portal vein, and hepatic veins. Liver biopsies of patients with IFALD show cholestasis, bile duct proliferation, periportal inflammation, and variable amounts of fibrosis.[12]

The improvement of IFALD is associated with a normalization of the direct bilirubin followed by a delayed resolution in elevated serum alanine aminotransferase concentrations.[31] Despite the normalization of bilirubin levels, significant residual liver damage and even cirrhosis may be present on subsequent liver biopsy.[12] In general liver damage of a degree less than cirrhosis is reversible. A recently reported nonradioactive IV $^{13}$C-methionine breath test differentiates cirrhotic from noncirrhotic infants with IFALD.[32] The prevalence of PN-associated cholestasis in neonates has been reported to be 25% to 33%, but recent therapy has reduced this substantially.[3,5,33]

The most efficacious treatment for IFALD is the institution of full enteral nutrition. This is associated with a normalization of direct bilirubin and elimination of the need for permanent venous access (the prime cause of sepsis in SBS). In a cohort of infants with IFALD and severe cholestasis it was noted that one quarter manifested a rapid decrease in serum direct bilirubin with the institution of enteral feeds and that

all patients normalized their direct bilirubins 3 to 4 months after the attainment of full enteral nutrition.[14] This argues strongly for the early and persistent advancement of enteral feeds in SBS.

In certain SBS patients the conversion to enteral feeds is impossible; however, modification of IV lipid dose and type is successful in avoiding and treating IFALD. For more than 10 years it has been known that the administration of standard soy-based (omega-6) IV fat emulsions (Intralipid) at greater than 1 gm/kg/day is associated with the evolution of IFALD.[34,35] Conversely, the infusion of lipid emulsions at doses of less than or equal to 1 gm/kg/day has been demonstrated to help prevent and treat IFALD in pediatric SBS patients.[35,36] Although concern for lipid deficiency states exist with fat restriction, biochemical evidence of essential fatty acid deficiency in neonates treated with omega-6 lipids at 1 gm/kg/day is rare. Even lower parenteral lipid allotments of less than 0.5 gm/kg/day have been suggested for the treatment of cholestasis, but lipid deficits do occur at these doses.[36]

The classic clinical sign of essential fatty acid deficiency is a dry, scaly rash, and its biochemical hallmark is an elevated triene-to-tetraene ratio. In human nutrition the requirement for essential fatty acids (α-linolenic acid, linoleic acid) is estimated to be only 2% of total calories provided; however, the lipids that are truly essential in neonates remain to be fully defined and may include the omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).[37] If lipid restriction is used in SBS patients, additional parenteral glucose calories are necessary to meet caloric requirements and complete lipid profile monitoring on a monthly basis is recommended.

A new finding in neonates with SBS is that the provision of parenteral fish oil (omega-3 fatty acids) at 1 gm/kg/day is associated with the reversal of hyperbilirubinemia (in 89% of patients) and that it has no evident adverse effects.[3,38] In these studies, resolution of cholestasis was achieved in a mean time of 81 days. This is roughly equivalent to the interval for normalization of direct bilirubin seen in children with IFALD after full transition to enteral feeding.[14] It is also of interest that the protracted provision of fish oil emulsions (containing primarily EPA and DHA) at 1 gm/kg/day was not associated with biochemical evidence of essential fatty acid deficiency in neonates.[39] The commercial product Omegaven, an IV fish oil formula, is not U.S. Food and Drug Administration (FDA) approved; however, it may be obtained on a compassionate-use basis with an investigational new device (IND) application as rescue therapy for patients with established IFALD. A randomized controlled trial of Omegaven at 1 gm/kg/day versus an equivalent quantity of soy-based lipid (Intralipid) has been initiated as a prophylactic treatment for pediatric IFALD. A randomized controlled trial of an FDA-approved oral fish oil preparation as therapy for SBS children with an elevated alanine aminotransferase (ALT) has also commenced. The mechanisms by which omega-3 lipids exert their putative protective effects on the liver remain to be elucidated, but it is known that the omega-3 fatty acids are antiinflammatory, whereas the omega-6 fatty acids tend to be proinflammatory.[40]

Other novel lipid emulsions are also being tested. SMOF, which contains lipids as 30% soybean, 30% medium chain triglycerides (MCT), 25% olive oil, and 15% fish oil, has been shown to be well tolerated in surgical patients.[41] Efficacy data in infants with IFALD are currently being obtained in a randomized controlled trial comparing SMOF to soybean-based Intralipid (both at 2 gm/kg/day).

In the presence of the described case series data, we use a prophylactic lipid strategy. This approach is additionally supported by the finding that the majority of patients with SBS, even those successfully enterally salvaged, appear to have fibrosis or cirrhosis on liver biopsy.[12] Hence all SBS patients (including neonates) who are not on a randomized controlled protocol and are projected to be PN dependent for longer than 3 weeks are placed on Intralipid at 1 gm/kg/day. If a patient evolves a direct bilirubin elevation higher than 2 mg/dL for 2 consecutive weeks while on lipid restriction (1 gm/kg/day), we switch lipids to Omegaven at 1 gm/kg/day. With this policy patients have attained adequate growth, not demonstrated biochemical fatty acid deficiency, and usually normalized their direct bilirubin levels. It is acknowledged that in the absence of randomized controlled trial data, the ideal lipid solution and dosing strategy remains to be determined.

Once some enteral intake is possible in patients with IFALD, the use of ursodeoxycholic acid to promote bile flow is considered. This medication may be taken orally or administered through a G-tube. Side effects are rare, but efficacy has not been well established in SBS patients with IFALD. Ursodeoxycholic acid has been studied prospectively in cholestasis of pregnancy, and reductions in transaminase elevations and hyperbilirubinemia have been noted.[42]

A concern in PN-dependent patients with IFALD is the potential for accumulation of copper and manganese in the liver.[43] Whether these trace elements cause an actual pathologic overload state in IFALD patients is undefined, but the usual practice is to halve the dose of the trace mineral mix in the PN and follow serum levels to ensure that no deficiency states evolve.

## CATHETER-ASSOCIATED BLOODSTREAM INFECTIONS

SBS patients often require a central venous catheter for the administration of PN or chronic hydration. This type of line may be placed at bedside, in the operating room, or in the interventional radiology suite. Key technical elements of insertion include the maintenance of aseptic technique, avoiding the ligation of vessels and obtaining radiologic confirmation of line position. Experienced interventional radiologists can even use collateral vessels as a means to enter the central circulation.

One of the major complications of central venous lines is catheter-associated bloodstream infections (CABSIs). Various protocols have been implemented to standardize line care, and salutary results have been reported.[44] However, SBS children on HPN remain a high-risk group, perhaps because of stool contamination of the central line or bacterial translocation. Their baseline infection rates are approximately 10/1000 catheter days, and the most frequent causative organisms are enteric gram-negative bacteria.[45]

Any suspicion for CABSI needs to be thoroughly assessed. A child with a catheter and symptoms of fever, lethargy, irritability, or ileus (abdominal distension) may have CABSI. The most important investigation to confirm CABSI is a blood

culture through the central line. If the patient's clinical presentation is congruent with CABSI, broad-spectrum IV antibiotics (such as a combination of vancomycin and piperacillin/tazobactam) are started immediately through the central line, as soon as blood cultures have been obtained. In the event that 48-hour blood cultures are negative, antibiotics may be halted. Otherwise, a 14-day course is completed. Once the organism's sensitivities are available, the antimicrobial therapy can be narrowed. Hemodynamic instability and fungal infections mandate central line removal. Three consecutive days of positive bacterial blood cultures despite appropriate IV antibiotics also usually culminate in catheter loss.

Ethanol has been demonstrated to have the ability to penetrate the biofilm that forms on central lines, and no bacteria or fungi have been reported to be resistant to this agent.[45,46] A recent retrospective study of infants with SBS who were on HPN and received 70% ethanol locks three times per week showed a greater than fourfold reduction in CABSI (from 9.9 to 2.2 infections/1000 catheter days) and a significant decrease in the need for line replacement.[45] It should be noted that the administration of metronidazole in patients with ethanol lock therapy may cause a disulfiram type reaction. A randomized controlled trial of ethanol locks for pediatric SBS has been registered.

## BACTERIAL OVERGROWTH

Bacterial overgrowth can occur in up to 60% of patients with SBS.[47] Areas of disordered motility and bowel dilation offer an ideal environment for abnormal bacterial propagation. The adverse effects of bacterial overgrowth consist of abdominal pain, worsening motility, mucosal ulceration with bleeding, deconjugation of bile acids, and the generation of toxic byproducts such as D-lactic acid. It is also thought (though not proven in humans) that bacterial overgrowth potentiates translocation and hence septicemia.

The treatment for suspected bacterial overgrowth is largely empiric. A typically used approach is the enteral administration of antibiotics for 7 days followed by an interval of no antibiotic administration for a week or greater. Antibiotics that are commonly used include those effective against anaerobes (i.e., metronidazole) or gram-negative organisms (i.e., ciprofloxacin). Endoscopy with quantitative duodenal cultures to guide therapy appears to be useful in selected cases,[22] and bowel lengthening and tapering operations should be considered in those SBS patients where the complications of bacterial overgrowth cannot be managed medically.[48]

D-lactic acidosis is a problem associated with SBS and bacterial overgrowth. In the course of normal anaerobic mammalian metabolism,[49] L-lactate is generated and easily converted to L-pyruvate, rendering it available for intermediary metabolism. However, bacteria produce D-lactic acid. This moiety is not metabolized by mammalian enzymatic systems and hence toxic levels can accumulate. Signs of D-lactic acidosis in neonates include an anion gap acidosis and seizures, whereas older children may additionally demonstrate confusion, slurred speech, and delayed cognition. The diagnosis is confirmed by laboratory assay of serum D-lactate. The treatment for this condition is rehydration and eradication of the underlying bacterial overgrowth using enterally administered antibiotics.

Another problem found with bacterial overgrowth is that serum vitamin $B_{12}$ levels may be inaccurate. Because bacteria can produce a biologically inactive analogue, accurate assessment for vitamin $B_{12}$ deficiency in SBS requires the measurement of serum methylmalonic acid and homocysteine.[50] If vitamin $B_{12}$ (which acts a cofactor) is not present in sufficient quantities, the metabolism of methylmalonic acid and homocysteine is impaired, hence elevating the serum concentrations of these substrates. Should a deficiency state be revealed, vitamin $B_{12}$ can be supplemented intravenously, by intramuscular injection, or in older children intranasally.

## DECREASED INTESTINAL MOTILITY

Bowel motility disorders are relatively frequent in SBS neonates and children. Erythromycin administered orally or directly into the stomach increases gastric emptying and improves antroduodenal coordination. Studies in normal individuals indicate that this augmentation of motility is, at least in part, due to the induction of phase III of the migrating motor complex.[51] Azithromycin, a longer-acting analogue of erythromycin, may also be used to improve gastric motility. Tachyphylaxis to both erythromycin and azithromycin is common.

In pediatric SBS the use of other agents that may promote motility is problematic. Octreotide may accentuate bowel ischemia, whereas metoclopramide can induce tardive dyskinesia. The latter complication has resulted in the FDA issuing a "black box" warning regarding the protracted use of metoclopramide. Domperidone is available for the treatment of gastroparesis in the United States only by an IND application through the FDA because of concerns regarding cardiac arrhythmias. In 2000 cisapride was also withdrawn from the U.S. market due to its association with the induction of torsades de pointes in susceptible individuals. Cisapride may be obtained from the manufacturer for patients who meet specific selection criteria (including a normal electrocardiogram), follow a defined monitoring protocol, and use a regulated dosage regimen. The reason that cisapride is still used, despite its potential for serious adverse side effects, is that it promotes motility in the stomach and throughout the small intestine.[52]

## INCREASED STOMA OUTPUT OR DIARRHEA

Diarrhea or high stoma output is common in pediatric SBS. Ileostomy effluent has high contents of zinc (17 mg/L), so careful monitoring and repletion are necessary.[53] Stoma refeeding may help obviate deficiency states and is generally an effective method of promoting fluid and nutrient absorption. If no mechanical, ischemic, or infectious problems are evident, loperamide may be used to decrease stool or stoma output. Unfortunately, loperamide elixir is sometimes solubilized in alcohol and this will cause paradoxical diarrhea in SBS. Alternatives include a specific request to the pharmacy that loperamide elixir be compounded without alcohol or the use of loperamide pills (that may be crushed and administered as a water suspension).

## HYPERGASTRINEMIA

It has been estimated that 50% of pediatric patients with SBS have gastric hypersecretion that manifests as high output and low pH.[54] As gastrin degradation occurs in the intestine, it is surmised that SBS with attendant intestinal loss may lead to elevated levels. The mechanism causing hypersecretion may

actually be more complex because many gastrointestinal regulatory hormones that act on the stomach are synthesized in the small intestine. The period of high gastric output tends to be early in the clinical course following massive intestinal excision and can be effectively blocked by proton pump inhibitors or H2-receptor antagonists. However, because idiopathic upper intestinal dysmotility and vomiting are frequently associated with intestinal failure, more extended courses of acid blockade may be necessary.

### PROMOTING BOWEL ADAPTATION

Bowel adaptation following substantial intestinal loss is characterized by enhanced villus height, greater crypt depth, thicker muscle, and an increase in protein and deoxyribonucleic acid content.[55,56] Although studies in humans are difficult, clinical data would suggest that adaptation begins within days of intestinal resection and progresses for years. This process may be quantified by an increase in the absorption of nonmetabolized sugars (D-Xylose and 3-0 methylglucose), higher serum levels of triglycerides and fat-soluble vitamins, improved weight retention, and the augmented synthesis of the nonstructural amino acid citrulline within the intestinal mucosa.[4,7,57] The two major means by which intestinal adaptation can be promulgated are the administration of intraluminal nutrients and the use of various trophic hormones. The best-studied hormonal therapy in SBS is a 33–amino acid peptide derived from the proglucagon gene called glucagon-like peptide 2 (GLP-2).

GLP-2 appears to enhance adaptation in most SBS animal models and is released by L-cells that are primarily resident in the ileum and right colon. The subcutaneous injection of teduglutide, a protease resistant form of GLP-2, was found in a randomized controlled trial to significantly increase villus height, plasma citrulline concentration, and lean body mass in adult patients with SBS.[58] A recently reported, but as yet unpublished phase III trial of teduglutide, appeared to attain its primary statistical end point of a 20% reduction in PN volume in 63% of treated adult SBS patients versus 30% of controls. As yet no clinical trial using teduglutide in pediatric SBS patients has been started. A detracting aspect of GLP-2 therapy is that its effects seem to be predicated on continued administration of the agent. Theoretic concerns also exist regarding the induction of gastrointestinal malignancy.

Growth hormone has been tested in adult SBS patients. However, an initially encouraging open-label study suggesting improved intestinal adaptation along with a decreased requirement for PN was not confirmed by a randomized prospective controlled trial.[59,60] Other trophic hormones with potential efficacy, but not as yet studied in humans with SBS, are insulin-like growth factor-1 and epidermal growth factor.[61]

## Surgical Treatment

The surgical treatment options for patients with SBS include bowel conservation at the time of first presentation, autologous intestinal reconstructive surgery, and intestinal transplantation.

### BOWEL CONSERVATION

The initial surgical operation in SBS is aimed at preserving as much intestine as possible. In cases where the viability of the bowel is in question, the use of a "second-look" operation within approximately 24 hours may be used. With this approach, marginally viable intestine is left in situ, the patient is resuscitated, and the bowel is then reassessed at a second operation. Only the frankly necrotic intestine is then excised. The use of a temporary transparent plastic silo to cover the bowel is also helpful to avoid the risk of inducing abdominal compartment syndrome. With the silo approach, delayed abdominal closure can be accomplished once bowel edema has subsided.

The prompt establishment of bowel continuity through stomal closure is associated with more rapid weaning from PN.[5] Usually the surgeon waits approximately 6 weeks between operations in an effort to minimize the vascularity of any adhesions that may have formed. In practice the closure of stomas is often governed by the anticipated stress that the operation would place on the ventilatory capacity of the child. For example, a neonate with underlying lung disease is likely to have an operation deferred if operative fluid loss and resultant replacement is anticipated to cause a marked exacerbation of pulmonary problems. Careful discussions among the surgeon, intensivist, and anesthesiologist are mandatory when considering the timing of surgery in ill SBS patients.

Massive pediatric small bowel loss, as is sometimes encountered in malrotation with volvulus and necrotizing enterocolitis ("NEC totalis"), has prompted some surgeons to recommend expectant management. This approach, as an automatic fallback, is to be discouraged. Advances in the treatment of SBS have made long-term survival of such patients likely, and a productive life on HPN is possible.[62] In most cases of severe SBS the family and surgeon should consider the options for bowel rehabilitation, HPN, and intestinal transplantation. Communication with a specialized SBS center may be highly beneficial in helping define expectations and planning appropriate care.

### AUTOLOGOUS INTESTINAL RECONSTRUCTION SURGERY

Autologous intestinal reconstruction surgery (AIRS) comprises a set of operations that use the patient's bowel to improve intestinal absorption and function. The initial procedures proposed included the creation of reversed (antiperistaltic) segments, recirculating loops, intestinal valves, and colon interpositions.[63–65] Pediatric surgeons also applied tapering and plication operations to promote motility in neonates with dilated bowel due to intestinal atresia.[66,67]

The first small intestinal "lengthening" procedure was described in 1980.[68,69] Called the *longitudinal intestinal lengthening and tailoring operation* (LILT), it is an ingenious but technically demanding operation that takes advantage of the fact that small intestine is supplied by two separate leaves of mesentery. By carefully splitting the mesentery and then severing and anastomosing the dilated (adapted) intestine in an isoperistaltic manner, the bowel is lengthened and tapered (Fig. 88-3). A helpful minor technical modification of the original operation can reduce the number of anastomoses

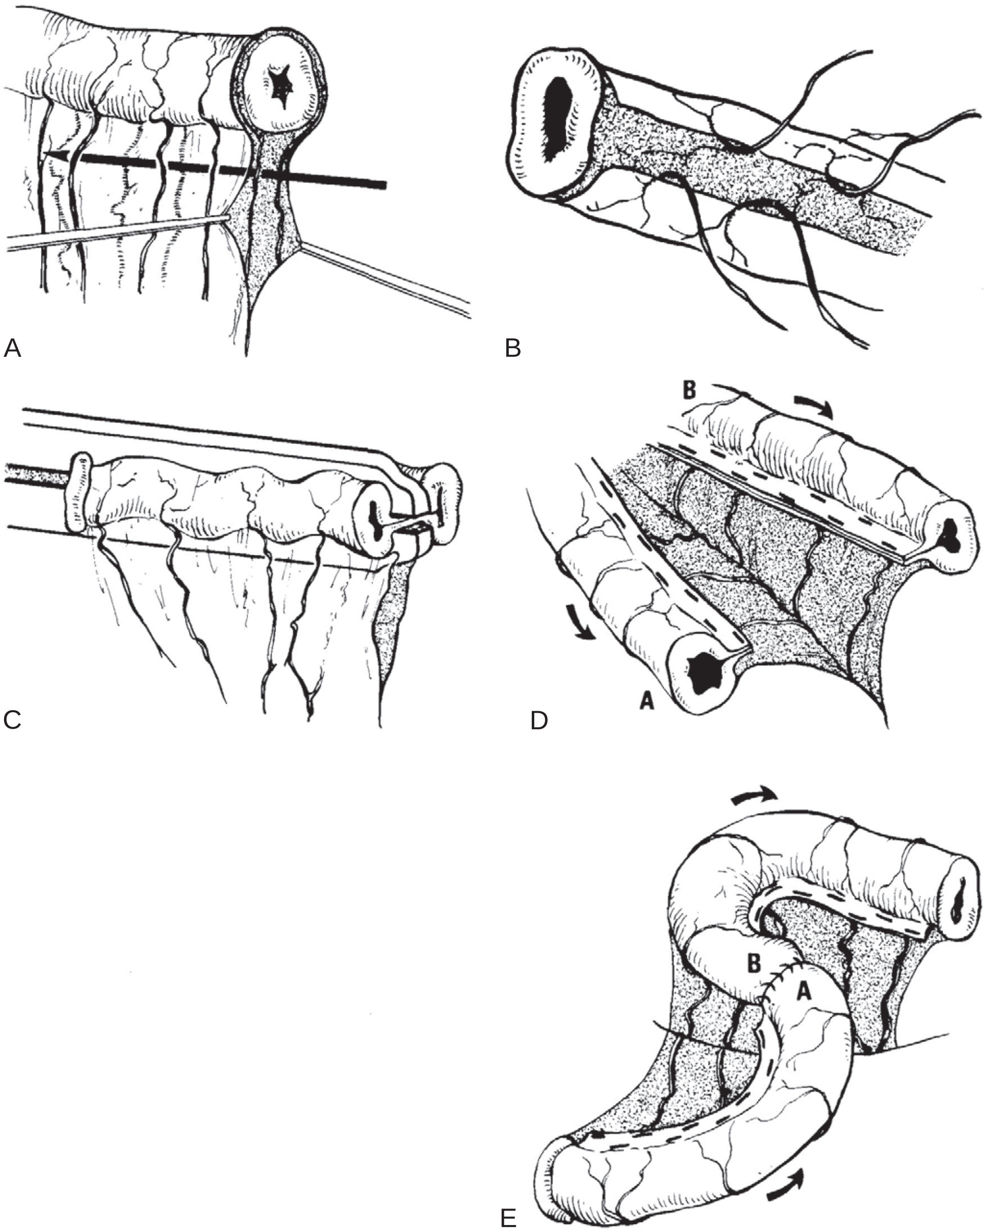

**FIGURE 88-3** Longitudinal intestinal lengthening and tailoring operation. **A,** Creation of the mesenteric tunnel. **B,** View of the divided mesentery. **C,** Division of the dilated bowel into two hemiloops. **D,** The two new hemiloops. **E,** Reanastomosis in an isoperistaltic manner. (Reproduced with permission from Bianchi A: Intestinal loop lengthening—a technique for increasing small intestinal length. J Pediatr Surg 1980;15:145-151.)

needed.[70] In pediatric patients the LILT is associated with an improvement of fat balance, carbohydrate absorption, and intestinal transit time.[71] Described complications of the LILT procedure include leak along the suture/staple lines or anastomoses, devascularization of the bowel after division of the mesenteric leaves, sepsis, recurrent bowel dilation, and dysmotility.[72]

Another creative, two-stage bowel elongation technique, termed the *Iowa I operation,* has been described.[73] It relies on the formation of collaterals between the antimesenteric portion of the small intestine and the abdominal wall during a first operation and then the transverse division, as well as isoperistaltic anastomosis of the bowel at a second operation (Fig. 88-4). This procedure was subsequently modified so that the small intestinal loop to be lengthened was approximated to the liver (Iowa II) or another intestinal loop (Iowa III).[74,75] A case report applying these principles was published, and the techniques used are diagrammed in Figure 88-4.[76]

In 2003 a conceptually simple bowel lengthening and tapering operation called the *serial transverse enteroplasty operation* (STEP) was introduced.[77,78] The three indications for this procedure are refractory SBS (in which enteral feeding advancement cannot be attained), neonatal atresia with limited distal bowel (usually $< 35$ cm in a neonate), and severe bacterial overgrowth. A contraindication to surgery is end-stage IFALD with portal hypertension; in this case transplantation rather than STEP is recommended. The STEP procedure is based on the alternate transverse application of surgical

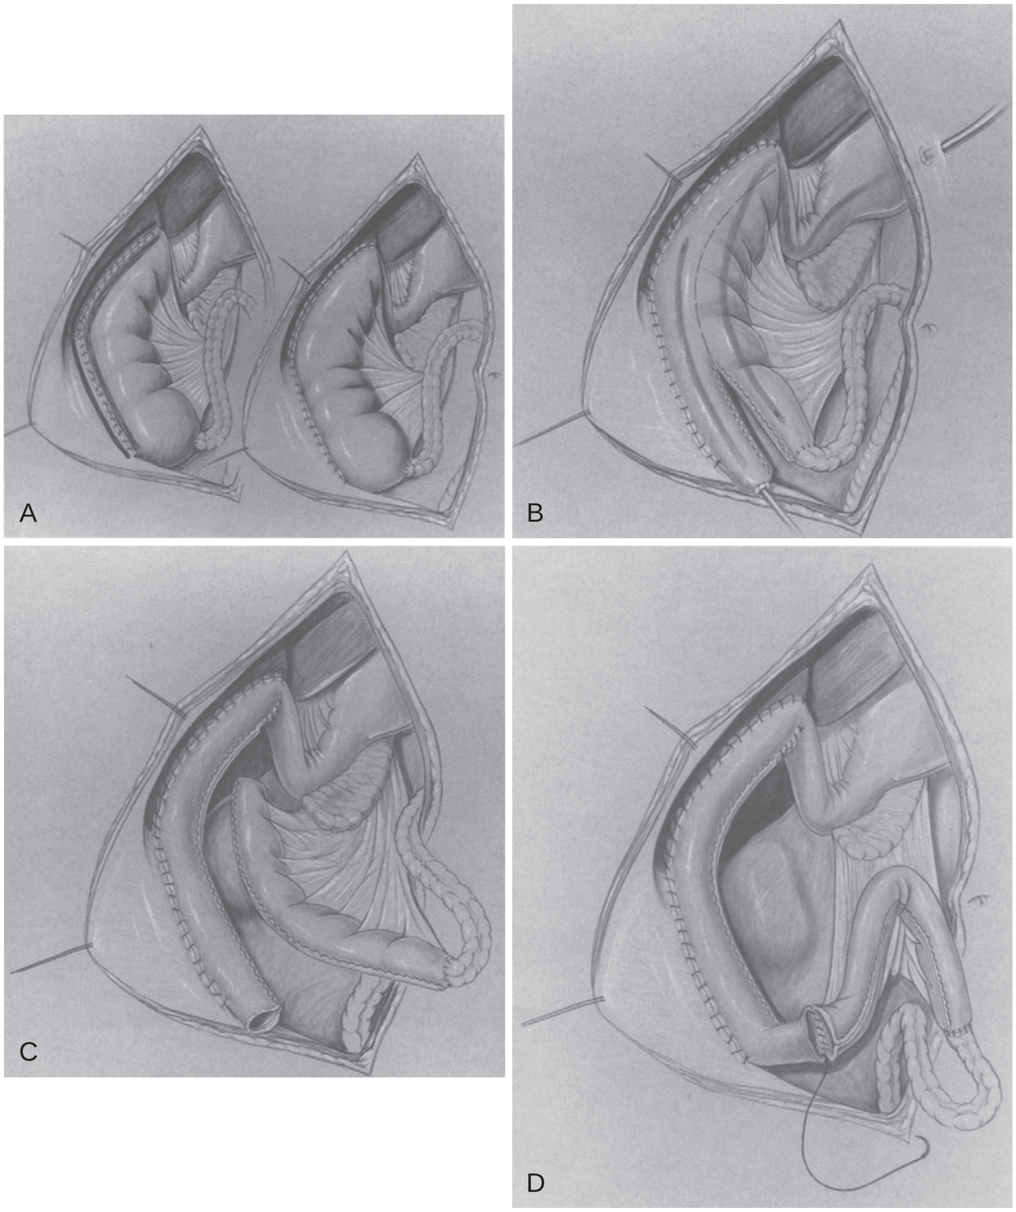

**FIGURE 88-4** Iowa procedure. **A,** Approximation of the dilated intestine to the liver and abdominal wall with a row of sutures. The creation of seromyotomies is then followed by a second row of sutures to create a hepatomyoenteropexy. **B,** Division of the bowel into two hemiloops. **C,** The newly divided hemiloops. **D,** Reanastomosis in an isoperistaltic manner. (Reproduced with permission from Kimura K, Soper RT: A new bowel elongation technique for the short-bowel syndrome using the isolated bowel segment Iowa models. J Pediatr Surg 1993;28:792-794.)

stapling devices to dilated bowel using a transmesenteric approach. A zigzag lengthening and tapering of the intestine ensues (Fig. 88-5). The post-STEP diameter of neonatal bowel is usually 1.5 to 2 cm, and in older children the final bowel width is often calibrated to the nondilated duodenal diameter. The ultimate lengthening obtained is contingent on the dilation of the original adapted bowel and can be greater than 100%. A complete video and technical review of this operation is available at http://www.orlive.com/childrenshospitalboston/videos/serial-transverse-enteroplasty-bowel-lengthening-and-tapering.

The salient advantages of this operation are that it is technically straightforward, can form a uniform bowel channel regardless of variable underlying bowel dilation, and can be repeated if the bowel subsequently redilates. Animal studies have shown that the STEP is associated with improved nutrient absorption, enhanced growth, and an overall increase in bowel surface area as reflected by elevated serum citrulline levels.[4] The latter effect is felt to be secondary to bowel adaptation that is induced by the STEP operation. Interestingly, a rodent model of the STEP has shown elevations of postprandial GLP-2 levels and increased GLP-2 receptor expression, both of which may mediate this adaptive response.[79] STEP operations performed in pigs also demonstrate that the surgery does not inhibit the migrating motor complex and hence may actually improve motility by reducing dilated bowel caliber.[80]

PN-dependent children who have been treated with the STEP operations have shown statistically significant increases in weight for age Z score, weight for height, upper arm

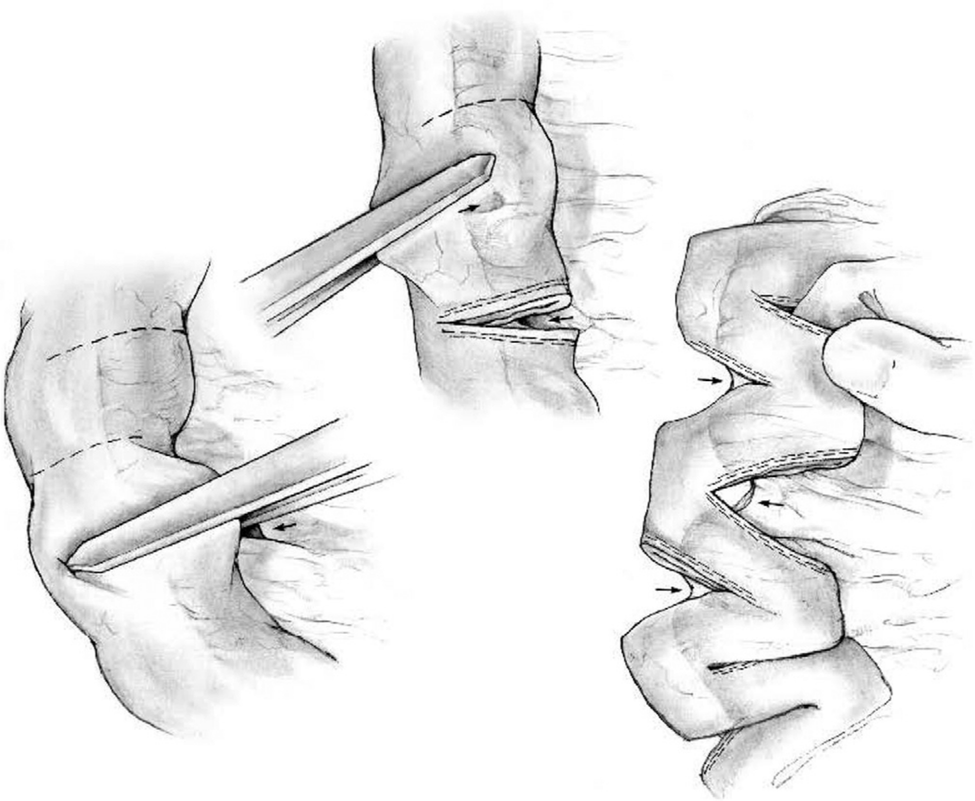

**FIGURE 88-5** The serial transverse enteroplasty. The dilated bowel is flattened, and the stapler is applied perpendicularly to the long axis of the bowel, from alternating sides. A small defect in the mesentery is created at each point of stapler application. The end result is a zigzag pattern to the lengthened bowel. (Reproduced with permission from Kim HB, Fauza D, Garza J: Serial transverse enteroplasty (STEP): A novel bowel lengthening procedure. J Pediatr Surg 2003;38:425-429.)

anthropomorphic tests, D-xylose absorption, and enteral tolerance.[81–83] As predicted from the initial animal paper, neonates with intestinal atresia have had successful bowel-preserving STEP operations on the dilated proximal bowel segment with a primary anastomosis to the distal remnant bowel.[77,84,85] Finally, the STEP has been used effectively to treat medically resistant bacterial overgrowth and D-lactic acidosis in an adolescent with SBS and segmental bowel dilation.[48]

Due to the observation that intestine dilates as it adapts, it is theoretically feasible to repeat bowel-lengthening operations. The original STEP operation case report described a child who was first treated by a LILT and then when enteral feeding advancement was not possible, a STEP was performed.[78] The LILT itself cannot be repeated because of the longitudinal mesenteric splitting that is required; however, no such technical restrictions exist for the STEP. Using a large animal model, it has been shown that an initial STEP operation can, after a period of adaptation, be safely followed by a second STEP.[86] This work has been confirmed by the clinical application of sequential STEP operations in SBS children.[87,88]

The International STEP Data Registry (www.childrenshospital.org/cfapps/step) is a voluntary web-based outcomes repository and has been helpful in tracking the results of the STEP operation. The first report of the Registry involved 19 centers with a median follow-up of 12.6 months.[89] The indications for STEP were SBS (76%), bacterial overgrowth (16%), and neonatal atresia (8%). The mean small intestine length was substantially increased in all groups, and for the SBS cohort, enteral tolerance was significantly increased from 31% to 67% of total calories. Notable complications included nonoperative bowel obstruction (5%) and fluid collection or abscess (8%). Late outcomes demonstrated progression to transplantation in 8% of patients and an overall mortality of 8%. The most recent compilation of data from the Registry was presented at the 2010 annual meeting of the Surgical Section of the American Academy of Pediatrics and consisted of 111 patients, 14 of whom had multiple STEP operations. Among the PN-dependent children, 66% showed improved enteral tolerance following the operation and 47% were weaned from PN completely. The median time to reach full enteral autonomy was 21 months.

Other promising approaches to AIRS are bowel stretch and the tissue engineering of small intestine. The application of tension across the gastrointestinal tract to induce growth has been used clinically in the treatment of esophageal atresia, and animal models using various small intestine lengthening devices have been described. These include the use of internal screws, extension struts, and Nitinol springs.[90–93] The ideal stretching modality would either induce growth rapidly or allow the lengthening bowel to remain in continuity during treatment. Using tissue-engineering principles, neonatal rat intestine has been implanted on a scaffold and anastomosed to the remaining bowel.[94] In this model weight gain, improved vitamin $B_{12}$ levels, and an increase in brush border enzymes have been noted. Further, the implantation of VEGF microspheres into the construct appeared to increase epithelial proliferation and microcapillary density.[95]

### INTESTINAL TRANSPLANTATION

The first successful combined liver intestine transplant in a patient with SBS was reported in 1990.[96] With the improvement of surgical techniques, as well as a better understanding of immunosuppression regimens, liver/intestinal and multivisceral transplantation has become feasible in neonates and children with SBS. The prime indication is progressing IFALD in the presence of intestinal failure. The decision when to transplant is a dynamic one. If IFALD can be ameliorated, transplant may be avoided. Patients with IFALD are best treated by early referral to an intestinal rehabilitation center (with transplant access). Recent data indicate that the majority of these patients will not require transplantation.[2]

The 10-year patient and graft survival for small bowel transplants that include the liver are 42% and 39%, respectively.[97] The major problems attendant with intestinal transplants remain infection, chronic rejection, poor growth while on immunosuppression (especially steroids), and posttransplant lymphoproliferative disease (PTLD). Nonetheless, liver/intestine and multivisceral transplant is a viable salvage option in selected children.

For HPN-dependent adolescents and young adults with stable liver function, a consideration of isolated intestinal transplant is sometimes warranted. Although many such patients are content with HPN, some are not. A careful appraisal of the risks inherent with isolated intestinal transplant needs to be balanced with the potential for an improved quality of life, namely being free of HPN and eating orally. Intermediate results such as receiving an intestinal graft but still requiring a central line for PN and/or hydration also need to be discussed. The decision to transplant in this cohort remains highly individualized and is hampered by a paucity of data regarding long-term quality-of-life outcomes.

## Multidisciplinary Short Bowel Program

Children with SBS require specialized, nutritional, medical, and surgical management. This has led to the evolution of intestinal failure centers across North America that, in turn, have been associated with reduced rates of morbidity and mortality.[2,98–100] The key elements of a successful SBS program include a multidisciplinary outpatient clinic, an expert inpatient ward, and a unified group of dieticians, nurses, pharmacists, social workers, gastroenterologists, and surgeons who work together. An integrated intestinal transplant service is ideal, and a close liaison with such a group is necessary. Other valuable input is derived from aligned gastrointestinal pathologists, diagnostic radiologists, interventional radiologists, endocrinologists, and speech pathologists. Commonly, SBS centers function under the joint leadership of a surgical and medical director. Although significant resources are required, multiple pediatric hospitals have recently established comprehensive regional SBS programs in an effort to enhance the quality and efficiency of care.

# CHAPTER 90

# Alimentary Tract Duplications

Dennis P. Lund

Duplications of the alimentary tract include a wide variety of mass lesions throughout the course of the gastrointestinal tract that are either tubular or cystic. The first report was by Calder in 1733,[1] and these lesions have been referred to by a number of descriptive names depending on their location and associated structures. What are now commonly referred to as *alimentary tract,* or *enteric, duplications* have been variously referred to as *giant diverticula, enterogenous cysts, ileum or jejunal duplex, giant thoracic cysts, duplications, reduplications,* and *unusual Meckel diverticula.* No single classification system adequately explains the embryology, location, and clinical manifestations of all of these lesions.

In 1937 William E. Ladd tried to simplify the nomenclature by suggesting the use of the term "duplications of the alimentary tract,"[2] and we owe the widespread use of the term to his influence. Ladd applied the term to congenital lesions having three characteristics: (1) the presence of a well-developed coat of smooth muscle, (2) an epithelial lining representing some type of intestinal tract mucosa, and (3) intimate anatomic association with some portion of the gastrointestinal tract. Ladd and Gross reported 18 such cases in their 1941 text *Abdominal Surgery of Infancy and Childhood,*[3] and Gross reported 68 cases in his 1953 text *Surgery of Infancy and Childhood.*[4] Swenson also devoted a chapter to the topic in his 1958 text *Pediatric Surgery.*[5]

Alimentary tract duplications have a reported incidence of 1 in 4500 by autopsy series[6] and can occur anywhere from the oropharynx to the anus. There seems to be a slight predominance in males.[7] A meta-analysis by Heiss of 12 large series of enteric duplications encompassing 580 patients is shown in Table 90-1. Heiss's study demonstrated that about 20% of these lesions occurred in the chest and the remainder were located in the abdomen, with a small percentage being thoracoabdominal.[8] Although the embryologic site of origin is not certain, it is common to refer to duplications as foregut, midgut, or hindgut derived, depending on their location. Enteric duplications frequently contain mucosa similar to that of their adjacent gastrointestinal location, but this is not always the case. For example, some duplications contain gastric mucosa and may cause peptic ulceration or bleeding as the presenting symptom regardless of location, and the presence of rectal mucosa has even been reported in cervical duplications. In 10% to 20% of patients, enteric duplications are multiple and the presence of one such lesion should warrant a search for others.[7]

Finally, children with enteric duplications seem to have a high incidence of other associated anomalies. Spinal malformations have been noted in a number of cases, particularly with thoracic or thoracoabdominal lesions, and intestinal malrotation or atresias have been associated with abdominal duplications. Urinary tract anomalies have been reported with midgut and hindgut malformations; and in one series, all patients with multiple duplications also had a skeletal or urinary tract anomaly.[7]

## Embryology

Ladd's motivation for use of the term *alimentary tract duplications* derived from his belief that they shared a similar embryologic mechanism. As the science of embryology has advanced, multiple theories have arisen to explain the occurrence of enteric duplications, but no single theory accounts for all the known variants. Four major theories have been implicated and are able to account for most of the variants seen.

### PARTIAL OR ABORTIVE TWINNING

The first possibility is that duplications may arise as a function of partial or abortive twinning. Doubling anomalies of the head, mouth, upper alimentary tract, hindgut, and lower genitourinary tract have been reported, and this mechanism seems most likely to account for them. Several cases that describe complete doubling of the colon, bladder, urethra, and external genitalia have been reported.[9] Some of these children had severe skeletal anomalies as well. The timing of these twinning anomalies may explain the extent of the twinning; for example, a split in the primitive streak earlier in gestation followed by subsequent caudal growth may result in complete twinning of the caudal end of the fetus, whereas a split at a later date may result in only colonic duplication.

**TABLE 90-1**
**Location of 580 Enteric Duplications**

| *Location* | *No.* | *%* |
|---|---|---|
| Cervical | 6 | 1 |
| Mediastinal | 95 | 18 |
| Thoracoabdominal | 13 | 2 |
| Gastric | 35 | 7 |
| Duodenal | 30 | 6 |
| Jejunal and ileal | 282 | 53 |
| Colonic | 68 | 13 |
| Rectal | 19 | 4 |
| Other | 3 | 0.5 |
| Total | 580 | 100 |

Meta-analysis from Heiss K: Intestinal duplications. In Oldham KT, Colombani PM, Foglia RP (eds): Surgery of Infants and Children: Scientific Principles and Practice. Philadelphia, Lippincott-Raven, 1997.

### SPLIT NOTOCHORD THEORY AND ANOMALOUS ADHESION

In 1960 Bentley and Smith postulated the theory of split notochord syndrome to describe the many anomalies involving the spine, gastrointestinal tract, and skin in the thoracic region.[10] According to this theory, in the third week of gestation (stage 8), the notochord appears growing cephalad, starting in close association with the endoderm, and normally separates from the endodermal cells. During this separation, a gap sometimes appears in the notochord through which a diverticulum from the foregut (endoderm) can herniate by incomplete detachment. These endodermal cells from the developing foregut then attach to ectoderm to form a cyst, or, if they remain attached to the notochord, may act as a barrier to later anterior fusion of the vertebral mesoderm, resulting in anterior spina bifida of the type seen with neuroenteric cysts. This mechanism may account for the dorsal location of most alimentary tract duplications in the chest and would explain those instances of spinal column anomalies associated with them. Whether it accounts for all foregut duplications is not known. A similar mechanism of anomalous adhesions may also explain the rare long duplications arising in the abdomen but seemingly tethered to the spinal column high in the chest. Such adhesions would have to occur early, possibly even before the appearance of the notochord, to account for the long distances such duplications sometimes traverse.[11]

### DIVERTICULA AND CANALIZATION DEFECTS

The fetal gastrointestinal tract goes through what some embryologists referred to as a “solid stage” after which progressive growth of the luminal side of the intestine generally from the cranial to caudal direction leads to the formation of a lumen. For years, it has been known that many diverticula exist in mammalian embryos.[12] These diverticula are most frequently located in the ileum, the site of most enteric duplications. Thus it seems reasonable to postulate that this mechanism may contribute to the formation of enteric duplications. However, this theory fails to explain instances of heterotopic mucosa, particularly that of stomach, or that the majority of duplications are in the bowel mesentery, whereas most diverticula are located on the antimesenteric side of the bowel. Bremer postulated that some enteric duplications result from errors in canalization of the intestine.[13] Moutsouris, who examined many embryos, thought this might also play a role in the formation of atretic segments.[14] What is clear is that the lumen is normally completely restored by the 18-mm stage. Bremer suggested that duplications arise as a result of incomplete or defective vacuolization of the intestine. This theory explains the presence of duplications without associated anomalies but suffers from many of the same shortcomings of the diverticula theory.

### ENVIRONMENTAL FACTORS

Lastly, it is known that there are significant environmental stresses on the fetus at different times. Mellish and Koop postulated that trauma and hypoxia could induce duplications and attempts at twinning.[15] This theory is supported by data that suggest other anomalies, particularly intestinal atresias, may be induced by intrauterine vascular accidents.[16] These embryologic theories are indeed theories, and it is unclear which, if any, play a role in the development of enteric duplications. It is clear, however, that during embryologic development, there is much tissue growth, differentiation, migration, preprogrammed cell death, and tissue adherence. Disorders of any of these mechanisms of development may be involved in the formation of enteric duplications. Most likely, just as there are many forms of malformations known as *enteric duplications,* there are also many factors leading to their development.

## Clinical Manifestations

Enteric duplications are generally cystic or tubular masses. They present in a variety of ways depending on their size, location, adjacencies, and whether they contain heterotopic gastric mucosa. The majority of duplications are diagnosed in the first 2 years of life. Frequently, the presenting symptoms of an enteric duplication can be confused with other gastrointestinal pathology such as acute appendicitis. Many duplications will have few or no symptoms and are found incidentally in the pursuit of symptoms such as cough, abdominal pain, or gastroesophageal reflux. The diagnosis of enteric duplication may be made by prenatal ultrasonography. Cystic masses appear as black holes on ultrasonography and are therefore easily seen if they are of sufficient size.[17]

If the mass is in the chest, it may present as wheezing, pneumonia, or dysphagia that may prompt a chest radiograph. Other potential symptoms include failure to thrive, respiratory distress, and vomiting. Chest pain is a rare symptom unless the mass acutely enlarges from hemorrhage or infection.

Abdominal pain, vomiting, and an abdominal mass are the most common symptoms and signs attributable to enteric duplications located in the abdomen.[18] Because a duplication is a cystic mass, acute distention with secretions or infection of the mass may cause severe abdominal pain. If the duplication contains heterotopic gastric mucosa, ulceration and bleeding or even perforation may result. An acutely enlarging cystic mass may cause obstruction of the adjacent bowel and result in nausea, vomiting, and cramping. A large duplication may even cause localized volvulus of the adjacent intestine. A mobile mass may be palpable in up to 50% of patients.[19] Gastric

and duodenal duplications may cause vomiting, abdominal distention, melena, and perforation. Gastric duplications in particular may be quite large. Duplications in the stomach have also been reported to present similar to hypertrophic pyloric stenosis with gastric outlet obstruction.[20] Duodenal duplications, which most often present with abdominal pain,[21] may be a cause of recurrent pancreatitis and may result in significant morbidity.[22]

Duplications of the midgut or hindgut are more likely to cause abdominal pain, distention, melena, or perforation. Those arising in the ileum may be confused with acute appendicitis and may be difficult to diagnose preoperatively. Small bowel duplications may also present as intussusception by acting as a lead point.

Colon and hindgut duplications may simply present as a second opening on the perineum. In females, this opening may be in the back wall of the vagina, suggesting the possibility of a rectovaginal fistula.[23] Hindgut duplications may also cause symptoms by mass effect, obstructing the urinary tract or causing severe constipation, particularly if they are intrapelvic. Presacral duplications can mimic sacrococcygeal tumors such as teratoma or dermoid cyst.

## Diagnosis

Antenatal diagnosis of duplications of the alimentary tract is becoming much more common because of the availability of prenatal ultrasonography. Experience with antenatal diagnosis began to appear in the literature as early as 1984,[24] but reports were rare. As more experience was acquired over the ensuing decades, the majority of cases were identified in the chest or the upper abdomen, where they were more easily visualized by ultrasound. Chest lesions may occasionally cause hydrops fetalis as a result of mediastinal shift and are managed with in utero thoracoamniotic shunting.[25] By 2000, 14 abdominal cases of duplication were diagnosed antenatally.[26]

The experience in prenatal ultrasound detection has increased rapidly: By 2003, the group in Montreal reported their 22-year experience with enteric duplications and described 18 patients who had a prenatal diagnosis.[27] Interestingly, in their cohort of neonates with the diagnosis of enteric duplication, the incidence of volvulus was 23.8%, arguing for either early surgical intervention or close postnatal follow-up when the prenatal diagnosis of enteric duplication is made.

The history and physical examination are extremely important in establishing any diagnosis, and this is no different in the case of an enteric duplication. The history may include the symptoms just mentioned, and on physical examination an abdominal mass may be palpable. The mass is typically boggy and mobile and may or may not be tender depending on the child's symptoms. Chest masses may be accompanied by locally diminished breath sounds if the mass is large. Laboratory evaluation is of little help except that the child may be anemic if the lesion has caused bleeding because of heterotopic gastric mucosa. The patient with a duplication cyst in the head of the pancreas may have elevated serum amylase and lipase levels along with the other manifestations of pancreatitis.

Postnatal diagnosis can also be aided by ultrasound examination because these lesions are usually quite visible. The cysts are typically anechoic on ultrasonography unless there had been ulceration and bleeding. The wall is typically 2 to 3 mm thick because it is composed of smooth muscle and mucosa, as opposed to other types of cysts such as mesenteric, omental, or ovarian cysts, which are typically larger and have a simpler wall. The mucosal lining of an enteric duplication cyst produces a characteristic echogenic signal on the inside of the cyst (Fig. 90-1).[27a] Other forms of ultrasound such as in endoscopic ultrasonography[28] have been used to accurately diagnose enteric duplications, particularly in the foregut.

Other radiologic studies such as plain radiographs, gastrointestinal contrast studies, and computed tomography (CT) or magnetic resonance imaging (MRI) may assist in the diagnosis and localization of the mass (Fig. 90-2). Gastrointestinal contrast often will not image the lesion per se because cystic duplications do not communicate with the intestine. However, gastrointestinal imaging may show an impression from the mass on the intestine and can be helpful in the diagnosis

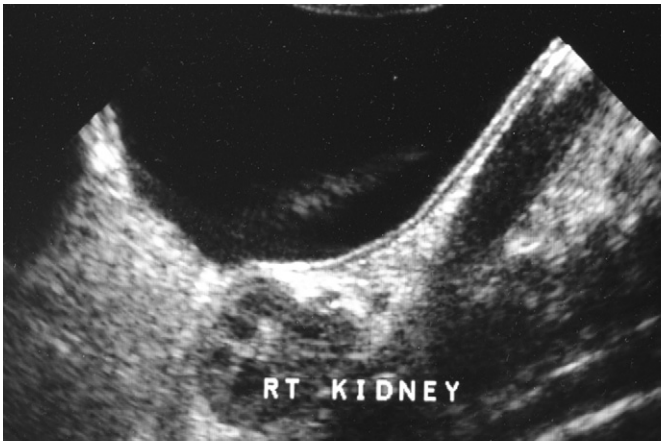

**FIGURE 90-1** Ultrasound study of an ileal duplication shows the characteristic echogenic signal of the mucosal lining.

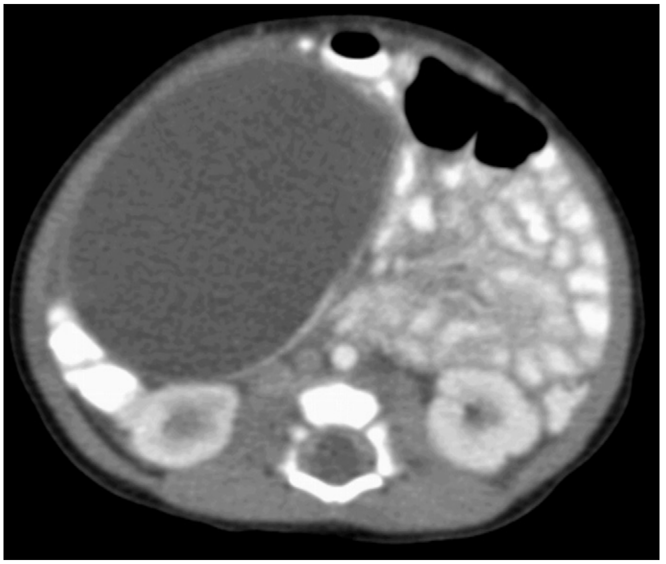

**FIGURE 90-2** Computed tomography scan demonstrates a large cystic mass in the region of the head of the pancreas that turned out to be a duodenal duplication. (Courtesy Dr. Aimen Shaaban.)

FIGURE 90-3 A barium enema study shows anterior compression of the rectum from a rare anterior rectal duplication.

(Fig. 90-3). On CT, enteric duplications typically appear as cystic masses with an enhancing rim and can therefore be confused with an abscess (Fig. 90-4). However, in the absence of a clinical picture of sepsis (e.g., fever and elevated white blood cell count), such an image on CT should suggest an enteric duplication rather than an abscess. Preoperative investigation of other structures including the urinary tract may be necessary to delineate the extent and the impact of the duplication on surrounding structures and may influence the safe treatment of the lesion.

Midgut and hindgut duplications may be more difficult to diagnose, and their diagnosis is often made at operation.

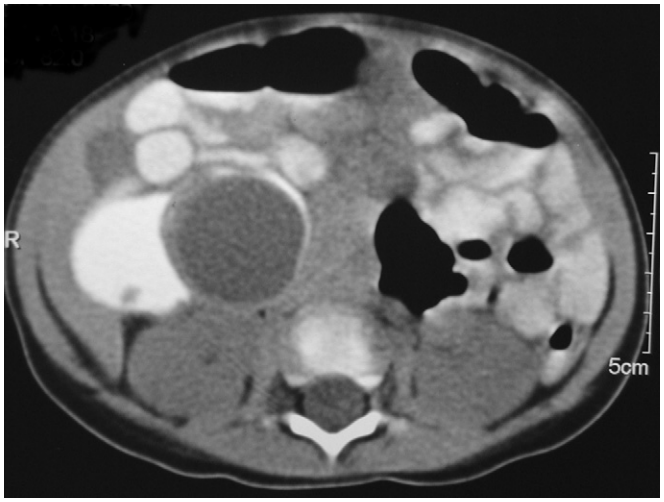

FIGURE 90-4 Computed tomography scan from an infant showing a cystic duplication of the ileum with an enhancing rim.

These lesions may present as volvulus or intussusception and are discovered only at exploration. In a child with anemia and abdominal pain, it may be helpful to evaluate the child with a technetium-99m pertechnetate scan just as one would use to diagnose Meckel diverticulum because ectopic gastric mucosa will concentrate the agent.[29] In fact, enteric duplications are often confused with Meckel diverticulum because many of them are located in the ileum. Therefore the wary surgeon should always include both conditions in the differential diagnosis when evaluating a patient for either.

## Cervical Esophageal Duplications

Duplication cysts of the cervical esophagus are exceedingly rare. A recent case report and literature review cites 18 cases requiring surgical intervention.[30] Almost all such cases present early in life with respiratory distress that can be life threatening. Symptoms often appear before a mass is apparent. Intubation, rapid diagnosis, and intervention are often necessary. The mass may be appreciated on physical examination, but CT is the best diagnostic modality. The differential diagnosis includes other cystic masses of the neck such as lymphatic malformations and cysts of the airway or bronchial apparatus, or thyroglossal cysts. Treatment consists of excision if possible. If complete excision is not possible, the mucosa should be removed from the duplication to allow for obliteration of the cyst cavity.

## Thoracic and Thoracoabdominal Duplications

Approximately 20% of alimentary tract duplications arise in the thorax or are thoracoabdominal. In the differential diagnosis of mediastinal masses in infants and young children, enteric duplications are second only to neurogenic tumors.[31] The majority of lesions are located in the lower half of the posterior mediastinum and may protrude into either hemithorax, or even both. Many of these fall into the class of lesions also referred to as *neuroenteric cysts* because they are associated with connections from the enteric duplication to the spinal canal with associated vertebral anomalies. There is also a class of rare cystic lesions existing in the central nervous system such as in the cerebellum or the optic nerve, without connection to the gastrointestinal tract but containing heterotopic gastrointestinal mucosa that cause symptoms by local pressure on the nervous structure.[32,33] Although neuroenteric cysts are most common in the thoracic region, they may occur in other locations where they make up a much smaller percentage of the enteric duplications seen below the diaphragm.[34] Lesions in the thorax should be suspected when vertebral anomalies are noted. Almost all patients with neuroenteric cysts have vertebral anomalies, but not all enteric duplications in the thorax are neuroenteric. In one series, 5 of 21 patients with thoracic duplications had vertebral anomalies.[35]

When thoracic lesions have been identified on prenatal ultrasonography, attempts at in utero therapy have been made in the setting of fetal distress such as hydrops.[25] The most common symptom of a thoracic enteric cyst is respiratory

distress, although often they are asymptomatic and may be noted on routine radiographs taken for other reasons.[7,35] Occasionally, enteric duplications may be noted in association with other anomalies such as esophageal atresia or diaphragmatic hernia. The combination of a thoracic enteric duplication with other anomalies including spinal anomalies should prompt a search for multiple duplications because these may occur in up to a third of cases. Once a cystic mass is suspected in the chest, the best technique for evaluation of the lesion is CT, which should include the abdomen because one fourth of thoracic enteric duplications are associated with a second duplication in the abdomen.[35,36] A barium swallow study may be helpful to delineate the relationship of the duplication to the esophagus and to help with operative planning (Fig. 90-5). An echocardiogram may also be helpful if a pericardial cyst is suspected; although the vast majority of enteric cysts will occur in the posterior mediastinum, pericardial cysts are more likely to be located in the anterior or middle mediastinum. Finally, if the cyst is neuroenteric, MRI of the spine will be helpful to detail the intimate nature of the cyst with the spinal column and spinal canal. MRI has largely replaced the use of myelography for this purpose.

Treatment of thoracic and thoracoabdominal alimentary tract duplications consists primarily of excision, and this should be performed whenever possible. Removal may be accomplished thoracoscopically, although this is not always possible. Decompression of the cyst may assist in removal, but often the dissection is aided by leaving the cyst intact as long as possible if the cyst is small. Cysts in the wall of the esophagus can be removed by opening the esophageal muscle and performing an extramucosal excision of the cyst, leaving the esophageal mucosa intact. After cyst removal, particularly if the removal was performed through the thoracoscope, the surgeon must be sure that the esophageal lumen was not entered by instilling fluid or air in the lumen. An unrecognized esophageal leak will lead to mediastinitis and severe morbidity.

If there is an intraspinal component to a neuroenteric cyst, collaboration should be sought with a neurosurgeon and the intraspinous portion of the cyst should probably be removed first. This will lead to less morbidity from the potential for meningitis and will reduce postoperative swelling when the cyst is removed.

Large thoracoabdominal cysts may be removed in a staged manner to avoid the morbidity of a thoracoabdominal incision. When undertaking a staged approach, the remaining portion of the duplication must have a mechanism for decompression (e.g., drainage into the intestine), avoiding postoperative sepsis due to leakage from an obstructed cyst. In cases in which the entire cyst cannot be removed, it is important to remove the entire mucosal lining so that the cyst cavity does not recur and potential ectopic gastric mucosa is removed. Curettage and gauze packing of the cyst cavity to promote sclerosis are discouraged because these forms of treatment have higher complication rates than complete removal or formal mucosal stripping.

## Abdominal Foregut Duplications

Gastric and duodenal duplications, most of which are cystic, can often be quite large (Fig. 90-6) and are frequently symptomatic. They cause symptoms due to mass effect and pressure on surrounding structures, resulting in gastric outlet obstruction, pancreatitis,[22] or ulcer-type symptoms from unbuffered hyperacidity with poor feeding and abdominal pain. In infants they may mimic hypertrophic pyloric stenosis.[37]

**FIGURE 90-5** Barium swallow study shows compression of the midesophagus from an esophageal duplication. This teenage boy presented with chest pain, and the duplication was resected thoracoscopically.

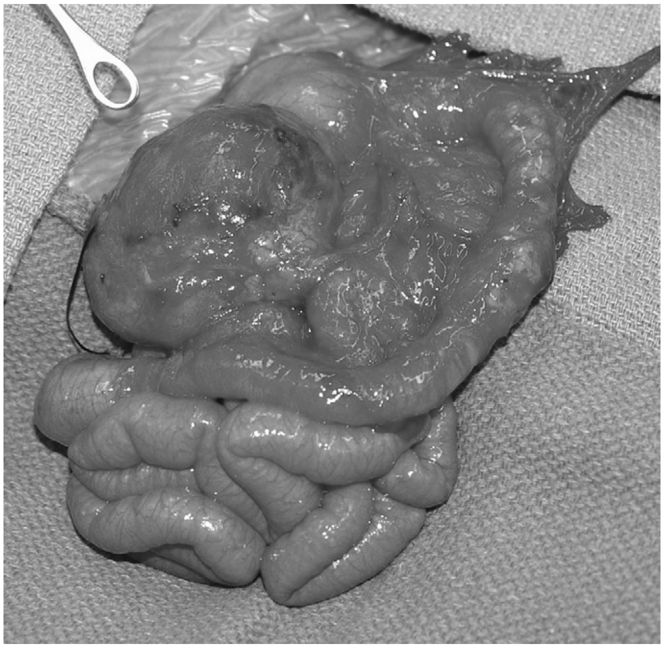

**FIGURE 90-6** This cystic mass occurred in an infant with vomiting and gastric outlet obstruction and was completely resected. The computed tomography scan of this giant duodenal duplication is shown in Figure 90-2. (Courtesy Dr. Aimen Shaaban.)

The term *gastric duplication* can be somewhat confusing because it is sometimes used to refer to lesions in association with the stomach, and some may use this term to refer to lesions containing ectopic gastric mucosa, regardless of their location. For purposes of this discussion, the term *gastric duplication* refers to those lesions associated with the stomach, which most often occur on the greater curvature. Patients typically present at a young age, and a palpable mass is frequently present. These lesions may be seen on antenatal ultrasonography.[38] Signs and symptoms may include failure to thrive, vomiting, anemia, gastroesophageal reflux, and abdominal pain. Such lesions may lead to perforation with pneumoperitoneum[39] or spontaneous hemoperitoneum.[40] Ultrasound evaluation is typically diagnostic of a large cystic mass in the upper abdomen and differentiates this lesion from hypertrophic pyloric stenosis. If the mass is in the right upper quadrant, it can be confused with a choledochal cyst, but foregut duplications are not usually associated with jaundice unless they obstruct the common bile duct. Upper gastrointestinal contrast studies may help delineate the extent of the lesion and its relationship to the stomach, duodenum, and pancreas.

The treatment of a gastric duplication is resection. Frequently, these lesions are large or may be intimately involved with either the gastroesophageal junction or the pylorus. Resection without violating the lumen of the stomach is ideal but often impossible. Segmental gastric resection or even partial cyst resection with mucosal stripping might be necessary. A gastrostomy or even a feeding jejunostomy may be beneficial if gastric emptying is likely to be prolonged after resection. Finally, the surgeon should be aware of the rare instance of communication of a gastric duplication cyst with the pancreatic ductal system, although this is more likely to occur with duplications arising in the duodenum.[41]

Duodenal duplications may present as biliary or pancreatic symptoms such as jaundice or pancreatitis. Symptoms are typically vague, consisting of upper abdominal pain with or without nausea and vomiting (80%),[21] early satiety, or failure to thrive. The lesions are most commonly located in the medial and posterior portions of the second and third portions of the duodenum. These cysts may be confused with choledochal cysts, especially if the major symptom is jaundice. Recurrent bouts of pancreatitis have also been reported. These lesions most commonly contain duodenal or small intestinal mucosa and may occasionally communicate with the lumen of the duodenum. A mass compressing the duodenum may be noted on upper gastrointestinal series or ultrasonography during an investigation of vague abdominal symptoms. It is especially important to have good imaging preoperatively with duodenal duplications. CT, endoscopic retrograde cholangiopancreatography, and MR cholangiography may all be helpful to determine the relationships of the cystic mass with the pancreas and the biliary tree.

Although endoscopic or percutaneous drainage of a duodenal duplication may be possible, the preferred treatment is resection. In certain cases in which resection would have the potential for significant morbidity, internal drainage may also be safe and efficacious. The treating surgeon must have command of a variety of techniques to perform such procedures because these cases can be challenging. For example, localized duodenal resection and reconstruction may suffice,[42] but marsupialization of the cyst to the duodenum or to a Roux-en-Y loop of intestine may be preferable depending on the anatomy of the lesion. Finally, a pancreaticoduodenectomy (Whipple procedure) may occasionally be necessary to adequately deal with the cyst.[22] Whatever procedure is chosen, it is safest to use intraoperative cholangiography to ensure that the biliary tree is intact and unobstructed after the cyst is treated. In cases in which the cyst contains gastric mucosa, it is wisest to remove all such ectopic gastric mucosa either by cyst excision or mucosal stripping.

## Duplications of the Small Intestine

Duplications found in proximity to the small intestine are the most common enteric duplications encountered, and the majority of these occur in the ileum. They may be either cystic or tubular, and most are located on the mesenteric side of the intestine, unlike Meckel diverticula, which occur on the antimesenteric side of the intestine. Frequently, the duplication shares its muscular wall and blood supply with the adjacent intestine such that the duplication resides in the leaves of the mesentery. This has implications for treatment of the duplication in that resection of the duplication may necessitate resection of the adjacent bowel. Communication with the lumen of the intestine may be variable. Increasingly, intestinal duplications are diagnosed as an intestinal anomaly on prenatal ultrasonography.

Signs and symptoms due to small intestinal duplications may vary as well, but abdominal pain and/or a mass are the most common. Small cystic duplications can act as a lead point for small bowel intussusception or result in localized volvulus. If the duplication enlarges or swells, it can lead to compression of the adjacent intestine and cause obstructive symptoms. This is more likely if the duplication is tubular and has a proximal communication with the bowel. Duplications that have a distal communication are less likely to become engorged or cause obstructive-type symptoms. Some duplications contain ectopic gastric mucosa that can cause peptic ulceration, bleeding, or perforation. Those with ectopic gastric mucosa can be diagnosed by technetium-99m pertechnetate scanning (Meckel scan), and patients who pass blood per rectum should be evaluated with this test. Frequently, the correct diagnosis of a duplication is not made until an operation is undertaken.

In a report from Beijing Children's Hospital, Li and colleagues[43] studied the blood supply of small intestinal duplications in 80 cases. They characterized two types of duplications on the basis of their blood supply. In type I lesions (parallel type), the duplication seemed to be more to one side of the mesentery with an artery supplying the duplication while the opposite vessel went directly to the native bowel. In type II lesions (intramesenteric type), the duplication was truly centered in the mesentery and vessels from both sides of the mesentery traversed the duplication to get to the native bowel. Li and colleagues[43] found that type II lesions represented the minority of lesions (24.6%), but more than 90% of these lesions were associated with thoracic vertebral anomalies, whereas only 5% of type I lesions had spinal anomalies. The authors cited these findings to argue that these two types of intestinal duplications must have different embryologic causes. They also suggested that knowledge of the vascular

anatomy of intestinal duplications allows for resection of these lesions without the need for resection of the adjacent bowel.[43]

Optimal treatment for small intestinal duplications is removal. In the case of cystic duplications, this is usually accomplished by excising the duplication with its adjacent bowel with primary reanastomosis (Fig. 90-7). This can be done either by open or by laparoscopic technique.[44–46] Laparoscopy may also be a useful adjunct to open operation to diagnose these lesions and to allow for decompression of large lesions in order to do an open resection through a much smaller incision. Limited resection should have no deleterious effect on the patient. If resection is not possible, one may drain the lesion into a Roux-en-Y loop of small intestine or create a large window to adjacent intestine. At the time of operation, it is wise to thoroughly inspect the length of the intestine because of the high incidence of multiple lesions in these patients. There have also been reports of duplications in association with intestinal atresia, which would present in the newborn period.[35] Infants who have duplications diagnosed on prenatal ultrasonography do not need to undergo resection in the neonatal period unless they present with bowel obstruction. However, resection should be undertaken within a few months to avoid complications such as obstruction or volvulus, and these patients should be followed closely. At least six cases of adenocarcinoma arising in small intestinal duplications, mainly later in life, have been reported, so these lesions should not be left indefinitely if they can be resected without much morbidity.[47]

Long tubular duplications of the small intestine represent a greater surgical challenge, particularly if resection of the adjacent intestine would lead to short-bowel syndrome. Ectopic gastric mucosa, if present, should be removed, either by limited resection or by mucosal stripping, because this can lead to bleeding or perforation. The duplication should be carefully inspected and the mesentery opened to ascertain if it is possible to resect only the duplication while leaving the adjacent intestine intact. The technique pioneered by Bianchi for longitudinal intestinal lengthening can be used for the mesenteric dissection.[48] Finally, creation of large windows (marsupialization) between the duplication and the adjacent intestine both proximally and distally may suffice so that the duplication is well drained. This can easily be accomplished with a linear gastrointestinal stapler. If marsupialization is chosen for treatment, these patients must be followed in case they later develop symptoms that may be secondary to retained gastric mucosa.

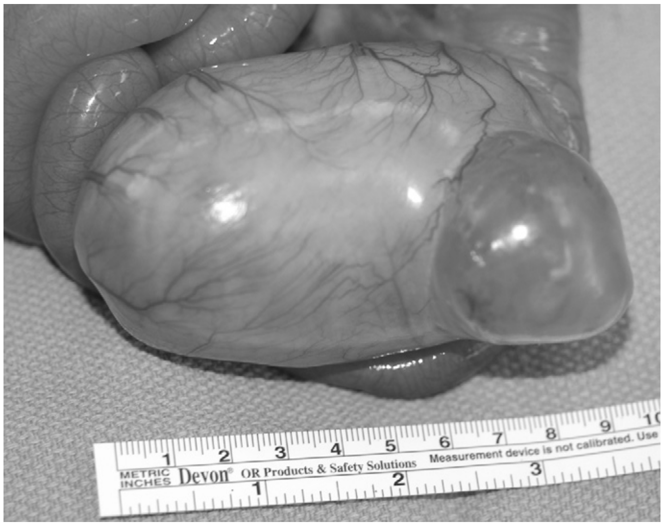

**FIGURE 90-7** This cystic duplication of the ileum with the adjacent 5 cm of bowel was resected from a 2-month-old girl. Intestinal continuity was reestablished with a primary anastomosis. This mass was diagnosed on prenatal ultrasonography.

## Hindgut Duplications

Duplications of the colon and rectum constitute about 17% of all enteric duplications. They can be simple cystic lesions in the wall or mesentery of the colon or quite extensive, running the entire length of the colon and emerging on the perineum as a separate opening, sometimes in the back wall of the vagina They also may be associated with abortive twinning anomalies and have been reported in conjoined twins[49] and with duplication or other anomalies of the urinary tract and the genitalia,[50] in which case these complex anomalies may also be associated with lower spinal anomalies. Colonic duplications usually contain colonic mucosa and rarely contain ectopic gastric mucosa. Rectal duplications typically are cystic masses of variable size that present in the presacral space behind the rectum, although occasional anterior masses are seen (see Fig. 90-3). They can present in the newborn period or any time later in childhood, and even occasionally in teenagers (Fig. 90-8).

There seem to be three general classes of hindgut duplications. The first are the cystic or short tubular masses that reside in the mesentery of the colon and are analogous to many midgut duplications. These tend to be rare. The second are the masses that reside in the midline, usually in front of the sacrum or coccyx and behind the rectum. These will sometimes be intimately involved in the blood supply of the rectum, especially if they extend upward into the abdomen,

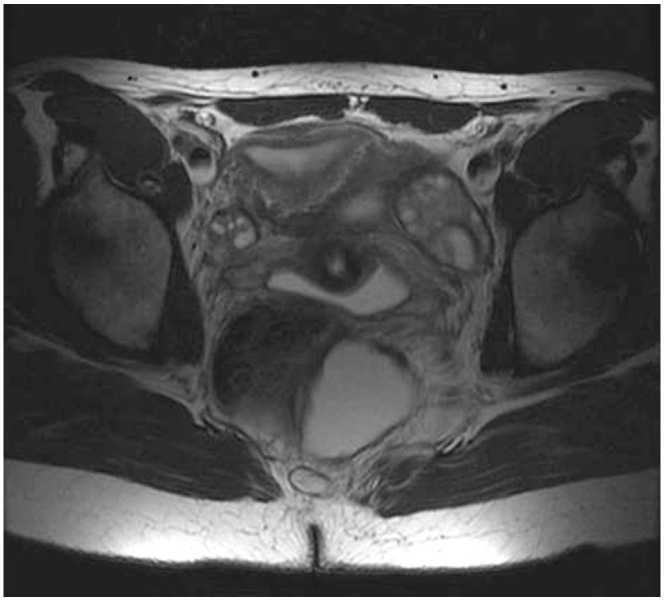

**FIGURE 90-8** Magnetic resonance image in a 17-year-old girl with a rectal duplication that became infected. It was initially treated with percutaneous external drainage followed by subsequent resection using a posterior sagittal approach.

and may require extensive resection and reconstruction. Other times, they are much more like cystic masses that can be excised without interfering with the blood supply of the rectum. Finally, there are side-to-side duplications of the colon and rectum that can vary in length and location. These tend to occur more frequently in females and may be associated with other lower abdominal and caudal anomalies such as genitourinary anomalies or spina bifida. Treatment of these lesions can be quite complex and frequently involves partial resection and/or fenestration of the extra lumen.

Given the myriad of duplications that occur in the hindgut, it is not surprising that there may be a wide variety of symptoms associated with them. A cystic mass may be present, or there may be distention and obstructive symptoms. Many are minimally symptomatic or may be associated with vague abdominal pain, constipation, or failure to thrive. Duplications that open into the vagina can present with signs and symptoms of rectovaginal fistula (Fig. 90-9), such as passing gas or stool through the vagina. Rectal duplications can present as pain or rectal obstruction. Rare cases can also be associated with urinary obstruction or retention. They can be confused with perirectal abscesses or fistulas if they become infected. Other presentations include rectal bleeding or prolapse.[51]

The diagnosis of hindgut duplications may be difficult. Accurate imaging and preoperative evaluation with CT, MRI, and sometimes a barium enema are essential to determine proper treatment. Second openings on the perineum may be studied by retrograde injection of contrast media. Rectal duplications should be evaluated by CT or MRI, which will show the extent of the lesion, as well as the relationship to the rectum, spine, and urinary tract. A triad of findings—presacral mass, rectal stenosis, and sacral bony anomalies—known as the Currarino triad is inherited in an autosomal dominant condition.[52] Just as with some small intestinal duplications, short or cystic hindgut duplications may sometimes only be diagnosed at the time of operation. Technetium scanning is rarely helpful because hindgut duplications rarely contain gastric mucosa.

As with most enteric duplications, surgical removal (when possible) is the optimal treatment. With short cystic duplications of the colon, this may be done with only a limited colon resection or simply by "shelling out" the lesion from the mesentery.

If a presacral duplication presents as an abscess, it is wise to drain it externally rather than through the rectum. Transrectal drainage leads to contamination of the lesion with fecal flora and recurrent abscess formation. Midline presacral rectal duplications can frequently be removed using a posterior sagittal approach,[53] sometimes with an associated limited rectal wall resection but often without. A nerve stimulator may be helpful to delineate the pelvic and sphincteric muscle during

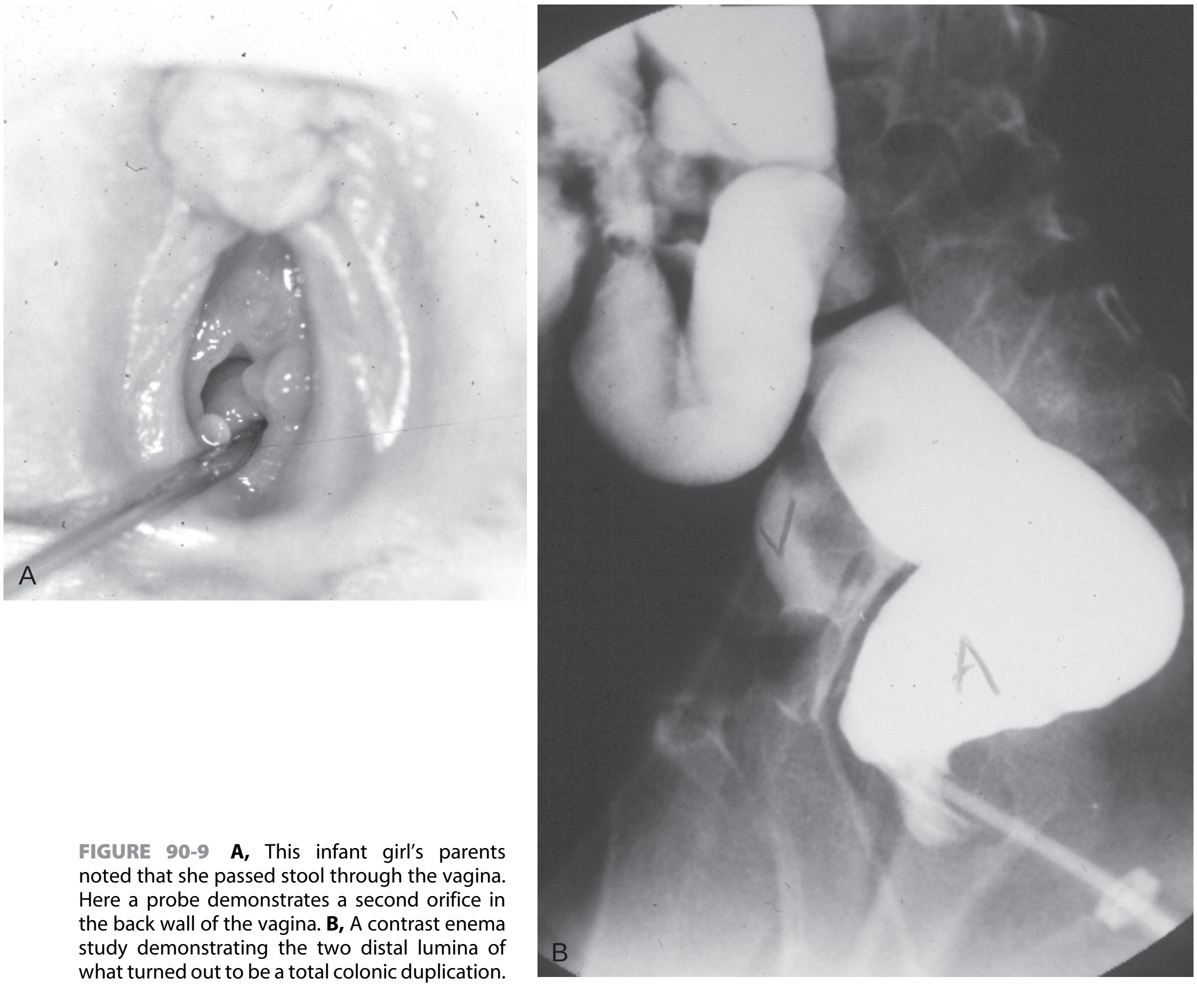

**FIGURE 90-9** **A,** This infant girl's parents noted that she passed stool through the vagina. Here a probe demonstrates a second orifice in the back wall of the vagina. **B,** A contrast enema study demonstrating the two distal lumina of what turned out to be a total colonic duplication.

the dissection and during the reconstruction. It is always wise to have the bowel prepared preoperatively if possible in case bowel resection is required. It is also wise to "prep" the patient in the operating room in such a way that a combined abdominal and perineal approach is available if necessary. Midline duplications in front of the rectum are fortunately rare but represent a formidable surgical challenge. Resection is difficult and dangerous because it may be necessary to move the rectum out of the way to resect the lesion, and there is risk to the bladder neck and sphincter. In some cases, these procedures may be approached from above with removal of the mucosa from the lesion while leaving the muscular wall in place. If anatomic distortion or extensive inflammation is anticipated, stenting the ureters immediately before laparotomy may aid in dissection. To avoid the risk of pelvic sepsis, the surgeon should always be prepared to use a temporary diverting colostomy when the resection and reconstruction become tenuous or complicated. The most common complication of resection of a rectal duplication is recurrence if all the mucosa of the duplication is not removed.

Long tubular duplications of the hindgut require a creative surgical approach. Resection often would require total or significant subtotal colectomy due to the shared blood supply of the native bowel and the duplication. This is not usually a desirable option in a small child. Also, there are frequently variations of the duplication in the region of the ileocecal valve; for example, there may be a cystic component in the distal ileum with a long tubular component adjacent to the colon.[23] Finally, if there is a portion of the duplication opening onto the perineum or into the genitourinary tract, that communication also must be treated. Cases of long side-by-side duplication of the colon may be treated by fenestrating the two lumina extensively both proximally and distally. This can be done through a colotomy at either end using a linear stapling device or a hand-sewn side-to-side anastomosis. If there is an opening to the perineum, the distal portion of the duplication that does not pass through the sphincter mechanism (e.g., a pathway that opens into the back wall of the vagina) should ideally be resected and the mucosa should be removed or at least be left so that it is well drained and separated from the fecal stream. To adequately treat such duplications, the surgeon may have to move the rectum or reconstruct the sphincter complex after resection.

## Conclusion

Intestinal duplications may present in diverse ways and encompass a wide variety of lesions from the neck to the anus. They can be simple and cystic, complex, multiple, or tubular. They can have other anomalies associated with them including spinal and genitourinary anomalies. Optimal treatment is resection, but in complex cases a variety of approaches may be required including fenestration or mucosal stripping. With proper treatment, children born with enteric duplications should do well and have excellent long-term outcomes and quality of life.

CHAPTER 91

# Mesenteric and Omental Cysts

Richard R. Ricketts

Mesenteric and omental cysts are rare; the incidence is approximately 1 per 105,000 admissions to general hospitals and 1 per 20,000 admissions to pediatric hospitals.[1,2] Modern series show that nearly one third of mesenteric cysts occur in children younger than 15 years and that one fourth occur in patients younger than 10 years.[3–5] These cysts are reportedly more common in females than in males and in white persons than in nonwhite persons.[4,6–10] In pediatric series, however, the age range is from birth to 18 years (mean, 4.35 years) and the cysts occur slightly more often in males (60%). The experience reported in this chapter is with 16 children admitted to Children's Healthcare of Atlanta at Egleston over 30 years.

## History

A mesenteric cyst was first recorded in an autopsy of an 8-year-old boy by the Florentine anatomist Benevieni in 1507.[11] In 1842 vonRokitansky[12] first described a chylous mesenteric cyst; Gairdner[13] reported an omental cyst in 1852. The first successful surgery for a cystic mass in the mesentery was performed by the French surgeon Tillaux[14] in 1880. Pean performed the first successful marsupialization of a mesenteric cyst in 1883.[9] In 1890 Carson presented the first U.S. report of a chylous cyst of the mesentery.[11] An estimated 600 cases of mesenteric cysts were recorded in the literature by 1950.[9] By 1994 that number had grown to 820 patients.[15,16] Since then there have been several series reported in children[3,17–19] and adults,[20] bringing the total to about 1000 cases.

## Embryology

Several mechanisms have been suggested to account for the development of mesenteric and omental cysts including failure of the embryonic lymphatic spaces to join with the venous system, deficiency of the normal lymphaticovenous shunts in perinodal tissue, failure of the leaves of the mesentery to fuse, occult trauma, neoplasia, and localized degeneration of lymph nodes.[11,21] The most commonly accepted theory, proposed by Gross,[22] is benign proliferation of ectopic lymphatics in the mesentery that lack communication with the remainder of the lymphatic system. These cysts are thought to arise from lymphatic spaces associated with the embryonic retroperitoneal lymph sac, analogous to cystic hygromas of the neck arising in association with the jugular lymph sac.[23] The role of lymphatic obstruction is questionable because experimental occlusion of lymph channels in animals fails to produce these cysts owing to the rich collaterals in the lymphatic system.[11,21,23] In addition, obstructed lymphatics have not been demonstrated with lymphangiography.[9] As of now, there is no conclusive evidence accounting for the embryologic events leading to the formation of these cysts.[24]

## Classification Systems

Beahrs and colleagues[11] classified cystic disease of the mesentery into four categories on the basis of possible etiology: embryonic and developmental cysts, traumatic cysts, neoplastic cysts, and infective cysts. In this system, mesenteric, omental, retroperitoneal, dermoid, urogenital, and enteric duplication cysts would be classified as "embryonic and developmental." Traumatic and infective cysts would have no endothelial lining. "Neoplastic" cysts would include cystic lymphangiomas.[24] This classification system creates confusion in terminology because most mesenteric and omental cysts in children are actually benign proliferation of lymphatic tissue and thus could be considered "neoplastic" or "embryonic."

Some authors differentiate between cystic lymphangiomas and mesenteric-omental cysts on the basis of histology.[3,21,25–27] Cystic lymphangiomas are simple cysts with an endothelial cell lining, foam cells, and thin walls that contain small lymphatic spaces, lymphoid tissue, and smooth muscle. The wall of a mesenteric cyst lacks smooth muscle and lymphatic spaces, and the lining cells are cuboidal or columnar.[21] Lymphangiomas occur in the mesentery or retroperitoneum and tend to present early in life with acute abdominal symptoms, whereas mesenteric cysts are limited to the mesentery and present in adulthood as asymptomatic masses.[21,25]

A more recent classification system, that of de Perrot,[28] is based on the origin of the cyst: lymphatic origin (lymphangioma); mesothelial origin (mesothelial cyst, cystic mesothelioma);

enteric origin (duplication cysts); and urogenital cysts, cystic teratomas (dermoid), and nonpancreatic pseudocysts (traumatic and infectious).

Because the evaluation and therapeutic objectives for mesenteric, omental, and retroperitoneal cysts are the same and because they are all anterior extensions of what were retroperitoneal structures during the embryonic stage,[29] they share common characteristics. In this chapter, a "mesenteric cyst" is defined as any cyst located in the mesentery; it may or may not extend into the retroperitoneum. It has a recognizable lining of endothelial or mesothelial cells.[3] An "omental cyst" has the same histologic characteristics but is confined to the greater or lesser omentum. Because mesenteric, omental, and retroperitoneal cysts are all of lymphatic origin, the term "cystic lymphatic malformations" may be more appropriate.[24]

## Spectrum of Disorders and Differential Diagnosis

Mesenteric cysts can occur in the mesentery anywhere along the gastrointestinal tract from the duodenum to the rectum.[11] They may extend from the base of the mesentery into the retroperitoneum. Omental cysts are located in the lesser or greater omentum. Mesenteric cysts are 4.5 times more common than omental cysts.[10] In a thorough review of 162 cases reported between 1950 and 1985, Kurtz and colleagues[2] found that 60% were located in the small bowel mesentery, 24% in the large bowel mesentery, and 14.5% in the retroperitoneum. The most common location is in the ileal mesentery. In the colonic mesentery, cysts occur most commonly in the sigmoid mesocolon.[4,9] Cyst location in several pediatric series is shown in Table 91-1.

The differential diagnosis of mesenteric and omental cysts is shown in Table 91-2. Modern imaging studies can usually determine the organ where cystic lesions within the abdominal cavity originate. The differentiation between intestinal duplication cysts and mesenteric cysts may be problematic because both are often intimately associated with the bowel wall. The former share a common blood supply and muscular layer with the adjacent bowel and have a well-defined mucosal layer that mesenteric cysts lack.[1,3,5,30,31] At the time of surgery, duplication cysts require resection of the involved bowel, whereas mesenteric cysts can often be enucleated from between the leaves of the mesentery.[32]

**TABLE 91-2**

Ascites

The pathologic features of these cysts can vary considerably. They can be single or multiple, unilocular or multilocular; they can have serous, chylous, hemorrhagic, or mixed fluid contents; and their lining can vary from a flattened endothelial monolayer to a cuboidal or columnar epithelium to patchy fibrosis.[4,10,26,29,33] Rarely, the cyst wall contains calcium.[6,9,33] Unlike duplication cysts, mesenteric and omental cysts contain no mucus-producing cells.[4] Mesenteric cysts are most commonly single and multiloculated; the fluid is generally serous when the cyst involves the distal small bowel or colonic mesentery and chylous when it is located in the proximal small bowel mesentery.[5,9] Omental cysts almost always contain serous fluid.[33] The features of the cysts in this series are shown in Table 91-3.

## Clinical Presentation

The clinical presentation of mesenteric and omental cysts can vary from an incidental finding during laparotomy performed for another reason to an acute, life-threatening intra-abdominal catastrophe. In adults, these cysts are found incidentally in approximately 40% of patients[7,9,10] and present as acute abdominal emergencies in up to 60% of patients. The classic presentation is that of a low-grade, partial intestinal obstruction combined with a palpable, freely movable abdominal mass.[6] The most common mode of acute presentation in children is a small bowel obstruction, sometimes associated with volvulus and intestinal infarction.[5,25,33–35] In a series of

82 children operated on for volvulus, mesenteric cyst was the cause in 3.54% of cases.[36] Small bowel obstruction can also develop from acute enlargement of the cyst secondary to hemorrhage or from extrinsic compression of the bowel as it is stretched over an enlarging cyst (Fig. 91-1). The general mode of presentation of our 16 children is shown in Table 91-4. In no patient was the cyst found incidentally, although four patients were asymptomatic. In one of these four, a cystic intra-abdominal mass was identified by prenatal ultrasonography.

*All three omental cysts excised.

In this series, 75% of the patients had abdominal symptoms and all patients had findings on abdominal examination. In only two patients (12.5%) did the condition present as an acute abdominal emergency.

The following case summaries illustrate the varying presentations of mesenteric and omental cysts:

1. A 7-day-old female infant presented with a 48-hour history of vomiting and diarrhea and was found to have fever, abdominal distention, and erythema of the abdominal wall. *Escherichia coli* sepsis was documented. The patient had multiple infected omental and mesenteric cysts involving the greater omentum and transverse mesocolon, all of which were excised. The patient recovered.
2. A 3-day-old male infant presented with signs and symptoms consistent with a small bowel obstruction. He was found to have one ileal multiloculated mesenteric cyst with volvulus that required small bowel resection with primary anastomosis.
3. A 2-year-old boy had an asymptomatic abdominal mass that was found to be a multilocular mesenteric cyst involving the transverse mesocolon and pancreas. Excision

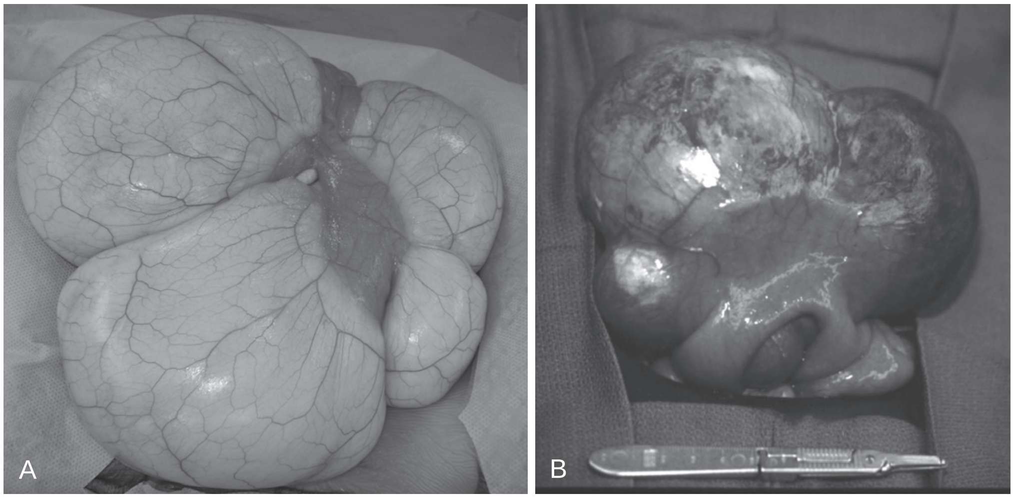

**FIGURE 91-1** **A,** Multiple mesenteric cysts filled with chylous fluid surrounding proximal small bowel. **B,** Large multilocular mesenteric cyst compressing overlying bowel and causing chronic partial intestinal obstruction.

of the cyst and distal pancreatectomy were performed for cure.

4. A 2-year-old girl presented with a 2-week history of asymptomatic abdominal distention. She was found to have a single 30- by 40- by 10-cm multilocular mesenteric cyst that extended along the base of the mesentery from the ligament of Treitz to the transverse mesocolon. Near-total excision of the cyst with marsupialization of the residual cyst into the peritoneal cavity and sclerosis of the wall with tincture of iodine resulted in long-term cure.
5. A female fetus was found to have an intraabdominal cystic mass on routine prenatal ultrasonography. After birth, the infant was jaundiced, which suggested a choledochal cyst; this was excluded by normal radionuclide scanning. After phototherapy, the patient remained asymptomatic but had a palpable, freely movable, nontender abdominal mass. She underwent elective resection of an omental cyst at the age of 6 months (Fig. 91-2).
6. A hydropic full-term female infant died from congestive heart failure. Autopsy revealed a 14-cm multiloculated cyst in the mesentery.
7. A 12-year-old girl with chronic abdominal pain was found to have a cystic mass on CT scan. Exploration revealed intestinal ischemia secondary to compression of the superior mesenteric artery by several mesenteric cysts. Subtotal intestinal resection resulted in short-bowel syndrome.
8. A 1-year-old boy with a right-sided reducible inguinoscrotal swelling since birth presented with irreducibility of the swelling of 3 days' duration. At laparotomy he was found to have a large mesenteric cyst of the terminal ileum, which communicated with the inguinoscrotal swelling.[37]

Complications associated with mesenteric and omental cysts include intestinal obstruction (most common), volvulus, hemorrhage into the cyst, infection,[38] rupture, torsion of the cyst,[10] obstruction of the urinary or biliary tract,[39] and malignancy.[2,5,8,9,11,40,41] The reported incidence of malignant conditions (sarcoma, lymphangioendothelioma, or, rarely, adenocarcinoma) is 3%,[2] although in a recent adult series of 16 patients (ages 12 to 68 years), there were three malignant cysts (18.8%).[20] No malignant mesenteric or omental cysts have been reported in children.

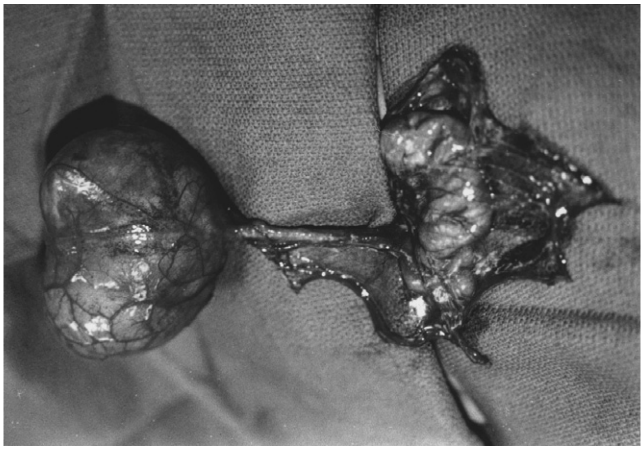

FIGURE 91-2 Asymptomatic but palpable, freely movable omental cyst first seen on prenatal ultrasound.

# Diagnosis

On physical examination, a majority of children with mesenteric and omental cysts have abdominal distention with or without a palpable mass. A definite mass may be difficult to palpate because of its large size, soft and fluid consistency, and great mobility. The mass may be huge, filling the abdominal cavity and simulating ascites.[17,38,42–45] It is dull to percussion. Omental cysts can sometimes be distinguished from ascites by the relative sparing of the flanks; ascites causes the flanks to bulge out, whereas omental cysts do not. If there is no other reason for ascites (e.g., liver or renal disease), a mesenteric or omental cyst should be considered.[32] If a definite mass is palpable, mesenteric cysts are generally movable in the transverse plane, whereas omental cysts are movable in the transverse and craniocaudal planes.[3,9]

Modern imaging studies can usually establish (or at least strongly suggest) the diagnosis of a mesenteric or omental cyst. A plain abdominal radiograph shows a gasless, homogeneous, water-dense mass that displaces bowel loops around it.[33] Omental cysts may compress bowel loops posteriorly, whereas mesenteric cysts may be surrounded by bowel loops.[31] Fine calcifications can sometimes be seen.[6,33] Abdominal ultrasonography and computed tomography (CT) have almost eliminated the need for contrast studies such as upper gastrointestinal series, barium enema, and intravenous pyelography. Abdominal ultrasonography is currently the imaging procedure of choice.[25,30,31] This test reveals a well-circumscribed, thin-walled, fluid-filled cystic structure that usually contains thin internal septi and sometimes contains internal echoes from hemorrhage, infection, or debris (Fig. 91-3).[3,30,31] Enteric duplication cysts are thick-walled structures that share a common muscular wall with the adjacent bowel.[31] They also have a clearly visible mucosal lining on ultrasonography. CT, with the administration of a gastrointestinal contrast

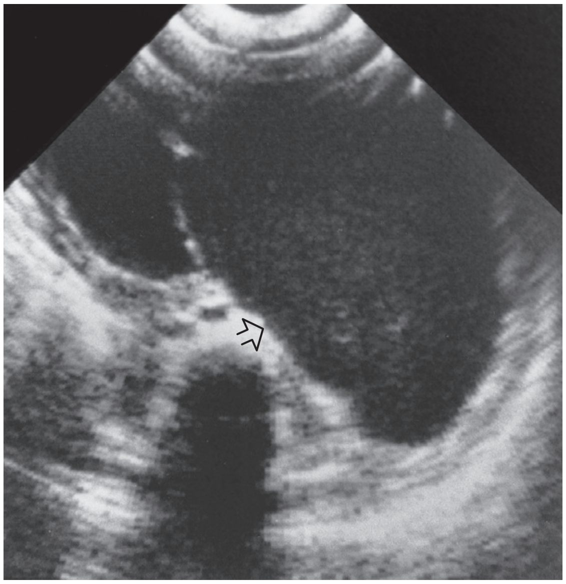

FIGURE 91-3 Ultrasonogram showing a large, multilocular cystic mass in the anterior abdomen, consistent with the diagnosis of a mesenteric cyst. Fine internal echoes represent hemorrhage within the cyst (*arrow*).

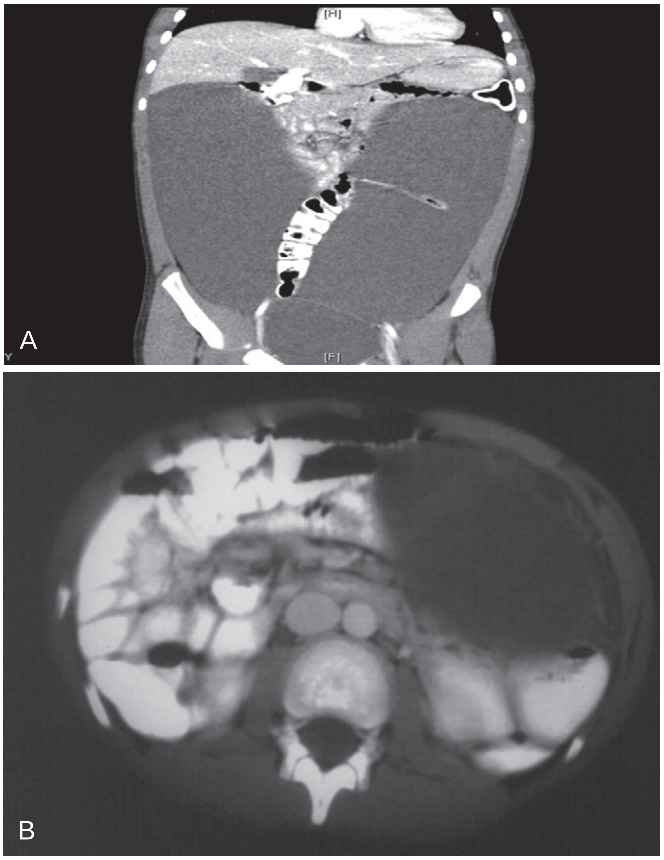

**FIGURE 91-4** **A,** Computed tomography scan with gastrointestinal contrast showing a large cystic mass surrounding a loop of colon. **B,** Computed tomography scan demonstrating a large unilocular cyst that is displacing bowel loops laterally and posteriorly.

agent, can show the relation of the bowel to the cystic mass (Fig. 91-4) and demonstrate that the cyst does not arise from any other organ such as the kidney, pancreas, or ovary.[9] A normal radionuclide scan of the biliary tract excludes choledochal cysts from diagnostic consideration.

## Treatment

The goal of surgery is complete excision of the mass. Omental cysts are easily removed and almost never require bowel resection.[29,33] Omental cysts can be excised using laparoscopic techniques.[42,46–48] Partial drainage of the cyst may be necessary to confirm the site of origin of the cyst and allow its removal through the umbilical port.[49] The preferred treatment of mesenteric cysts is enucleation.[2,9,29,32] In adults, the cyst can often be "shelled out" from between the leaves of the mesentery[32]; in children, however, bowel resection is frequently required to totally eradicate the mass and ensure that the blood supply to the bowel is not compromised. A bowel resection is necessary in only about 33% of adults, but 50% to 60% of children with mesenteric cysts require resection.[2,3,5,18,33,50] For this reason, a mechanical bowel preparation is recommended before surgery, if time permits.[1] If bowel resection is required, intestinal continuity can usually be reestablished primarily. The laparoscopic approach to resection of mesenteric cysts was first described by Mackenzie in 1993.[51] In many cases the cyst must be drained before it can be excised laparoscopically.[15,49,52–54] For those cases requiring a concomitant bowel resection, either an intracorporeal technique or a laparoscopic-assisted extracorporeal technique can be used.

If enucleation or resection is not possible, the third option is partial excision with marsupialization of the remaining cyst into the abdominal cavity. Approximately 10% of patients require this form of treatment.[2] If this procedure is done, the cyst lining should be sclerosed with 10% glucose solution,[4] electrocautery, or tincture of iodine in an attempt to minimize recurrence. Percutaneous injection of the lyophilized incubation mixture of group A *Streptococcus pyogenes* OK432 has been successful in the treatment of large, nonresectable lymphangiomas in children.[26] The mechanism of action of OK432 seems to be related to activation of the white cells (an increased number of natural killer cells and T cells) and an increase in cytokine-mediated endothelial permeability (increased activity of tumor necrosis factor and interleukin-6), resulting in shrinkage of the cystic spaces.[26] This agent may be useful to complement the surgical treatment of mesenteric cysts extending into the retroperitoneum. Partial excision and drainage are not indicated because of the high recurrence rate associated with these procedures.[2]

A simple and universal pathologic classification system that considers the different varieties of mesenteric cysts has been proposed by Losanoff and colleagues (Fig. 91-5).[26] Types 1 and 2 are easily cured with resection or enucleation, with or without concomitant bowel resection. Types 3 and 4, extending into the retroperitoneum, require complex surgical procedures and often sclerotherapy as well. Recurrence in types 3 and 4 is more common than in types 1 and 2.

The surgical treatment used for the current series is shown in Table 91-4. All three omental cysts were totally excised. Eleven of the 13 (85%) mesenteric cysts were completely excised; 2 (15%) were marsupialized into the peritoneal cavity and had the cyst lining sclerosed with electrocautery (1) or tincture of iodine (1). Of the completely excised cysts, 5 (45%) required concomitant bowel resection and 1 required distal pancreatectomy. None of the cysts was simply drained. No major short- or long-term complications, deaths, or recurrences occurred in this series.

## Outcome

The overall results of treatment in patients with mesenteric and omental cysts are favorable. The reported recurrence rate ranges from 0% to 13.6%, averaging about 6.1% in a series of 162 adults and children.[2] Most recurrences occur in patients with retroperitoneal cysts or those who had a partial excision.[2,10,25,29] The overall mortality rate in adults and children is 2%.[2] Only two deaths have been reported in children since 1950. One was a 26-month-old girl who presented with small bowel infarction from volvulus associated with a mesenteric cyst,[55] and the second was the baby with hydrops reported here.

## Summary

Mesenteric and omental cysts are rare, but they are more commonly encountered in children's hospitals than in adult general hospitals. Most cysts are developmental in origin and

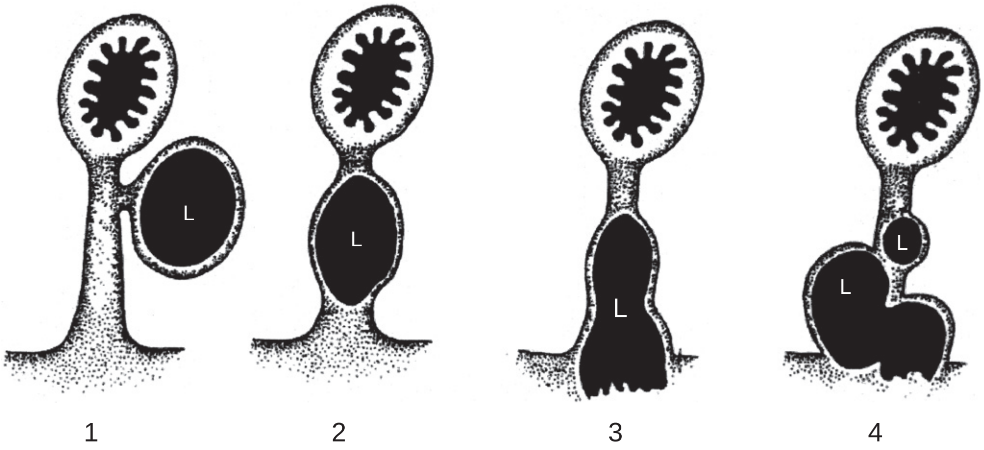

FIGURE 91-5 Classification of mesenteric cysts. Type 1—pedicled; easily resected. Type 2—sessile in leaves of mesentery; requires bowel resection. Type 3—extending into retroperitoneum; often incompletely resected. Type 4—multicentric; may require complex operations, sclerotherapy, or both. (From Losanoff JE, Richman BW, El-Sherif A, et al: Mesenteric cystic lymphangioma. J Am Coll Surg 2003;196:598.)

are related to a congenital abnormality of the lymphatic system. This leads to altered production and flow of lymph in ectopic lymphatic tissue, which lacks communication with central channels. The cysts can be located in the mesentery or omentum of any part of the gastrointestinal tract and may extend into the retroperitoneum. With modern imaging studies, these cysts can usually be differentiated from cystic lesions of other organs within the abdominal cavity. They may present incidentally, insidiously, or as an acute life-threatening emergency. In children, acute presentations from intestinal obstruction with or without volvulus are relatively common. In adults, less acute modes of presentation are the rule. The goal of treatment is complete removal of the cyst by either resection or enucleation. In children, concomitant bowel resection is often required. At times, a portion of the cyst wall must be left in situ and marsupialized into the peritoneal cavity and sclerosed. The short- and long-term prognosis of children with mesenteric and omental cysts is excellent, with a low recurrence rate, few complications related to treatment, and essentially no mortality.

CHAPTER 92

# Ascites

Eugene D. McGahren III

Ascites is the pathologic accumulation of excess fluid in the peritoneal cavity. The word "ascites" is derived from the Greek *askos* and *askites* meaning "bag," "bladder," or "belly."[1] Ascites has been recognized since the time of Hippocrates (400 BC), while modern descriptions of ascites in fetuses and infants date to the seventeenth century.[2–5] A wide variety of conditions, both congenital and acquired, cause ascites in infants and children (Table 92-1). The more common causes of ascites are addressed in this chapter.

## Anatomy and Pathophysiology

There are two major sources of abdominal lymph fluid. One is the flow of blood through the liver. Blood flow from the hepatic artery and portal vein perfuses the hepatic sinusoids and then exits via the hepatic veins. Pressure in the sinusoids is typically low because precapillary resistance is greater than postcapillary resistance. The space of Disse is a location in the liver defined by the hepatocytes on one side and the sinusoidal lining cells on the other side. Hepatic lymph is formed by the filtration of sinusoidal plasma into the space of Disse. It then drains from the liver via transdiaphragmatic lymphatics to the thoracic duct, which then empties into the subclavian vein. The sinusoidal endothelium is highly permeable to albumin, and the concentration of protein in hepatic lymph is close to that of plasma. Thus there is normally no significant osmotic gradient across the sinusoidal membrane.[1]

The second major source of abdominal lymph fluid is via the mesenteric venous system. The mean pressure of the mesenteric capillary is about 20 mm Hg. Intestinal lymph drains from regional lymphatics into the thoracic duct. The mesenteric capillary membrane is relatively impermeable to albumin. Because the concentration of protein in the mesenteric lymph is only about 20% that of plasma, there is a significant osmotic gradient that promotes the return of lymph fluid into the capillary under normal conditions. In an adult-sized patient, there is normally less than 150 mL of free fluid in the abdomen and the normal flow of lymph into the thoracic duct is about 800 to 1000 mL per day.[1]

Ascites occurs when there is an alteration in the normal hydrostatic, osmotic, and electrochemical forces that determine fluid balance. Increases in or aberrations of hydrostatic and/or osmotic pressures of the hepatic and mesenteric capillaries may cause a net transfer of fluid from blood vessels to lymph vessels that exceeds the drainage capacity of the lymph system. Such alterations in hydrostatic pressure may result from cardiac insufficiency or compromise of blood flow through the caval or portal venous systems. Changes in colloid pressure may result from hypoproteinemia secondary to liver compromise or from disturbances in capillary membrane permeability from a variety of inflammatory, metabolic, genetic, or neoplastic causes. Abnormalities in lymphatic drainage may result from trauma including surgery and child abuse or congenital or other anomalies that result in obstruction of the lymphatic system. Finally, ascites may be caused by direct communication between the urinary tract and the abdominal cavity. In this instance the ascites is partially the urine itself, as well as the fluid resulting from the inflammation caused by the urine.[1,6,7]

## Clinical Features

Abdominal distention is the most common physical finding associated with ascites.[5,8] Other physical signs may include bulging flanks, prominent abdominal wall vasculature, an everted or protuberant umbilicus if there is an umbilical hernia, or an inverted umbilicus if there is no hernia, inguinal hernias, scrotal or labial edema, a fluid wave, total body edema, and shifting dullness to percussion.[6–10] Other physical findings related to the underlying cause of the ascites such as a cardiac murmur, enlarged liver, spleen, or kidney, or an abdominal mass may be present. Urinary output may be diminished due to intravascular depletion, increased intra-abdominal pressure, or urinary leak.[11] Respiratory compromise may result from significant fluid accumulation and its pressure on the diaphragm.[2,12] Signs of peritoneal irritation suggest a primary inflammatory or infectious etiology of the ascites. Secondary infection of the ascitic fluid, otherwise known as *spontaneous bacterial peritonitis* (SBP) or *bacterial ascites* (BA), may also occur. Infected ascites may present with fever, nausea, vomiting, or encephalopathy. It is best diagnosed by a paracentesis that demonstrates an elevated polymorphonuclear neutrophil (PMN) count of greater than 250/μL. The sample may also identify the offending organism.[5,13]

**TABLE 92-1**
**Causes of Ascites**

| | |
|---|---|
| **Hepatocellular** | Glycogen storage disorders, lysosomal storage disorders, galactosemia, alpha-1 antitrypsin deficiency, viral hepatitis, neonatal hepatitis, congenital hepatic fibrosis, cirrhosis, hepatic or portal vein thrombosis, Budd-Chiari syndrome, malignancy, venoocclusive disease, biliary atresia |

| **Chromosomal** | Trisomy 21, Turner syndrome |
| **Cardiac** | Congestive heart failure, arrhythmias |
| **Infection** | Appendicitis, tuberculosis and atypical aflatoxin B, cytomegalovirus, parvovirus, syphilis, varicella zoster, enterovirus, listeriosis, toxoplasmosis, hepatitis A, chlamydia, fungus |
| **Renal/Urinary** | Posterior urethral valves, ureteroceles, ureteral stenosis, urethral stenosis or atresia, neurogenic bladder, bladder perforation, nephrotic syndrome, urogenital sinus, cloacal malformation |
| **Gastrointestinal** | Atresia, malrotation, volvulus, necrotizing enterocolitis, intestinal perforation, enteropathy, meconium peritonitis, lymphangiectasia, trauma (including child abuse), congenital obstruction from peritoneal band, gastroschisis, omphalocele, postcardiac surgery, postabdominal surgery for tumor, other abdominal surgery, lymphangioma, intussusception |
| **Pancreatic** | Pancreatitis from any cause, pseudocysts, trauma |
| **Gynecologic** | Ruptured ovarian cyst, hydrometrocolpos |
| **Miscellaneous** | Ventriculoperitoneal shunt, peritoneal dialysis, pseudomyxoma peritonei, granulomatous peritonitis, myxedema, neoplasms (e.g., lymphoma, neuroblastoma, ovarian), metabolic storage diseases |

# Diagnosis

Beyond physical examination, plain radiographs of the abdomen typically show medial displacement of bowel, as well as diffuse abdominal opacification with ground-glass appearance. Separation of the properitoneal fat stripe from the colon and separation of air-filled bowel loops are two other nonspecific findings. The liver may have a rounded appearance and may appear pushed to the center. Calcifications may be present if the ascites is associated with bowel perforation and peritonitis, particularly in the prenatal period (Fig. 92-1).[6,7,14]

Ultrasonography is sensitive for detecting free fluid in the peritoneal cavity. Free fluid in the abdomen appears as shifting echo-free zones in dependent locations. Small amounts of fluid can be detected in the hepatorenal or splenorenal fossa, as well as in the pelvis. As little as 50 to 100 mL may be visible in the abdomen on ultrasound (see Fig. 92-1).[6] Repositioning the patient can help differentiate free from loculated fluid collections. Ultrasonography may also be helpful in identifying inciting causes of ascites and is particularly helpful in diagnosing urinary tract anomalies that are associated with ascites such as posterior urethral valves.[8] Ultrasound cannot distinguish between types of ascitic fluid, however. Prenatal ultrasound routinely detects fetal ascites and may aid in prenatal and postnatal strategies to aid the infant.[14,15] Computed tomography (CT) may be helpful in determining the cause of ascites, but it does not usually add any information about the fluid beyond what the ultrasound has obtained.

Ascitic fluid may be obtained by paracentesis and analyzed according to the clinical suspicion (Table 92-2). Ultrasound may be helpful in locating a site to be aspirated, especially if there are scars from previous surgery.[1] An aspirate of 10 to 20 mL should be sufficient for complete analysis. Macroscopic appearance is assessed and may appear straw colored, turbid, bloody, or chylous. Laboratory evaluation of ascitic fluid should include a cell count with differential, Gram stain and culture, cytology if indicated, and chemical analysis including pH, lactate dehydrogenase, albumin, protein, amylase, bilirubin, creatinine, and triglyceride levels.[6,7,16]

# Hepatocellular Ascites

Neonatal and viral hepatitis, biliary atresia, inborn errors of metabolism, congenital hepatic fibrosis, Budd-Chiari syndrome, and alpha−1 antitrypsin deficiency commonly lead to cirrhosis, portal hypertension and, subsequently, ascites in children. Hepatocellular ascitic fluid is a transudate that results from increased portal venous pressure, increased intraluminal pressure in the mesenteric capillaries, and loss of fluid into the peritoneal cavity. Loss of albumin potentiates this fluid loss and triggers renal absorption of sodium and water.[16–19] Diagnosis of each of these conditions is based on the results of various tests such as specific biochemical assays for inborn errors, viral cultures, tests for viral antibody titers, and liver histologic testing. Analysis of ascitic fluid should include a serum-ascites albumin gradient (SAAG). A gradient greater than 1.1 g/dL is 97% accurate in predicting portal hypertension.[19,20] The cell count should be low, and no bacteria should be visualized, although primary peritonitis can complicate preexisting ascites.

Guidelines of therapy for ascites of hepatic cause include salt and fluid restriction. Sodium intake should be limited to 1 to 2 mEq/kg day for infants and children and 1 to 2 g/day (44 to 88 mEq of sodium/day) for adolescents. Water intake should be no more than 75% of daily maintenance, although severe water restriction is unnecessary unless there is significant hyponatremia (<125 mg/dL).[8,16,19] Gentle diuresis is commonly undertaken with salt and fluid restrictions. The goal of diuresis is to attain an excretion of extracellular water and sodium. Spironolactone is a favored initial agent due to its potassium-sparing characteristic. Furosemide may be used temporarily with spironolactone at the start of diuretic therapy because spironolactone takes a few days to be effective.[7,16,19] Repeated large-volume paracentesis is required in patients for whom salt and fluid restriction fails, particularly if there are symptoms of respiratory insufficiency. Paracentesis in which the removed ascitic fluid is replaced with salt-poor albumin or dextran has been shown to be safe and effective, especially when combined with diuretic therapy and sodium restriction.[11,19,21–23]

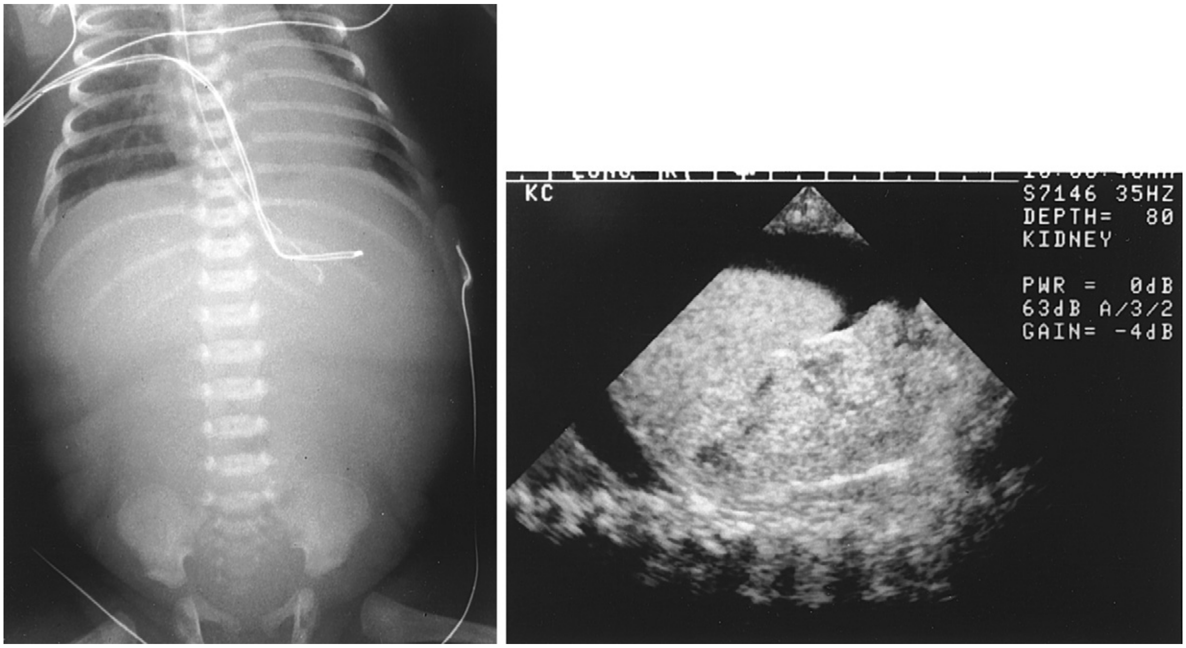

FIGURE 92-1 A newborn with hepatocellular ascites. The plain radiograph shows diffuse opacification with minimal bowel gas; the ultrasonogram shows fluid in the hepatorenal fossa.

**TABLE 92-2**
**Laboratory Analysis of Ascites**

| *Type of Ascites* | *Albumin Level* | *Bilirubin Level* | *Triglyceride Level* | *pH* | *Creatinine Level* |
|---|---|---|---|---|---|
| Hepatocellular | 2-3 g/dL | ≈Serum level | <50 mg/dL | 7.35 | <1 mg/dL |
| Biliary | ≈3 g/dL | 2-3 Times serum level | <50 mg/dL | >7.4 | <1 mg/dL |
| Chylous | <3 g/dL | <1 mg/dL | 1000-1500 mg/dL | 7.5 | <1 mg/dL |
| Urinary | <1 g/dL | <1 mg/dL | <50 mg/dL | <7 | ≈5-10 mg/dL |

Peritoneovenous shunting for intractable ascites of hepatic and other causes has been described in a few infants and children with good results.[24–26] Limitations attributable to the large size of the pump mechanism and venous tubing have made the use of such devices less common in pediatric applications. Modifications have been made by manufacturers to help customize Denver-type shunts for newborns.[25] An intraperitoneal vascular port has been successfully used for palliative relief of tense malignant ascites caused by hepatocellular carcinoma.[27] A newborn peritoneal dialysis catheter is also effective in draining ascitic fluid in a controlled manner. Transjugular intrahepatic portosystemic shunt therapy has been successful in managing ascites in a teenager and may have a role for therapy in selected children.[28]

## Biliary Ascites

Biliary ascites usually results from a spontaneous perforation of the common bile duct, most commonly at the junction with the cystic duct.[29–33] Rare instances of cystic duct perforation have been reported.[34,35] Spontaneous biliary duct perforation is a relatively rare condition with about 150 cases reported in the literature as of 2003,[36] with few reported since. Although many theories have been proposed, the cause of bile duct perforation is speculative. Distal duct obstruction, pancreatic fluid reflux up the common bile duct, congenital weakness of the common bile duct, or a localized mural malformation of the wall of the common duct and pancreaticobiliary maljunction have been proposed as possible causes.[31,37–39] It has been suggested that the proposed bile duct wall defects that may predispose to perforation may be part of a larger spectrum of defects that includes malformations such as choledochal cysts.[36] Perforation of the biliary tree in conjunction with choledochal cyst has been reported in case studies.[40–42] Biliary ascites may also result from perforation of the biliary tree due to trauma.[33,43]

Biliary ascites from spontaneous bile duct perforation typically occurs in infants and toddlers up to about age 2 years but may occur in older children as well.[33,39,44–48] It may also occur prenatally.[45] Most patients are otherwise healthy and have no predisposing conditions associated with the disorder. A typical presentation is the development of progressive painless abdominal distention with jaundice over a 1- to 4-week period. Vomiting, abdominal pain, and clay-colored stools may also be present. The condition is usually indolent in its presentation, although if biliary peritonitis is the initial presentation, the patient may be toxic appearing. However, most patients can tolerate large amounts of bile in the peritoneal cavity without evidence of infection or peritonitis.[33]

Physical examination is notable for abdominal distention, presence of fluid within the abdomen, and possibly inguinal hernias and bile-stained hydroceles.[33,36,39,44–47]

Biliary ascites should be suspected when the presentation and findings noted earlier occur in the absence of any liver disease. Ultrasound can confirm the presence of fluid within the abdomen, and nuclear scintigraphy and MRCP can aid in the identification and localization of a biliary leak.[36,46,47,49] Diagnosis can be definitively established by paracentesis. The fluid is bile stained with bilirubin levels of 100 to 400 mg/mL, although the level may be lower in more chronic presentations.[36]

The primary goal in the treatment of biliary ascites is typically external drainage.[33,36,44,45,47,50] The approach may involve exploration of the right upper quadrant with cholecystostomy and cholecystography to document the size and location of the perforation. If there is evidence of distal obstruction, some advocate giving consideration to a biliary-intestinal anastomosis but this is not commonly necessary.[44,50] If the perforation is confined to the cystic duct, cholecystectomy may provide definitive treatment.[35] Additional internal drainage procedures such as cholecystojejunostomy or duodenotomy with sphincteroplasty are usually unnecessary and fraught with difficulty because in most cases no intrinsic obstruction exists and inflammation tends to distort the anatomy.[31,51] The region is frequently densely scarred, and a sac filled with thick bile can be mistaken for a choledochal cyst.[36] External drainage can be accomplished by placing a Penrose or closed suction drain in the porta hepatis. A cholecystostomy tube or, less commonly, a T-tube may be useful to help with decompression and to further assess the biliary tree in the future.[44,52] External drainage has also been successfully accomplished using percutaneous technique, thus avoiding laparotomy.[47] Alternatively, laparoscopic technique may allow localization of the leak and precise drain placement.[44] There has been a recent report of endoscopic retrograde cholangiopancreatography assisted biliary stent placement facilitating treatment of spontaneous biliary leak.[48] Bile duct stenosis is the most common complication after external drainage. Portal vein thrombosis, bile leak, and cholangitis have also been reported.[36,47] If a choledochal cyst is the cause of the biliary leak, then excision of the cyst with appropriate enteric-biliary anastomosis is indicated.[40–42]

With adequate external drainage, most patients survive and need no additional surgical intervention. Eighty percent of perforations heal within 3 weeks.[29,31–33,44,47,51] Antibiotics and complete bowel rest with total parenteral nutrition (TPN) are important adjuncts in these patients. Fat-free enteral infant formulas are also used, but no studies have compared these two nutrition options in patients with biliary ascites. The cholecystostomy and peritoneal drains should remain in place until normal ductal anatomy has been demonstrated through the cholecystostomy.

# Chylous Ascites

Chylous ascites is the excessive collection of lymph fluid in the peritoneal cavity. In infants and children it is most commonly idiopathic (45% to 60% of cases) and is presumed to be due to congenital malformations of the lymphatic channels.[4,5,8,53,54] Known congenital lymphatic abnormalities that lead to chylous ascites include atresia or stenosis of the major lacteals at the base of the mesentery or the cisterna chyli, mesenteric cysts, generalized lymphangiomatosis, and lymphangioma.[5,8,55–57] The next most common cause of chylous ascites is thought to be obstruction of lymphatic channels by conditions such as intussusception, malrotation, incarcerated hernia, primary or metastatic cancer, tuberculosis, gastroschisis, omphalocele, or inflammatory lesions causing lymph node enlargement.[5,8,9,53,56–60] A large intraabdominal lymphangioma may mimic ascites.[61,62] Finally, injury to the lymphatics is responsible for an additional 15% to 20% of cases of chylous ascites. This may result from trauma, surgery for a variety of conditions, and child abuse. Ascites may not be noticed until days or weeks after the inciting event.[3,4,58,63–65]

Chylous ascites can occur in children of all age groups, although most are infants and toddlers.[5,8,53] Abdominal distention is the most common presenting sign. This may develop gradually or acutely and may be accompanied by abdominal pain and respiratory compromise.[*] Other signs and symptoms may include vomiting, diarrhea, inguinal hernia, and edema.[5,68]

The main confirmatory diagnostic study is abdominal paracentesis, which reveals a milky white fluid if the patient is receiving a fat-containing enteral diet. However, the fluid may appear less milky or amber if the child has not been receiving enteral feeds. The fluid is characterized by an elevated triglyceride concentration (often $> 1000$ mg/dL), a cell differential that is predominantly lymphocytes (70% to 90%), and elevated total protein and cholesterol concentrations.[4,5,6,8,20,53]

Determining the cause of the chylous ascites can be a challenge, especially if the child has no obvious conditions that may commonly predispose to a lymph leak. Studies such as ultrasonography, CT, and gastrointestinal contrast studies may be helpful in identifying predisposing conditions such as malrotation, lymphangioma, tumor, or mesenteric cysts. In newborns in whom ascites has no readily recognizable explanation, a congenital lymph channel malformation is the most likely diagnosis. Lymphangiography is described in older series, but it is difficult to perform in children and it has helped to direct treatment in only a minority of children in whom it has been used.[8,20]

Surgically correctable lesions such as malrotation, mesenteric cysts, intussusception, or incarcerated hernias should be corrected. In patients without a surgically correctable lesion, the initial treatment is aimed at reducing lymph flow through the damaged or obstructed lymph channels. This is accomplished by suspending enteral intake and initiating TPN. Some patients respond quickly to this intervention, with resolution of the ascites within 2 weeks. If the patient's nutritional and hydration status can be maintained, courses of TPN of up to 10 weeks can be considered.[63,67] Because medium-chain triglycerides (MCTs) are absorbed directly into the portal system, and therefore do not stimulate lymph flow, they have been traditionally advocated in the treatment of chylous ascites. Hard data confirming the benefit of MCT formula have been lacking. Nonetheless, the use of a low-fat, medium chain-enhanced formula such as Portagen has been reported

*References 3, 4, 5, 8, 53, 58, 66, 67.

in multiple successful nonoperative treatment courses and should be considered as an adjunct to TPN or as the initial enteral formula in patients who respond to TPN.[9,63–65,67] Prolonged use of low-fat infant formulas has been associated with poor neurologic development, possibly from fatty acid deficiency.[54] Treatment with low-fat formula should therefore be limited to 3 to 6 months. Administration of somatostatin has been reported to successfully resolve chylous ascites in some cases.[69,70] Paracentesis in addition to bowel rest should be reserved for patients with respiratory compromise.

Surgical intervention is warranted if nonoperative therapy is not successful after 6 to 10 weeks or if the patient becomes otherwise symptomatic.[8,53,54,63] Location of the leak may be facilitated by feeding the patient a high-fat diet (usually milk) up to 6 hours before surgical exploration. This results in a copious creamy lymph flow from the leak area. Addition of Sudan dye to the milk may further aid in identifying the leak.[66,71] The most common location of the lymph leak is at the base of the superior mesenteric vessels, although various retroperitoneal and mesenteric lymphatics may be involved.[8,12,53,54,66,71] Complete mobilization of the duodenum and the head of the pancreas and a thorough exploration of the entire retroperitoneum should be performed.[56] Ligation of an identified leaking lymphatic is curative in 85% of patients.[8,67] Recent reports also describe the potential usefulness of laparoscopy in localizing lymph leaks and the use of fibrin glue in the control of lymph leaks.[12,66,72] Peritoneovenous shunting may be a useful treatment strategy as a primary surgical intervention or as an intervention in those children in whom surgical exploration has failed to resolve the ascites.[26,63,68,73] In some older series, mortality from chylous ascites was significant, ranging from 24% to 30%.[5,8] However, with current nutritional support and surgical intervention capabilities, a successful outcome can now usually be expected.

# Urinary Ascites

Urinary ascites is a rare condition, though a common cause of ascites in newborns, accounting for up to one-third of cases of isolated ascites.[2,6] Males outnumber females by a ratio of 7:1.[74] Obstruction of the lower urinary tract, particularly from posterior urethral valves, accounts for approximately 70% of cases of urinary ascites. Other obstructive causes of urinary ascites include ureteroceles, ureteral stenosis, neurogenic bladder, and urethral stenosis or atresia.[2,6,74,75,76] Urinary extravasation from a discrete perforation is noted in approximately 65% of patients with an obstructive cause. The posterior fornix is the weakest part of the urinary system. Thus the site of perforation is most commonly located in the renal pelvis, although bladder perforation is also common.[2,76] Other causes of urinary ascites that are not obstructive in nature include trauma to the urachal remnant, often as a result of attempted umbilical arterial catheterization; spontaneous rupture of the bladder in infants, sometimes associated with connective tissue disorders; and, in females with persistent urogenital sinus or cloacal malformation, leakage of urine directly into the peritoneal cavity through the uterus and fallopian tubes.[2,6,74–83] A recent case of urinary ascites was reported with only the presence of vesicoureteral reflux.[84]

Most patients with urinary ascites present soon after birth. However, prenatal ultrasound may also detect ascites.[85–89] On physical examination, abdominal distention, frequently with palpable flank masses, is the most common presentation. Respiratory distress and acidosis (absorption of urine from the peritoneal cavity) may be present. Potter syndrome (maternal oligohydramnios, renal, pulmonary, and chest wall hypoplasia) may be present. Prune-belly syndrome may also be a physical finding.[2,89,90] Hyponatremia, hyperkalemia, and an elevated serum blood urea nitrogen (BUN) level and creatinine level are also common.[2,74,91]

Workup should begin with abdominal ultrasonography, which will demonstrate the ascitic fluid. It will also identify most common urinary tract abnormalities that are associated with urinary ascites such as hydronephrosis, dilated ureters, and a dilated or thickened bladder.[6] Voiding cystourethrography (VCUG) demonstrates any obstructing lesions and may show the point of extravasation.[75,76,78] Intravenous pyelography (IVP) or renal scanning with diethylenetriamine pentaacetic acid (DTPA) or mercaptoacetyltriglycine (MAG 3) may provide information about the degree of renal parenchymal damage caused by long-standing obstruction and may show the point of extravasation.

Treatment ultimately addresses the underlying urinary tract obstruction if present. However, fluid resuscitation, antibiotics, and distal urinary tract drainage constitute the initial treatment in these patients.[75,76,78] Prenatal intervention for significant urinary obstruction may also be considered.[92] Urinary tract decompression may be accomplished by Foley catheterization, particularly in the case of posterior urethral valves. Cystoscopy with valve ablation is then performed electively. Other decompression strategies may include percutaneous nephrostomy or surgical vesicostomy or pyelostomy depending on the offending lesion and the condition of the patient.[75,76] Although there are some who advocate routine drainage of the ascites, typically drainage of the ascites or repair of the perforation is not necessary because the urinary ascites is reabsorbed once urinary drainage has been achieved and the perforation heals quickly.[2,74,76] Drainage of the ascites is necessary in the presence of respiratory compromise or infection.[2] Once the previously mentioned measures have been successfully completed, definitive operation can be undertaken to address the offending lesion. There is a risk of compromised long-term renal function due to the chronic obstruction. However, the spontaneous decompression of the obstruction that results in urinary ascites is felt to be protective of renal function. Thus a significant number of patients retain good renal function, although this must be monitored on a long-term basis.[2,6,74,85,87] With improvements in neonatal care and early recognition of these conditions, the mortality rate from urinary ascites has decreased from 70% to 0%.[76]

CHAPTER 93

# Polypoid Diseases of the Gastrointestinal Tract

Joseph L. Lelli, Jr.

Polyps are any masses that project into the lumen of the gastrointestinal tract. Some masses that appear to be polyps are subepithelial. True intestinal polyps, however, are of an epithelial origin. Polyps in children most commonly occur as an isolated lesion referred to as a *juvenile polyp*. However, more rarely, polyps in children can occur as a genetically related disease with features including multiple polyps (polyposis) in the gastrointestinal tract, heritability within a family, and an increased lifetime risk of developing a related cancer in the gastrointestinal tract or in other organ systems. Children with these features are considered to have a "polyposis syndrome." Polyposis syndromes in children are classified into two groups, namely adenomatous polyposis syndromes or hamartomatous polyposis syndromes (Table 93-1).

Polyps are common during childhood, occurring in approximately 1% of preschool and school-aged children.[1] Because of their high incidence, polyps of the gastrointestinal tract represent the most frequent cause of rectal bleeding in toddlers and preschoolers aged 2 to 5 years of age. Juvenile polyps are most common (80%) and are followed by lymphoid polyps (15%).[2] Adenomatous polyps occur in less than 3% of all children with polyps.

## Juvenile Polyps

Juvenile polyps were first described by Verse in 1908.[3] For many years, all polyps in children were considered adenomas[4] and were often treated with radical procedures. Horrilleno[5] first used the term *"juvenile polyp"* in 1957 to describe a histologically distinctive colorectal polyp that occurred predominately during childhood. In 1962 Morson[6] made an important contribution when he demonstrated that juvenile polyps were benign hamartomas, thereby distinguishing them from potentially malignant adenomas. Less radical treatment of these polyps, however, was slow to follow. The distinction between isolated juvenile polyps and juvenile polyposis was first made by McColl and colleagues in 1964,[7] and three distinct forms of juvenile polyposis were further defined by Sachatello in 1972.[8] Kaschula in 1971[9] followed by Enterline in 1976[10] reported cases of children with both juvenile and adenomatous polyps. Billingham[11] reported the presence of solitary adenomas in children with juvenile polyps in 1980. These early reports of the coexistence of juvenile and adenomatous polyps led to the identification of adenomatous and malignant changes in juvenile polyps.[12–14] However, only polyps associated with juvenile polyposis have malignant potential in children.[15–17] The distinction between the commonly occurring isolated juvenile polyps, which are benign, and the rare juvenile polyposis syndromes, which may be malignant, has become increasingly important.[15,16,18,19]

Jass[20] has proposed the following criteria for increased risk for cancer in children with polyps: (1) more than five juvenile polyps in the colon, (2) polyps throughout the gastrointestinal tract, and (3) any number of polyps associated with a family history of juvenile polyposis. Jass's criteria clarify the three distinct juvenile polyposis syndromes originally described by Sachatello in 1972.[8] On the basis of Jass's and Sachatello's studies, the following classification of juvenile polyps is most commonly used:

I. *Isolated Juvenile Polyps* (nonmalignant): fewer than five polyps confined to the colon without a family history of juvenile polyposis.

II. *Juvenile Polyposis Syndromes* (malignant potential):
   1. *Diffuse juvenile polyposis of infancy:* widespread polyposis of entire gastrointestinal (GI) tract in patients younger than 6 months of age.
   2. *Diffuse juvenile polyposis:* multiple polyps throughout the GI tract, but mostly in the stomach, distal colon, and rectum, usually occurring in patients 6 months to 5 years of age.
   3. *Juvenile polyposis coli:* multiple juvenile polyps confined to the distal colon and rectum in patients 5 to 15 years of age.

Juvenile polyposis syndromes, Cowden disease, and Peutz-Jeghers syndrome are all classified as hamartomatous polyposis syndromes (see Table 93-1).

TABLE 93-1
**Classification of Polyposis Syndromes**

| *Classification* | |

| Hamartomatous polyposis syndromes | 1. Juvenile polyposis<br>2. Cowden disease<br>3. Peutz-Jeghers syndrome |

## ISOLATED JUVENILE POLYPS

### Pathology

Juvenile polyps, which are also known as *retention, inflammatory* or *cystic polyps,* are the most common type of polyp found in the GI tract and account for 80% of polyps in children. Such polyps are generally considered hamartomas[6] or a malformation in which normal colonic tissue has become arranged in a haphazard manner.[20]

Grossly, the typical polyp has a glistening, smooth, spherical, reddish head and ranges from 2 mm to several centimeters in diameter (Fig. 93-1). Polyps will often have an ulcerated surface, which accounts for the rectal bleeding. A cross section shows cystic spaces filled with mucus (Fig. 93-2). Juvenile polyps are typically attached by a long, narrow stalk covered by colonic mucosa. This stalk predisposes the polyp to torsion, which results in venous congestion, surface ulceration, bleeding, and auto amputation.

Microscopically, the surface of the polyp has a single layer of colonic epithelium. This epithelial layer is often ulcerated or replaced with granulation tissue. When inflammation occurs, the epithelium may show a reactive hyperplasia that can mimic dysplasia or adenomatous changes.[21] The main body of the polyp consists of dilated or cystic epithelial tubules that are lined by normal colonic epithelium. These tubules and cystic lakes are embedded in a lamina propria and an abundant, loose, vascular, and fibrous stroma (Fig. 93-3). The stroma is usually heavily infiltrated with neutrophils, eosinophils, lymphocytes, and monocytes. Mitotic figures are rarely seen. Only two descriptions of malignant changes in a solitary juvenile polyp are present in the literature,[22,23] and according to Jass,[20] only one of these may be a true malignant condition. In a longitudinal study of patients with solitary polyps, no increased risk for developing colorectal cancer could be found.[24]

FIGURE 93-1 Typical juvenile polyp with its stalk attached.

FIGURE 93-2 Gross cross section of juvenile polyp with typical cystic "lakes" filled with mucus.

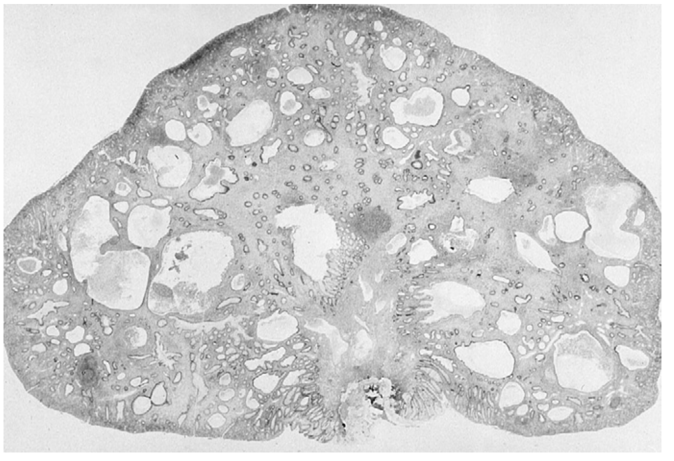

FIGURE 93-3 Photomicrograph of typical juvenile polyp. The surface shows a smooth, flattened, colonic epithelium. Large tubular and cystic lakes are present, embedded in an abundant, loose stoma.

### Etiology

The etiology of juvenile polyps is unknown, but several authors have suggested hereditary,[25] genetic,[26] hamartomatous malformation,[6] and inflammation.[27] Recent data suggest that juvenile polyps result from a structural rearrangement of the mucosa secondary to an inflammatory process.[28] The initial event is probably ulceration and subsequent inflammation of the mucosa, leading to obstruction of regional, small colonic glands of the mucosa. The obstructed glands proliferate, branch, and dilate, forming a cystic structure. The cystic structure pushes up the mucosa, leading to further ulceration, inflammation, and formation of granulation tissue. As the

cycle continues, an increasingly larger and larger mass pushes into the lumen. The fecal stream and peristalsis push the mass down the lumen, causing the stalk to elongate and resulting in the typical pedunculated appearance of the juvenile polyp.

### Incidence

Although the incidence of juvenile polyps is unknown, they are believed to occur in approximately 1% of all preschool children.[1] Most juvenile polyps appear in the first decade of life, with the peak incidence between 3 and 5 years of age.[1] The polyps are solitary in 50% of cases, with the remainder having 2 to 10 polyps. The location of these polyps has changed over the past 10 years. Historically, 70% of the polyps were found in the rectum. Today, only 40% are found in the rectum or sigmoid colon, whereas 60% are found evenly distributed throughout the proximal colon.[1] Juvenile polyps are rarely seen after adolescence.

### Clinical Presentation

The most common presenting symptom of a juvenile polyp is bleeding (93%) that results from ulceration of the polyp surface. Blood loss is usually minimal and appears as bright red streaks of blood over the surface of the stool. Abdominal pain (10%), which is believed to be caused by traction on the polyp from peristaltic activity, and prolapse of the polyp (4%) are other less common presenting symptoms. Prolapse of the rectum and encopresis have also been reported.[1] Many juvenile polyps will autoamputate, resulting in spontaneous cessation of rectal bleeding.[29]

The differential diagnosis of juvenile polyps encompasses all of the causes of rectal bleeding in toddlers through children who are 6 years of age. Anal fissures and rectal prolapse cause rectal bleeding but are easily distinguished from polyps on physical examination. Bleeding from Meckel diverticulum or duplication of the intestine usually causes more substantial blood loss than that from a polyp, and the blood usually commingles with the stool rather than coating it. Bleeding from an intussusception is accompanied by abdominal pain that is substantially worse than that seen with polyps. Inflammatory bowel disease is usually accompanied by diarrhea, which is not seen with polyps. Blood dyscrasias, such as Henoch-Schönlein purpura, should also be considered in the differential diagnosis.

### Treatment

The diagnosis and treatment of juvenile polyps requires a combination of history, digital rectal examination, and colonoscopy. The shift of juvenile polyps to the more proximal colon[29] and the concern for the presence of juvenile polyposis (>5 polyps), with its increased risk of malignancy, mandates that the entire colon be surveyed. Children with suspected polyps should have a digital rectal examination initially. Polyps in the rectum can be easily removed during anoscopy. Following removal of a rectal juvenile polyp, pancolonoscopy, in a well-prepared bowel, should be performed to determine if additional, more proximal polyps are present.[30] Children with juvenile polyposis and adenomatous changes are more likely to have right-sided polyps[31]; therefore all polyps should be removed and undergo histologic evaluation. Complications following endoscopic removal of polyps are rare.

## Polyposis Syndromes

Gastrointestinal polyps are the result of a defect in the balance between cellular growth promotion and cellular growth inhibition. The defect results from either an activated oncogene that has upregulated a growth-promoting protein or the loss of function of a growth-inhibiting protein, usually by the inactivation of a tumor suppressor gene. In the polyposis syndromes there has been inactivation of a tumor suppressor gene.[32,33] A resulting gastrointestinal cancer occurs when there are additional genetic defects. Polyposis syndromes can be classified into adenomatous polyposis syndromes and hamartomatous polyposis syndromes.

## Adenomatous Polyposis Syndromes

All of the adenomatous polyposis syndromes are distinguished by the development of a large number of adenomas in the colon. Additionally, these syndromes are associated with extracolonic manifestations such as duodenal polyps; benign soft tissue tumors such as osteomas of the mandible, long bones, and skull; and congenital hypertrophy of the retinal pigmented epithelium (CHRPE) (Table 93-2). Adenomatous polyposis syndromes include familial adenomatous polyposis (FAP), most common in children; Gardner syndrome; and Turcot syndrome.

## Familial Adenomatous Polyposis

FAP is distinguished by the progressive development of hundreds to thousands of adenomatous polyps in the colon. By 15 years of age 50% of those that carry the FAP gene will have polyps. The lifetime risk for developing a colorectal cancer is 100%; however, the average age for developing an adenoma in FAP is 16 years and 39 years for developing a colorectal cancer.[34]

**TABLE 93-2**
**Extracolonic Features in Familial Adenomatous Polyposis**

| *Cancer (Lifetime Risk)* | *Other Lesions* |
|---|---|
| Duodenal (1%-5%) | CHRPE |
| Pancreatic (2%) | Nasopharyngeal angiofibromas |
| Thyroid (2%) | Osteomas |
| Brain (medulloblastoma) (<1%) | Radiopaque jaw lesions |
| Hepatoblastoma (0.7% of children < 5 yr old) | Dental abnormalities |
| | Lipomas, fibromas, epidermoid cysts |
| | Desmoid tumors |
| | Gastric adenomas/fundic gland polyps |
| | Duodenal, jejunal, ileal adenomas |

CHRPE, congenital hypertrophy of the retinal pigment epithelium.

## HISTORY

The first case of adenomatous polyposis was recorded by Covisart in 1847,[35] but it was Chargelaigue,[36] who, 12 years later, gave the first definitive account of the disease in a 16-year-old girl and a 21-year-old man. The first pathologic description of these colonic polyps was reported by Virchow in 1867,[37] with Woodward in 1881[38] being the first to distinguish between neoplastic and inflammatory polyps. The first familial association of these polyps was described by Cripps in 1882[39] between a 9-year-old boy and his 17-year-old sister. However, the malignant potential of these polyps was not recognized until 1890 by Handford.[4]

The first recorded operations for polyposis are credited to Lilienthal[21] in North America and subsequently to Lockhart-Mummery at St. Mark's Hospital in London, as reported by Thompson and Watne.[40,41] Lockhart-Mummery, in 1925,[42] concluded that (1) multiple adenomatous polyps develop in succeeding generations, (2) afflicted individuals develop cancer at an early age, and (3) the adenomas are an antecedent to cancer. In 1927 Cockayne[43] described the mode of inheritance as Mendelian dominant, which was later confirmed by Dukes in 1930[44] and Lockhart-Mummery in 1939.[45] Since then, FAP has become a model for understanding the adenoma-carcinoma sequence.[46]

The detection of a deletion in chromosome 5q[47] in a patient with Gardner syndrome has led to characterization of the gene responsible for FAP, the *APC* gene.[48–57] The 5q deletion or alteration in the *APC* gene results in a gene product with a truncated protein, which subsequently causes the *APC* gene to act as a tumor suppressor gene.[32,33] Mouse models for FAP have been developed,[58] and these will facilitate research in gene therapy.

**FIGURE 93-4** Gross specimen of the total colon in a patient with familial adenomatous polyposis demonstrating thousands of adenomatous polyps. Note the large adenoma in the ascending portion of the colon.

**FIGURE 93-5** Close-up view of colonic mucosa demonstrating a "carpet" of small 1- to 2-mm adenomas in a patient with familial adenomatous polyposis.

## PATHOLOGY

FAP is defined as the presence of at least 100 visible adenomatous polyps in the large intestine.[59] However, patients with fewer polyps have been diagnosed as having FAP, and one patient who had early onset of colorectal cancer and had a 5q gene deletion had only one endoscopically detectable polyp.[60]

Colorectal polyps are the hallmark of FAP. Although 100 polyps is the usual threshold for diagnosing this disorder, patients coming to colectomy in their teenage years typically have thousands of polyps (Fig. 93-4). Two types of FAP seem to exist: the sparse type, which is characterized by hundreds of polyps, and the profuse type, which is characterized by thousands of polyps. Utsunomiya and colleagues[61] have shown that the history of the two types is different—patients with the profuse type tend to develop adenocarcinoma at an earlier age.

In FAP the polyps are typically scattered throughout the colon, which allows diagnosis by sigmoidoscopy. The polyps vary in size from 1 to 2 mm in diameter, and when present, pedunculated polyps can be 1 cm in diameter or larger (Fig. 93-5). During duodenoscopy, biopsy of normal-appearing duodenal mucosa may reveal microscopic adenomas too small to be seen macroscopically. These microadenomas may consist of only three or four dysplastic crypts that usually have a tubular adenomatous structure.[62]

Adenomatous polyps result from a neoplastic transformation of at least one epithelial cell that is in the proliferative portion of a crypt.[63] The transformed clone then populates the upper part of the crypt, which divides by budding.[63] Crypt fusion is then responsible for further growth of the adenoma. This neoplastic transformation, called *dysplasia,* implies atypical morphologic characteristics, with nuclear enlargement and stratification. Adenomas seem to pass through gradations of dysplasia until invasive adenocarcinoma develops.[64] Extension of neoplastic cells into the basement membrane of the colonic epithelium represents carcinoma in situ. As the neoplastic cells extend beyond the basement membrane, the tumor becomes microscopically invasive. Because the colonic mucosa does not contain lymphatics, metastasis does not usually occur until the tumor invades through the muscularis mucosa into the submucosa.

Small intestinal mucosa can also be involved with adenomatous polyps. Polyps of the small intestine are frequently found around the orifice of the common bile duct.[65] Polyps in this region are variable in size, are often microscopic, and involve only a few crypts. Adenocarcinoma of the duodenal papilla and periampullary regions occurs in 2.9% of patients with FAP[65] and has been found in the common bile duct of these patients.[66]

Gastric polyps occur in patients with FAP, but they are usually benign polyps of the fundic gland.[67] These polyps result from cystic dilation of specialized gastric glands rather than from dysplasia. No evidence that neoplastic transformation occurs in polyps of the fundic gland exists.[68]

## ETIOLOGY

The incidence of FAP ranges from 1 in 6000 to 1 in 12,000 births.[69–71] FAP is inherited as an autosomal dominant trait with a moderate incidence (10%) of new mutations.[72] The manifestations of FAP differ greatly, probably as a result of variation in the mutation of the *APC* gene. Although the occurrence of polyps is strongly related to genetics, the phenomenon of regression of rectal polyps after colectomy and ileorectal anastomosis was recognized in 1988[73,74] and points to the fact that the luminal environment also plays a role in the development of polyps.

FAP is caused by a mutation in the *APC* gene on the long arm of chromosome 5, where a variable deletion or alteration of the gene is associated with the disease. The *APC* gene codes for a protein product that acts as a tumor suppressor.[72] Because of this gene deletion, the probability of cancer (as diagnosed by biopsy during sigmoidoscopy) by 25 years of age is 90%.[4] In colorectal cancer cell lines that have an intact chromosome 5 introduced into the cells, the ability of the cells to induce tumor growth in mice is considerably reduced.[58,75] Similar results have been found for other tumor suppressor genes, namely the *TP53* gene on chromosome 17p and the deleted colorectal cancer gene (*DCC*) on chromosome 18q.[72] It has become apparent there is genetic heterogeneity in FAP. Certain germline mutations of the *APC* gene predispose to attenuated disease expression.[77,78] Further evidence indicates that additional modifier genes influence the severity of FAP.[79]

## CLINICAL PRESENTATION

Although FAP has been recognized in infancy and early childhood, it is most frequently identified in early adolescence. Most patients are asymptomatic, but some present with increased frequency of defecation, rectal bleeding, anemia, and abdominal pain. Most (90%) are identified by routine surveillance because of a familial history of adenomatous polyposis.

Diagnosis is established by sigmoidoscopy and occasionally by air contrast barium enema. Sigmoidoscopy usually reveals a carpet of polyps that cover the entire surface of the colon. Biopsy of at least 10 polyps will confirm the diagnosis. In some patients with FAP, most of the polyps will be located in the proximal colon. If the diagnosis of FAP represents a new mutation (no other family members are known to have the disease), a careful examination of all family members is required.

Polyps are found in the stomach in up to 50% of patients with FAP, but only 6% of the polyps are adenomatous,[67] with the rest being fundic gland polyps (hamartomas). Polyps occur in the duodenum less often than in the stomach; however, duodenal polyps are much more likely to be adenomatous. Several series have demonstrated that up to 98% of FAP patients have visible duodenal polyps or at least a histologic abnormality with dysplasia, unicrypt adenomas, or hyperplasia in the duodenal mucosa.[65,67,80] Adenocarcinoma of the duodenal papilla or periampullary region eventually develops in 2.9% of patients with FAP.[65] For these reasons, upper endoscopy is necessary in all patients with this disorder.

## TREATMENT

Malignant conditions of the colon will occur in all patients with FAP if left untreated. The average age for developing cancer is 39, with 7% developing cancer by age 20 and 15% by age 25.[81] Surgical removal of the entire colonic mucosa will prevent colorectal carcinoma. Most patients who present with symptomatic polyps already have a malignant condition.[81] Therefore colectomy is recommended at any age, if the child is symptomatic.

A wide range of surgical options exists. Total proctocolectomy with a permanent ileostomy prevents cancer but leaves a young patient with a permanent abdominal wall stoma. The physiologic and psychologic impact of a permanent ileostomy is substantial in adolescence. This operation can cause substantial sequelae because of the extensive pelvic dissection, namely, damage to the nervi erigentes with resultant bladder atony and in males, impotence. For these reasons, total proctocolectomy is not the treatment of choice for FAP in a pediatric patient.

Total abdominal colectomy with an ileorectal anastomosis and continued surveillance of the retained rectum has probably been the most common operation for FAP performed in the past. St. Mark's Hospital in London reported results with 215 patients undergoing this procedure.[40] Immediate postoperative complications included prolonged ileus (7%), anastomotic breakdown (2%), and bleeding (<1%), for a total complication rate of 10%. Frequency of defecation at late follow-up (6.5 years) was three stools per day, and less than 10% reported nighttime soiling. Continence was considered completely normal in 72%. Forty-four percent (44%) of the patients, however, required subsequent treatment for their rectal polyps. Depending on the density of the rectal polyps, the patients were evaluated every 3 to 6 months, with sigmoidoscopy and fulguration of any polyps greater than 5mm in diameter. Ten percent developed carcinoma in their rectal stump. The cumulative risk for rectal cancer was 10% at 50 years of age and 29% by 60 years of age.[81]

In more recent years, total colectomy with a rectal mucosectomy and an ileoanal pouch procedure has become the preferred operation for children with FAP. The J pouch is the preferred technique because of simplicity of construction and sparsity of complications.[82] Geiger and colleagues[83] reported a novel technique of a double-stapled, ileoanal, J pouch anastomosis with excellent outcomes. An inverse relationship exists between the size of the reservoir and the frequency of defecation.[84–87] Other factors that influence frequency of defecation include inflammation, sphincter function, and small intestinal motility. Larger reservoirs allow less frequent defecation but tend to be associated with more frequent bouts of inflammation of the reservoir ("pouchitis"), which probably results from stool stasis. In several recent series that studied 450 patients with reservoirs, the frequency of defecation ranged from 3.3 to 7.2 with an average of 5.8 stools per day.[88–93] Large series of patients with reservoirs, however, report an average rate of pouchitis of 23% and a pelvic sepsis rate of 8%.

### FOLLOW-UP

In addition to colonic polyps, patients with FAP can develop a large assortment of benign extracolonic manifestations and occasionally other cancers (see Table 93–1). Endoscopy of the upper gastrointestinal tract and sigmoidoscopy should be performed annually in all patients. Removal of polyps in the duodenum can be done by endoscopic snaring or by open duodenotomy. Size larger than 1 cm in diameter, rapid growth, polyp induration, severe dysplasia, or villous change suggests the need for a more aggressive intervention. Recent data have shown that 42% of adenomas of the ampulla of Vater that are larger than 1 cm in diameter contain a foci of cancer compared with only 13% of those smaller than 1 cm.[94] The incidence of duodenal cancer, however, remains low at 1% to 5%. Sigmoidoscopy can be done easily in patients with an ileoanal pull-through. The anal canal and any short segment of rectal mucosa left behind must be carefully evaluated.

### OTHER TREATMENTS

Drugs and several dietary supplements have been used to treat polyps. These include vitamin C,[95,96] sulindac,[96] dietary fiber,[97] and calcium.[98,99] In a randomized, double-blinded study of the use of sulindac, inhibition of both rectal and duodenal polyp growth was observed[100] and other studies have confirmed this finding.[71,101] In a randomized, double-blind, placebo-controlled study, however, standard doses of sulindac did not prevent the development of adenomas in subjects with FAP. Rectal cancer has been reported after prolonged sulindac treatment.

### GARDNER SYNDROME

Between 1951 and 1955, Gardner and colleagues[102–105] established the association of colonic familial adenomatous polyposis and the extracolonic findings of multiple osteomas, fibromas, and epidermoid cysts. They also demonstrated that the syndrome was inherited in an autosomal dominant pattern.[102,104] The natural history and treatment of the colonic polyps is the same as for those patients with FAP. The osteomas are most frequently found in the skull and facial bones, and abnormal dentition with impaction and early tooth decay and supernumerary teeth are seen.[106] Sebaceous cysts are most commonly found on the legs, followed by the face, scalp, and arms. Lipomas and fibromas are also seen.

Periampullary cancer was thought to be more prevalent in Gardner syndrome than in those with FAP, but surveillance of the duodenum in patients with FAP has shown a high incidence of duodenal abnormalities in all patients. Because detailed surveillance of all patients with familial polyposis has revealed many subtle extracolonic manifestations, the distinction between Gardner syndrome and FAP is becoming less clear. FAP is probably an all-encompassing syndrome, in which patients manifest different signs as the condition evolves.[107]

Desmoid tumors of the abdominal wall and mesentery of the small intestine occur in approximately 20% of patients with Gardner syndrome. These tumors also occur in patients who only have the colonic manifestations of FAP and are the leading cause of death in those who have undergone a prophylactic colectomy. Desmoid tumors are a dense, fibroplastic proliferation that may remain localized or may become widespread throughout the mesentery or the abdominal wall. All stages of fibrous dysplasia including fibrosarcoma have been seen. Most desmoid tumors appear after surgery, usually within 6 to 30 months.[108] Desmoid tumors of the body wall may be observed initially because many of them remain static or even regress over several years.[108] For those that continue to grow or reach 10 cm in diameter, complete local excision is met with a recurrence rate of less than 10%, which is satisfactory. Most intraabdominal desmoid tumors do not become evident until they have reached a nonresectable size. Because of the difficulty in resecting intraabdominal desmoid tumors, several drugs have been tried with varied rates of success. Such drugs include steroids; antiestrogen agents (progesterone, tamoxifen, and toremifene); and nonsteroidal anti-inflammatory agents.[109–115]

### TURCOT SYNDROME

Turcot, Despres, and St. Pierre[116] described two siblings who initially presented with colonic familial adenomatous polyposis and eventually died of intracranial brain tumors (glioblastoma and a medulloblastoma). Turcot believed that the brain tumors were extracolonic manifestations of FAP. Ependymomas and carcinoma of the thyroid (which are usually papillary in origin)[107] have also been described to occur in Turcot syndrome.

## Hamartomatous Polyposis Syndromes

Hamartomatous polyposis syndromes are distinguished by an overgrowth of cells that are native to the area in which they normally occur. The overgrowth is in general not considered to have malignant potential. Several of the syndromes in this category, however, have an increased lifetime risk of developing either intestinal or extraintestinal cancers. The hamartomatous polyposis syndromes include juvenile polyposis syndrome, Cowden disease, and Peutz-Jegher syndrome.

### JUVENILE POLYPOSIS SYNDROME

Juvenile polyposis syndromes are uncommon. These syndromes can be separated into three distinct clinical entities: diffuse juvenile polyposis of infancy, diffuse juvenile polyposis, and juvenile polyposis coli.[8]

#### Diffuse Juvenile Polyposis of Infancy

Diffuse juvenile polyposis of infancy presents within the first few months of life,[15] usually without any family history.[20] Presenting signs include diarrhea, rectal bleeding, intussusception, protein-losing enteropathy, macrocephaly, clubbing of fingers and toes, and hypotonia.[117–121] The extent of diarrhea, rectal bleeding, and protein-losing enteropathy is directly related to the number of polyps present. The entire GI tract is frequently involved. Treatment for this syndrome is usually aggressive, starting with total parenteral nutrition and intestinal rest. The latter measure reduces the protein and blood loss and decreases the incidence of intussusception.[122] When the nutritional status of the patient has been stabilized, portions of the intestine with the most polyps are

removed. Despite appropriate treatment, this disease is almost universally fatal; only 2 of 12 patients are reported as surviving beyond 2 years of age.[7,17,117–121,123–126]

### Diffuse Juvenile Polyposis

Children with diffuse juvenile polyposis are usually 6 months to 5 years of age and present with mild rectal bleeding and prolapse but may also have protein-losing enteropathy, intussusception, and malnutrition.[15] For this age group it is important to distinguish juvenile polyposis from familial adenomatous polyposis. Polyps associated with diffuse polyposis are found throughout the bowel, most often in the stomach, distal colon, and rectum.[15] Endoscopic polypectomies and segmental bowel resection are used in the treatment of this disease. These children usually do well, although the need for recurrent therapy is common.

### Juvenile Polyposis Coli

Juvenile polyposis coli occurs in children between the ages of 5 and 15 years of age. This disorder is usually characterized by bleeding of bright red blood from the rectum, anemia, rectal prolapse, or all of these disorders. Polyps are usually limited to the distal colon and rectum.[15] Approximately 50% of the patients will have a family history, indicating an autosomal dominant pattern of inheritance.[17] Associated congenital defects including cleft palate, malrotation, polydactyly, and abnormalities of the heart and cranium have been described.[20]

***Pathology*** Any child with five or more polyps, polyps throughout the GI tract, or even one polyp if the child has a family history of juvenile polyposis is considered to have a juvenile polyposis syndrome.[20] Most patients with such syndromes will have approximately 50 to 100 colorectal polyps. Patients with diffuse juvenile polyposis of infancy and diffuse juvenile polyposis will also have polyps in the stomach, small intestine, or both. The importance of identifying children with a polyposis syndrome lies in the need for long-term surveillance due to the high risk of carcinoma (17%) occurring at an early age (mean age at diagnosis of carcinoma is 35.5 years).[15]

The gross appearance of a polyp in juvenile polyposis is the same as one in isolated juvenile polyps. Approximately 20% of the polyps in juvenile polyposis, however, present grossly as a multilobular mass resembling a cluster of polyps attached to a stalk (Fig. 93-6).[18] Histologically, these polyps demonstrate more epithelium with a villous or papillary configuration. Epithelial dysplasia can occur in juvenile polyps[*] and in coexisting adenomas found in conjunction with juvenile polyps.[9,14,16,18,131–136] Severe dysplasia, which could be considered carcinoma in situ, has been found in patients with juvenile polyps associated with juvenile polyposis syndrome.[137] Lobular polyps have a higher propensity for more severe dysplasia (47%) than the nonlobular polyps (10%).[18] Several reports of infiltrating adenocarcinoma of the colon and rectum in association with juvenile polyposis exist.[8,12,129,131,138–140] According to the St. Mark's Polyposis Registry in London, the cumulative risk for cancer in patients with a juvenile polyposis syndrome by age 60 is 68%.[19,128]

*References 9, 12–14, 16, 18, 25, 127–132.

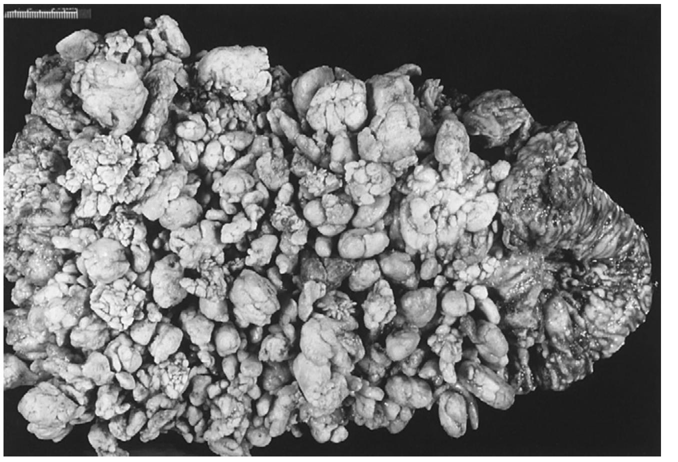

**FIGURE 93-6** Gross specimen of colon in a patient with juvenile polyposis syndrome. Note small adenomas and multilobular clusters of polyps attached to stalks.

***Treatment*** The autosomal dominant pattern of inheritance and the 68% cumulative risk for cancer by age 60 means that treatment must include long-term follow-up of patients with polyposis and their family members. Some advocate prophylactic colectomy and rectal mucosectomy with endorectal ileal pull-through as a primary treatment.[129] Others recommend regular screening (every 2 years) with colonoscopy and random biopsy[141] and subsequent colectomy if severe dysplasia, rapid polyp formation, or bleeding occurs.[16] One patient had a colectomy and ileosigmoidostomy at 4 years of age only to develop inoperable cancer of the sigmoid colon at 27 years of age.[18] First-degree relatives should be screened because of the familial nature of the disease. The approach to patients with juvenile polyposis should be similar to that taken for patients with familial adenomatous polyposis.

## PEUTZ-JEGHER SYNDROME

### History

The association of intestinal polyps with mucocutaneous pigmentation spots of the mouth, hands, and feet was first reported by Peutz in 1921.[142] In 1944[143] Jegher first reported two cases. In 1949[144] he and his colleagues added 8 more to 12 other cases he had collected from personal communications. Jegher and colleagues[144] subsequently defined the two main features of the syndrome: melanin spots on the buccal mucosa and lips, with variable melanin pigmentation on the face and digits, and polyposis of the intestinal tract. In 1954 Bruwer, Bargen and Kierland[145] were the first to use the term *Peutz-Jeghers syndrome*. In recent years, reports of intestinal and extraintestinal cancers have led to a reassessment of the management of these patients.[146]

### Pathology

Peutz-Jeghers syndrome is characterized by melanotic spots, ranging in color from brown to black, occurring on the lips, around the mouth, and on the buccal mucosa. These spots can also be found on the hands, feet, nasal mucosa, and conjunctivae and in the rectum.[146] The pigmented spots are usually present at infancy and usually fade at puberty.

Although the polyps associated with Peutz-Jeghers syndrome can be found anywhere from the stomach to the rectum, they occur most commonly in the small intestine (55%). Approximately 30% of these polyps are found in the stomach and duodenum, and 15% are found in the colon and rectum.[147] Grossly, the polyps range from a few millimeters to several centimeters and present as smooth, firm, pedunculated lesions that are lobulated, in contrast to juvenile polyps, which are not lobulated. Peutz-Jeghers polyps are classified histologically as hamartomas of the muscularis mucosa[146] and demonstrate strands of smooth muscle fibers that divide the polyp into sectors (Fig. 93-7).[148–150] Adenomas can occur concurrently with Peutz-Jeghers polyps.

### Etiology/Incidence

Peutz-Jeghers syndrome is rare and has an equal sex distribution; it has been described in all ethnic groups. Most cases of Peutz-Jeghers syndrome are inherited in an autosomal dominant pattern, but some develop de novo, most likely representing new, spontaneous mutations. Recently two groups of investigators have defined the genetic mutation associated with Peutz-Jeghers syndrome. In Peutz-Jeghers–affected individuals many (but not all) have a mutation of a novel serine/threonine kinase (LKB1 or STK11) with loss of kinase activity.[151,152] Routine genetic testing and gene therapy for this disease is under investigation but currently not available.[153]

### Clinical Presentation

Because of the familial association of Peutz-Jeghers syndrome, the syndrome is often revealed in patients through screening programs. If there is no family history, patients usually present with crampy abdominal pain related to transient intussusception of a polyp. Abdominal radiographs will often demonstrate dilated or partially obstructed small intestine but rarely complete obstruction. Anemia resulting from occult blood loss and malignant conditions are other presenting signs. Thirty percent of patients present with signs and symptoms in the first 10 years of life, with 50% presenting by 20 years of age.[154,147]

Several reports of intestinal tumors in association with Peutz-Jeghers syndrome have been published.[155–160] Malignant changes in hamartomatous polyps of Peutz-Jeghers syndrome have been commonly reported.[101,159,161–167] Separate adenomatous and carcinomatous changes in hamartomas have also been reported, which suggests that the adenoma-carcinoma sequence occurs in the small intestine of patients with Peutz-Jeghers syndrome.[161] A review of 72 patients with the syndrome[159] showed that 22% developed cancer. Nine cases were gastrointestinal or pancreatic in origin, and seven were extraintestinal. Compared with an age-matched general population, patients with Peutz-Jeghers syndrome had a relative risk for death from gastrointestinal cancer alone that was 13 times greater, and the risk for death from all cancers was 9 times greater. The chance of dying from cancer by the age of 60 is approximately 50% in patients with Peutz-Jeghers syndrome.[146]

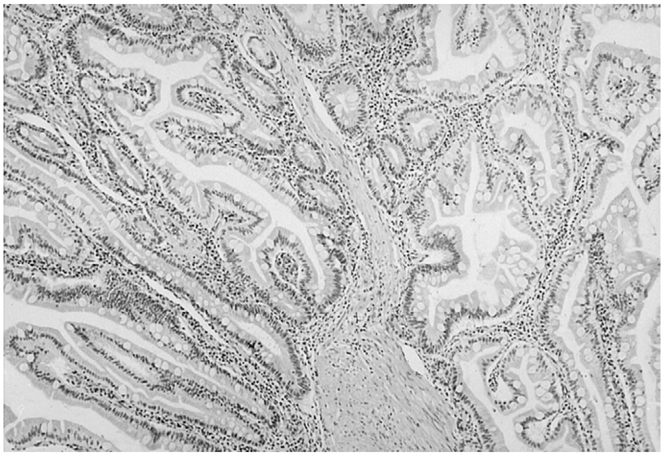

FIGURE 93-7 Photomicrograph of a Peutz-Jeghers polyp demonstrating a hamartomatous alteration of the muscularis mucosa. Smooth muscle fibers divide the polyp into sectors.

Extraintestinal tumors associated with Peutz-Jeghers syndrome include ovarian, cervical, and testicular neoplasms. Reported ovarian tumors include cystadenomas,[154,168,169] granulosa cell tumors,[135] and sex-cord tumors.[170–172] Adenocarcinoma of the cervix can occur and is usually associated with an ovarian tumor.[174] Sertoli cell tumors of the testicle have been found and cause gynecomastia in 50% of cases. These tumors are usually benign but have malignant potential[175–177]; thus an orchiectomy is recommended. Cancer of the breast, thyroid, bile duct, pancreatic, and gallbladder have all been described in association with Peutz-Jeghers syndrome.[146]

### Treatment

Peutz-Jeghers syndrome should be suspected in any child who presents with colicky abdominal pain or occult anemia and melanotic pigmented spots. Recommendations for treatment have changed over the past decade because of the increasing concern of malignancy. The management protocol proposed by Phillips and Spigelman[146] includes the following annual evaluations: (1) symptoms related to polyps, (2) blood count to detect anemia caused by blood loss, (3) breast and pelvic examinations with cervical smears and pelvic ultrasonography in girls, (4) testicular examination with ultrasonography in boys, and (5) pancreatic ultrasonography. In addition, esophagogastroduodenoscopy and colonoscopy are recommended on a biennial basis, along with small intestine contrast studies. Recently magnetic resonance imaging (MRI) has shown promise as a surveillance modality for small intestinal screening.[178] Mammography is recommended at 25, 30, 35, and 38 years of age, biennially until 50 years of age, and then annually.

All polyps larger than 0.5 mm found at endoscopy should be removed. Laparotomy with intraoperative enteroscopy is recommended for removal of all small bowel polyps greater than 15 mm in diameter. The previous practice of radical intestinal resections should be avoided because of the recurrent nature of the polyps and the ensuing short-bowel syndrome that can occur. Any intestinal or extraintestinal tumors should be treated aggressively. Historical data indicate that the chance of patients with Peutz-Jeghers syndrome dying by the age of 60 is close to 60% compared with 25% in an age-matched general population.[146]

## COWDEN DISEASE

Cowden disease is an autosomal dominant condition distinguished by multiple hamartomas that affects all three of the germ layers. Patients with Cowden disease are at an increased

risk of developing breast, thyroid, and endometrial neoplasias.[179,180] Eighty percent of patients present with dermatologic lesions including facial trichilemmomas, acral keratoses, papillomatous papules, or mucosal lesions. Other major but not necessarily pathognomonic criteria include breast carcinoma, thyroid carcinoma, macrocephaly, and endometrial carcinoma. Only 35% of patients who meet the criteria for Cowden disease will have gastrointestinal polyposis.[7] The polyps are typically juvenile polyps without any increased risk of developing a gastrointestinal cancer.

# Nonepithelial Polyps

## LYMPHOID POLYPS

### History

The first case of lymphoid hyperplasia of the terminal ileum was described by Marina-Fiol and Rof-Carballo in 1941 as reported by Patel and Awen.[181] Fieber and Schaefer[182] reviewed eight cases previously described in the literature and added four of their own in 1966. Byrne and colleagues[183] reported only 44 cases in the world literature; however, lymphoid polyps were identified in 60% of children studied by Franken for remote abdominal complaints.[184] Thus the incidence of lymphoid polyps is probably higher than reported, but clearly most of them are asymptomatic, and, therefore, never identified.

### Pathology

Lymphoid polyps vary in size from a few millimeters to 3 centimeters in diameter and are usually sessile in form. The polyps are caused by elevation of hyperplastic submucosal lymphoid aggregates. The overlying mucosa often becomes ulcerated, which gives the polyp the volcano-like appearance. Ulceration of the mucosa leads to occult blood loss. Hyperplasia of the submucosal lymphoid tissue is believed to be caused by nonspecific infections of childhood.[1,2,4,108]

### Incidence

Lymphoid polyps tend to develop in young children within the first few years of life as a result of exposure to new bacteria and viruses.[122] The peak incidence is at 4 years of age and significantly diminishes by 5 years of age.

### Clinical Presentation

Anemia resulting from blood loss and occasionally substantial rectal bleeding are the usual presenting signs of lymphoid polyps. Colonoscopy, air contrast barium enema, or both are the diagnostic methods of choice for diagnosing lymphoid polyps of the colon. An air-contrast barium enema will show small, uniform, umbilicated, polypoid filling defects that are distinct from juvenile or adenomatous polyps (Figs. 93-8 and 93-9).[183,184] Small elevations of otherwise-normal mucosa are seen on endoscopy, and biopsy will confirm the diagnosis. Histologic evaluation reveals lymphoid aggregates with large germinal follicles.[122]

### Treatment

Lymphoid polyps are benign, are self-limiting, and tend to regress spontaneously.[42,185] Once a histologic diagnosis is made, expectant measures will usually be rewarded by regression of

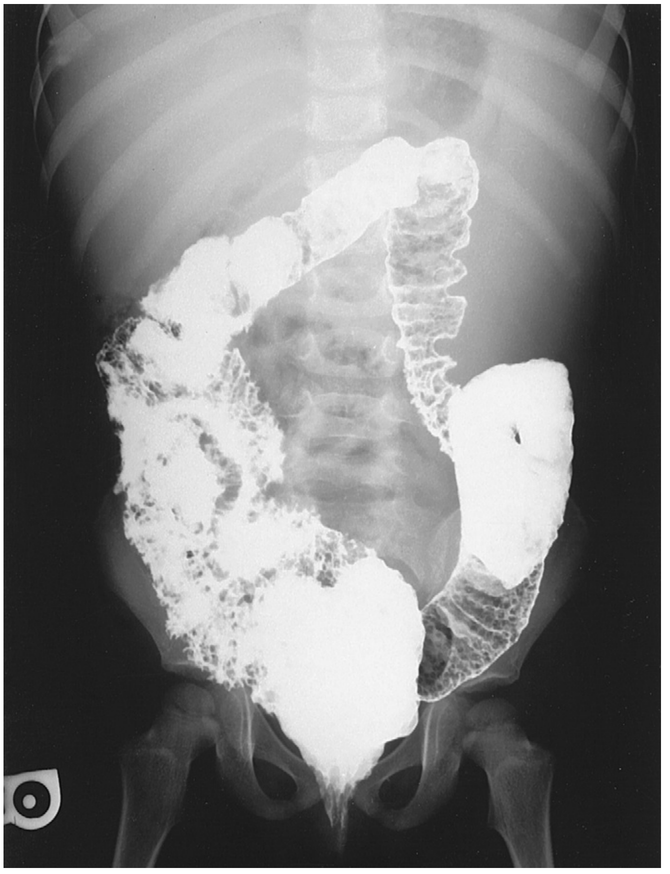

**FIGURE 93-8** Barium enema showing multiple, small 1- to 2-mm mucosal nodules throughout the entire colon and terminal ileum. The central umbilication within these nodules seen on this postevacuation film is diagnostic of diffuse lymphoid hyperplasia.

the lesions. Substantial uncontrolled bleeding and intussusception may require a more aggressive surgical approach.

CHAPTER 94

# Necrotizing Enterocolitis

Karl G. Sylvester, Gigi Y. Liu, and Craig T. Albanese

Necrotizing enterocolitis (NEC) is an acquired inflammatory disease that affects the gut of newborn infants nearly exclusively. Despite decades of research, NEC remains a leading cause of infant morbidity and mortality in neonatal intensive care units (NICUs). Increased rates of preterm birth and advances in neonatal care have contributed to a growing population of infants at risk for NEC. It is now the most common newborn surgical emergency and is associated with significant morbidity and mortality that exceeds all other gastrointestinal (GI) conditions requiring surgical intervention. Although the precise pathogenesis remains incompletely understood, clinical progress in recent years portends a shift in focus to prevention and the earlier identification of those infants most at risk or with progressive disease. Despite the recent completion of two successful prospective trials, the optimum surgical management of advanced disease with perforation remains controversial.

## Historical Perspective

Dating to at least 1888, there are several reports describing pathologic findings of intestinal perforation in neonates as the cause of death suggestive of NEC.[1–3] The first report of a successfully treated infant with a localized ileal perforation that was described as a disease resembling NEC is attributed to Agerty[4] in 1943. Subsequently, in 1953 Schmid and Quaiser[5] first used the term *necrotizing enterocolitis*. In 1964 Berdon[6] reported the clinical and radiographic findings of 21 patients with NEC. Then in 1975 Santulli[7] first hypothesized that the development of NEC had three essential components: injury to the intestinal mucosa, the presence of bacteria, and the availability of a metabolic substrate (to be taken as the presence of enteral feedings). This characterization remains a central tenet of our understanding of the overall pathophysiology of NEC (discussed later). Over the past several decades the management of infants with NEC has evolved from aggressive early operation to supportive care with the increasing realization that most infants can be managed, at least initially, nonoperatively.

The subsequent seminal work of Bell and colleagues[8] codified a severity-based classification scheme that is widely accepted due to its simplicity and clinical utility in suggesting therapy on the basis of likely outcomes. Bell's criteria (Table 94-1) can be summarized as indicating clinical findings suspicious for NEC (Bell's stage I), definitive NEC (Bell's stage II), and advanced NEC (Bell's stage III). In general, a stage I infant manifests clinical criteria that raise suspicion without definitive evidence such as pneumatosis intestinalis or bloody stool. In stage II, or definitive disease, there is nearly always evidence for pneumatosis intestinalis (Fig. 94-1). The hallmark of advanced disease is the appearance of pneumoperitoneum or other clinical findings to suggest irreversible tissue damage with perforation. In 1979 the International Classification of Diseases established a code for death from NEC, thereby allowing more precise epidemiologic and outcome analyses. Currently, the optimum surgical approach in order to realize the best short- and long-term outcomes in infants with intestinal perforation secondary to NEC remains the subject of intense scrutiny via ongoing clinical trials.

## Incidence

Although the overall reported incidence of NEC among newborn infants is relatively low and reported to fall between 5% and 10%.[9–11] The true incidence is unknown given a number of either early or suspicious cases of NEC that cannot be accurately tabulated. Conversely, the number of infants that are under consideration for either having or developing NEC can be quite high and is directly related to degree of prematurity. Perhaps more puzzling, the incidence of NEC varies significantly within the United States and throughout the developed world. For example, the worldwide incidence of NEC in very-low-birth-weight (VLBW, <1500 g) infants varies from 1% to 2% in Japan, 7% in Austria, 10% in Greece, 14% in Argentina, and 28% in Hong Kong.[12–16] The reasons for these disparities are unclear but are likely multifactorial including biologic (e.g., genetic) and environmental (e.g., variation in practice patterns). Irrespective of geographic reporting location, it is clear the incidence of NEC varies according to degree of prematurity and birth weight. NEC accounts for 1% to 7% of all NICU admissions in the United States, or 1 to 3 cases per 1000 live births.[9,17,18] In VLBW infants, the disease occurs in approximately 10% to 12%, but ranges between 2% and 22%, depending on the center of inquiry.[11,15,19]

**TABLE 94-1**
**Modified Bell Staging Criteria for Necrotizing Enterocolitis**

| *Stage* | *Systemic Signs* | *Abdominal Signs* | *Radiographic Signs* |
|---|---|---|---|
| IA<br>Suspected | Temperature instability, apnea, bradycardia, lethargy | Gastric retention, abdominal distention, emesis, heme-positive stool | Normal or intestinal dilation, mild ileus |
| IB<br>Suspected | Same as above | Grossly bloody stool | Same as above |
| IIA<br>Definite, mildly ill | Same as above | Same as above, plus absent bowel sounds with or without abdominal tenderness | Intestinal dilation, ileus, pneumatosis intestinalis |
| IIB<br>Definite, moderately ill | Same as above, plus mild metabolic acidosis and thrombocytopenia | Same as above, plus absent bowel sounds, definite tenderness, with or without abdominal cellulitis or right lower quadrant mass | Same as IIA, plus ascites |
| IIIA<br>Advanced, severely ill, intact bowel | Same as IIB, plus hypotension, bradycardia, severe apnea, combined respiratory and metabolic acidosis, DIC, and neutropenia | Same as above, plus signs of peritonitis, marked tenderness, and abdominal distention | Same as IIA, plus ascites |
| IIIB<br>Advanced, severely ill, perforated bowel | Same as IIIA | Same as IIIA | Same as above, plus pneumoperitoneum |

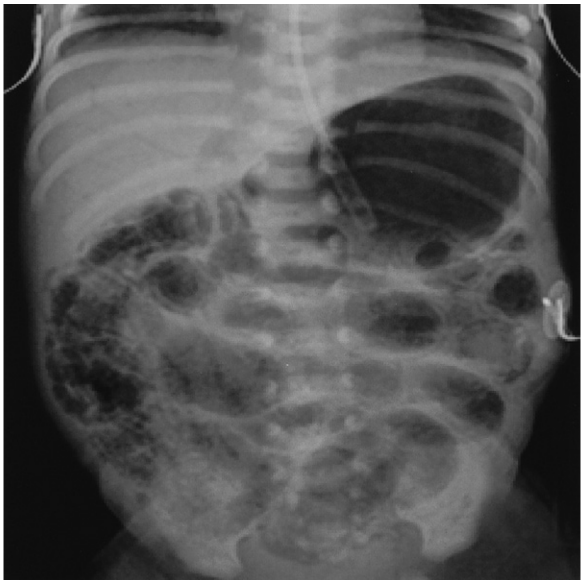

**FIGURE 94-1** Plain abdominal radiograph demonstrating extensive pneumatosis intestinalis (cystic and linear) and an arborizing pattern of air over the liver shadow representing gas dispersed within the radicles of the portal venous system.

Several confounding factors may account for the variability in incidence reporting including the number and survival of low-birth-weight (LBW) infants, the source of patient referrals (inborn or outborn), and the diagnostic criteria used to establish definitive NEC. A relatively large multicenter survey of VLBW infants noted an incidence of 10.1% for definite NEC (stage II) and 17.2% for suspected NEC (stage I), although there was considerable intercenter variability.[20] In another study, the incidence of definite NEC versus suspected NEC was 8.6% and 18.6%, respectively.[18] The observed variability in these and many other series may be underestimating the true frequency of NEC because the incidence is often defined as the total number of cases of NEC divided by the total number of patients admitted to the NICU. Thus these figures may include many premature infants who die within the first several days of life and before enteric feedings and therefore are unlikely attributable to NEC. In consideration of this, a notable historical study that excluded early neonatal deaths and included only infants who had been fed reported an incidence of 15%.[21]

# Epidemiology and Pathogenesis

## EPIDEMIOLOGY

### Age and Maturity

NEC is predominantly a disease of premature LBW infants rather than those who are small for gestational age. It is estimated that only 7% to 13% of all NEC cases occur in full-term infants.[22,23] Kliegman and Fanaroff[24] reported that the mean gestational age of 123 patients with NEC was 31 weeks (average birth weight, 1460 g). Infants with extremely low birth weight (ELBW) (<1000 g) and those 28 weeks' gestational age or younger are at greatest risk.[25,26] In a large multicenter prospective study from the NICHD Neonatal Research Network involving 4438 infants weighing between 501 and 1500 g, Lemons[11] demonstrated an inverse relationship between the incidence of NEC and birth weight. Specifically, the incidence of NEC was highest in infants weighing between 501 and 750 g (14%) and declined with increasing weight: 751 to 1000 g (9%), 1001 to 1250 g (5%), and 1251 to 1500 g (3%). These findings have been confirmed by others[23,27,28] and extended to document an inverse relationship between the age at onset of NEC and gestational age. Infants in whom NEC developed in the first week of life were more mature (average gestational age, 36.1 weeks) than those in whom NEC developed after

1 week of age (average gestational age, 33.4 weeks). Complications were more common, and the mortality rate was higher in patients with early-onset disease. Wilson[29] calculated the birth weight–specific, weekly attack rate in patients with NEC and found the risk period for NEC decreased as birth weight increased. They found a consistent pattern of sharply declining risk with attainment of age equivalent to 35 to 36 weeks' gestation. From these observations the authors speculated that functional maturation of the GI tract may play a principal role in determining the risk for NEC.

### Feedings

Approximately 90% of NEC cases develop in infants after feedings are initiated.[30–32] In a longitudinal cohort study reviewing the incidence of NEC for a 3-year period before and after implementing a "standardized feeding schedule" for infants weighing between 1250 and 2500 g and less than 35 weeks' gestation, Kamitsuka[33] reported an 84% reduction in the risk for NEC. Other studies have also suggested an association between an increase in the incidence of NEC and advancement of formula feedings at rates greater than 20 kcal/kg/day.[34,35] Despite these reports, randomized trials failed to demonstrate any difference in the incidence of NEC related to fast versus slow, early versus delayed, or continuous versus intermittent bolus feedings.[36–39] In a randomized trial involving 185 VLBW infants in which slow (15-mL/kg/day increments; 10-day schedule to full feeding) and fast (35-mL/kg/day increments; 5-day schedule to full feeding) feeding advancements were compared, Rayyis[39] demonstrated no significant difference in the incidence of NEC (13% vs. 9%), perforation (4% vs. 2%), and mortality (2% vs. 3%) between groups. In a review of randomized trials comparing continuous versus intermittent bolus tube feeding for premature infants weighing less than 1500 g, Premji and Chessell[38] found no significant differences in the incidence of NEC between the two groups.

In a randomized trial investigating the incidence of NEC in VLBW infants assigned to receive either minimal-volume feeding (20 mL/kg/day) for 10 days before advancing to full-volume feeding or a standard feeding advancement protocol (starting at 20 mL/kg and increasing by 20 mL/kg/day to full-volume feeding), Berseth[40] reported a significantly lower incidence of NEC in the minimal-volume group than in the standard group (1.4% vs. 10%). The prolonged use of "trophic feeding" volumes is thought to trigger maturation of GI structure and function. This study reinforces previous studies that gut stimulation protocols are beneficial to VLBW infants[41] and that initiation of a minimal-volume feeding protocol for 7 to 10 days followed by modest advancement of feeding may greatly reduce the incidence of NEC.[42] However, there are no contemporary studies that specifically address this issue.

### Pharmacologic Agents

Indomethacin is commonly used in premature infants to treat a hemodynamically significant patent ductus arteriosus (PDA). Indomethacin blocks prostaglandin synthetase, thus causing vasoconstriction. Spontaneous gastrointestinal perforation (SIP) and NEC have been noted in LBW infants treated with high-dose indomethacin.[43,44] It has been postulated that indomethacin increases mesenteric vascular resistance and reduces mesenteric blood flow by 16% to 20%.[45] Norton[46] demonstrated that the use of indomethacin as a tocolytic agent was associated with an increased incidence of NEC in babies delivered before 30 weeks' gestation (mean age at delivery, 27.6 weeks), although indomethacin did not increase the incidence of NEC in babies born after 32 weeks' gestation. Two randomized controlled trials involving more than 500 LBW premature infants receiving early low-dose indomethacin versus placebo for closure of a PDA demonstrated no difference in the subsequent incidence of NEC.[47,48] According to several recent Cochrane Reviews, ibuprofen appears to be as effective as indomethacin in leading to a PDA closure and with fewer reported cases of NEC or SIP.[49] Interestingly, although the continuous infusion of indomethacin for a PDA leads to fewer alterations in cerebral, renal, and mesenteric blood flow compared with bolus infusion, to date, insufficient evidence exists to demonstrate that this results in a lowered risk of NEC or SIP.[50] Earlier indomethacin may be associated with increased incidence of SIP but protection from NEC. Moreover, a PDA itself may predispose to NEC, independent of indomethacin.

### Cytokines and Growth Factors

Cytokines and growth factors play a critical role in mediating the interaction among enterocytes, endothelial cells, fibroblasts, and inflammatory cells that together are critical to the overall cellular pathophysiology of NEC. These soluble factors direct cellular proliferation, maturation, chemotaxis, and activation in both the local gastrointestinal milieu and systemically to effect the onset and progression of NEC (Table 94-2).[51–56]

### Growth Factors

Epidermal growth factor (EGF) is known to be an important trophic factor for the developing GI tract and has been shown to be present in high concentration in human breast milk.[57,58] Typically, EGF is secreted into the gut lumen primarily by the salivary and Brunner glands of the duodenum and binds to EGF receptors that have been demonstrated throughout the fetal and neonatal intestine, especially on the basolateral membrane of enterocytes.[59–64] EGF enhances proliferation and differentiation of epithelial cells but also has significant effects on healing of damaged mucosa and on intestinal adaptation after injury.[62,65–67] Significantly reduced levels of salivary and serum EGF have been demonstrated in premature infants in whom NEC developed versus age-matched controls.[68,69] Furthermore, lower levels of salivary EGF during the first week of life were associated with an increased incidence of NEC in a recent clinical trial[70] involving 327 premature and term neonates. Similarly, inactivation of the EGF receptor in knockout mice has been shown to result in hemorrhagic enteritis that is histologically similar to NEC.[71]

Several animal studies that administered EGF provide insight to the molecular mechanism underlying EGF-mediated protection against NEC. In studies using a neonatal rat model of NEC that involved asphyxia and cold stress, enterally administered supplements of EGF have been shown to significantly decrease the incidence and severity of NEC in rat pups[72] through down-regulation of the proinflammatory interleukin-18 (IL-18) and increased production of the anti-inflammatory cytokine IL-10.[73] Supplement of EGF in two rat models has successfully reduced intestinal epithelial cell apoptosis in the ileum, decreased intestinal permeability,

increased mucin production by goblet cells, and improved overall intestinal structure.[74,75]

Heparin-binding epidermal-like growth factor (HB-EGF) is a member of the EGF family of growth factors. HB-EGF initially was identified in conditioned medium of macrophage-like cells as a mitogen for fibroblasts and smooth muscle cells.[76] The presence of HB-EGF has been reported in both human amniotic fluid and milk.[77,78] An HB-EGF knockout mouse model has shown significantly increased intestinal permeability, delayed onset of angiogenesis, and increased incidence and severity of NEC.[79,80] According to several animal studies,[78,81–84] HB-EGF has been demonstrated to protect developing intestinal epithelium from hypoxic necrosis and cytokine-induced apoptosis, as well as to exert its cytoprotective effects via decreased reactive oxygen and nitrogen species production. Interestingly, simultaneous administration of both EGF and HB-EGF did not result in any additional protective effect against NEC.[83]

Erythropoietin (Epo) is a peptide produced by the kidneys that regulates red blood cell production in response to anemia. Since development of the recombinant protein, rEpo has become widely used in the NICU.[85,86] Epo has been found in human breast milk, and functional Epo receptors have been demonstrated in fetal and neonatal small intestine, thus

suggesting a possible role in GI development.[87–89] In a retrospective study comparing 260 VLBW infants who received recombinant Epo (rEpo) with 233 matched controls, Ledbetter and Juul[90] demonstrated a significantly lower incidence of NEC in the rEpo group (4.6%) than in the control group (10.8%). Studies in neonatal rats given rEpo enterally have demonstrated a dose-dependent increase in intestinal mucosa villus surface area and increased cellular proliferation, thus suggesting a role of rEpo as a trophic factor in the developing small intestine.[91] In a neonatal rat model of NEC involving exposure to hypoxia and reoxygenation, pretreatment with intraperitoneal injections of rEpo resulted in significantly decreased mucosal inflammation and necrosis, which was suggested to be mediated by decreased production of nitric oxide (NO).[92]

## Cytokines

Cytokines are endogenous mediators of the inflammatory cascade. Proinflammatory and antiinflammatory cytokine production is tightly regulated by complex feedback mechanisms to maintain homeostasis.[93,94] Overproduction of either may have significant untoward effects. Overproduction of proinflammatory cytokines (IL-1, IL-2, IL-6, IL-8, IL-12, tumor necrosis factor-alpha [TNF-α], interferon) and platelet-activating factor (PAF) may lead to shock, multiorgan failure, and death.[95,96] Overproduction of antiinflammatory cytokines (IL-4, IL-10, IL-11) may result in excessive suppression of immune function.[97,98] A number of different inflammatory mediators have been implicated in the pathogenesis of NEC, several of which are highlighted later.[99,100]

IL-1β in the gut can be found in macrophages, neutrophils, intestinal epithelial cells, endothelial cells, fibroblasts, dendritic cells, smooth muscle cells, and enteric glia.[101,102] Microbial products, inflammation, and TNF-α trigger its release.[101,102] Upon binding to the IL-1 receptor, IL-1β and its receptor activate the transcription factor NF-κB, which triggers release of acute phase proteins, IL-6, IL-8, and $PGE_2$.[101,102] Elevated IL-1β has been detected in full-thickness specimens of NEC intestine.[103] Edelson[104] detected a greater level of IL-1 receptors late in the course of severe NEC. Both IL-1β and IL-1 receptor may serve as markers for progressive disease.

Levels of IL-6 increase in the presence of microbes, microbial products, TNF-α, and IL-1β.[101,105] Upon binding to IL-6 receptors, which are only expressed on hepatocytes and some leukocytes, IL-6 triggers the STAT-4 pathway, resulting in production of acute phase proteins, B cell growth, antibody production, T-cell proliferation, and enhanced activity of hematopoietic growth factors such as granulocyte-macrophage colony-stimulating factor (GM-CSF).[101,105] Furthermore, it leads to the production of tissue inhibitors of metalloproteinases and inhibition of superoxide production.[106] Elevated IL-6 has been reported in the plasma and stool of babies with NEC,[107] but its mRNA expression in surgical intestinal specimens is not any higher than the controls.[105]

IL-8 is released in response to LPS, TNF-α, and IL-1β.[108] After binding to the chemokine receptors CXCR1 and CXCR2, which signal through phospholipase C and PI3-kinase, respectively, IL-8 is responsible for neutrophil activation and migration into tissues, as well as the production of acute phase proteins.[108] In a study evaluating serial serum levels of two proinflammatory cytokines (IL-1β, IL-8) and two antiinflammatory cytokines (IL-1 receptor antagonist [IL-ra], IL-10) in infants with NEC, Edelson and colleagues[104] demonstrated significantly higher levels of IL-8 and IL-10 in infants with severe NEC from the onset of disease through 24 hours than in infants with less severe NEC. Nadler[109] investigated the pattern of cytokine expression in infants undergoing resection for severe NEC and infants undergoing intestinal resection for other inflammatory conditions. Significant up-regulation of IL-8 mRNA was seen in the specimens from infants with NEC as compared with controls.

IL-12 is released in response to bacteria, bacterial products, and viruses and exerts its effect on T cells and NK cells upon binding to its receptor.[110] Its immunologic functions include the following: IFN-γ production, Th1 and NK cell proliferation, cytotoxic T lymphocyte and Th1 cell differentiation, macrophage activation, and production of complement-fixing antibodies.[110] Halpern[111] localized IL-12 via immunohistochemistry to monocytes in the intestinal mucosa and lamina propria in a neonatal rat model of NEC.

Tissue IL-18 levels peak in response to lipopolysaccharide (LPS or endotoxin), Fas ligand, gram-positive bacteria exotoxins, and IL-12 and subsequently induce the production of TNF-α and IL-1β.[112] Binding to the IL-18 receptor results in NF-κB activation and promotes Th1 or Th2 lineage maturation depending on the underlying genetic influence and cytokine environment.[113] Heninger[114] discovered infants with stage III NEC or above to have a higher frequency of the IL-18607 AA genotype, thus suggesting that this variation may be used for predicting the outcome of NEC.

IL-4, produced by Th2 cells, mast cells, B cells, and stroma cells, is a key regulator in humoral and adaptive immunity.[100,120] It has been demonstrated to possess cytoprotective effects in human intestinal epithelial cells by reducing bacterial translocation, increasing leukocyte superoxide production, and inducing decay-accelerating factor, which protects the host from the attack of autologous complement activation.[115,116] Genetic studies by Treszl[117] revealed that infants with NEC were less likely to possess the IL-4 receptor α-chain mutant allele compared with infants without NEC. Treszl[117] speculated that this mutant allele is associated with enhanced transduction of IL-4 signals, which shifts the development of lymphocytes to a more pronounced Th2 state.

IL-10, produced by Th2 cells, monocytes, and B cells, is an inhibitor of proinflammatory cytokine production and of several accessory cell functions of the macrophage, T cell, and natural killer (NK) cell lines.[118] Furthermore, IL-10 has also been shown to decrease the production of metalloproteinases[119] and suppress iNOS mRNA and NO expression in small bowel, liver, and serum.[120] It is postulated that diminished production of IL-10 in preterm infants resulted in persistent up-regulation of the inflammatory response and therefore increased susceptibility in the preterm neonate to long-term tissue damage after acute inflammatory conditions.[121] Although Edelson and colleagues[104] found significantly higher levels of IL-10 in infants with severe NEC from the onset of disease through 24 hours than in infants with less severe NEC, in a neonatal rat hypoxia-reoxygenation model of NEC, recombinant IL-10 administered subcutaneously was found to significantly attenuate the extent of intestinal injury when compared with control animals, thus suggesting a protective effect of its antiinflammatory properties.[122] Taken together, these findings indicate that IL-10 has the potential to be a marker of severe disease and may

be considered a therapeutic target to function as a strong cytokine inhibitor. The high level of IL-10 in severe NEC, in contradistinction to less progressive NEC, suggests a significant role for antiinflammatory mediators in the pathophysiology of NEC to dampen the inflammatory response.

IL-11 or adipogenesis inhibitory factor is a member of the IL-6 type cytokine family that uses the gp130 receptor subunit for intracellular signal transduction. IL-11 has been shown to be a pleiotropic cytokine that promotes epithelial regeneration and enhances adaptation after bowel resection.[123] Subcutaneous administration of recombinant IL-11 in rats undergoing placement of a defunctionalized (Thiry-Vella) loop of intestine or massive small bowel resection has resulted in prevention of mucosal atrophy in the defunctionalized loop and enhanced mucosal adaptation and absorptive function in the remaining intestine after resection.[124,125] In addition, Nadler[109] noted significant up-regulation of IL-11 mRNA in infants undergoing resection for severe NEC and found an inverse correlation between IL-11 expression and the likelihood of pan-necrosis, thus suggesting that IL-11 secretion may be an adaptive response to limit the extent of intestinal damage.

TNF-α has many proinflammatory effects including neutrophil activation, induction of leukocyte and endothelial adhesion molecules, and induction of other cytokines such as PAF.[126] TNF-α has been demonstrated to produce profound hypotension and severe intestinal necrosis similar to NEC in animals. This effect has been shown to be mediated by PAF and attenuated by PAF receptor antagonists.[127] Confirmatory studies in human neonates with NEC identified significantly elevated plasma levels of TNF-α compared with controls.[99] Pentoxifylline, a drug that has multiple effects including inhibition of production of TNF-α, was shown to reduce bowel necrosis in an adult rat ischemia-reperfusion model of bowel injury, as well as the incidence of NEC in a neonatal rat model.[128] Furthermore, two separate studies[129,130] have demonstrated a significant reduction in the severity of NEC in neonatal rats after intraperitoneal TNF-α antibody prophylaxis. However, the A(-308) and A(-238) allele variants of the promoter region of the TNF-α gene, which were reportedly associated with higher TNF-α production, fail to show any influence on the risk and course of NEC in VLBW infants.[131]

A tremendous amount of investigation has been performed to define the role of nitric oxide (NO) in the pathogenesis of a number of different inflammatory processes. Evidence supports a possible dichotomous function of NO as both a beneficial and a detrimental molecule, especially with regard to the GI tract.[132,133] NO is produced from arginine by three isoforms of nitric oxide synthase (NOS). NOS-1 (neuronal, nNOS) and NOS-3 (endothelial, eNOS) are constitutively present at low levels in the small intestine. NOS-2 (inducible, iNOS), which is expressed in the myenteric plexus, endothelial cells, gastric epithelial cells, and enterocytes,[134,135] is a form that can be induced in response to inflammatory cytokines.[136,137] The constitutive forms of NOS and constitutive levels of NO have been demonstrated to modulate a number of important functions in the GI tract including maintenance of mucosal integrity, regulation of mucosal permeability, modulation of water and electrolyte transport, regulation of blood flow, regulation of motility, and inhibition of leukocyte adhesion and activation.[138–142]

Inhibition of NO synthesis in a variety of animal models of intestinal injury induced by ischemia-reperfusion, LPS, or PAF has resulted in marked exacerbation of mucosal injury.[143–148] Administration of exogenous sources of NO including L-arginine, sodium nitroprusside, and nitroglycerin greatly attenuates these detrimental effects.[149–152] In a prospective study of 53 premature infants, Zamora[153] demonstrated a significantly lower plasma arginine level at the time of diagnosis in infants in whom NEC developed compared with controls. In the only randomized, prospective, placebo-controlled study of VLBW infants assigned to receive either daily L-arginine supplements (261 mg/kg) or placebo for the first 28 days of life, Amin[154,155] found a significantly lower incidence of NEC in the supplement group (6.7%) than in the control group (27.3%). Throughout the study, the group that received arginine supplementation had significantly higher mean plasma arginine levels than the control group did. Interestingly, in both groups the infants in whom NEC developed had significantly lower plasma arginine levels at the time of diagnosis than their respective peers did. It is not known whether the decreased arginine levels represent increased utilization for NO production, consumption for the synthesis of other proteins, or decreased enteral absorption. This study suggests the possible benefits of arginine supplementation and potentially other NO donors in the prevention of NEC.

The inducible form of NO synthase (NOS-2, iNOS) is induced in response to inflammatory cytokines. Within several hours of stimulation, NOS-2 expression and activity within the intestinal epithelium increase up to 15-fold and result in the production of large amounts of NO.[135] Although the low levels of NO produced by the constitutive isoforms of NOS may play a homeostatic role in the GI tract, sustained release of NO as a result of up-regulation of NOS-2 has been suggested to have deleterious effects by inducing cellular injury and failure of the mucosal barrier.[135,156,157] This is thought to occur by the reaction of excess NO with superoxide (O2−) to produce peroxynitrite (ONOO−), a potent reactive nitrogen intermediate that may trigger cytotoxic processes including lipid peroxidation and DNA damage.[157–159] In a prospective study investigating NOS-2 expression in the intestine of infants undergoing resection for NEC, Ford[160] demonstrated marked up-regulation of NOS-2 gene expression in the intestinal epithelium and increased apoptosis of enterocytes in the apical villi. In addition, increased levels of nitrotyrosine residues were detected in the apical villi, thus suggesting that the mucosal injury and increased apoptosis were mediated through the formation of NO and peroxynitrite. In a neonatal rat hypoxia model of NEC in which breast milk–fed animals were compared with formula-fed animals, Nadler and colleagues[161] demonstrated a significantly higher incidence of NEC, NOS-2 expression, and enterocyte apoptosis along with decreased IL-12 mRNA in the formula-fed group than in the breast milk–fed group. The decreased IL-12 expression is thought to be mediated by NO and theorized to contribute to intestinal injury by attenuating bacterial clearance. Furthermore, Whithouse has shown in a rat model that the progression of NEC to intestinal ischemia is associated with a shift from nitric oxide to superoxide production by the intestinal vascular endothelium.[162]

PAF, an endogenous phospholipid inflammatory mediator, has been shown to play an important role in the pathophysiology of intestinal injury in both animal and human studies.[12] PAF has diverse biologic effects including

mesenteric vasoconstriction, capillary leakage, increased intestinal mucosal permeability, and neutrophil and platelet activation.[163–165] Clinically, increased PAF levels have been demonstrated in formula-fed premature infants, as well as in those in whom NEC developed.[100,166] In a neonatal rat model of NEC, Caplan[167] showed that intestinal PAF concentrations, intestinal phospholipase A2 (PAF-synthesizing enzyme) mRNA expression, and intestinal PAF receptor mRNA expression are all elevated. In other animal experiments, exogenous PAF administration results in severe bowel necrosis[168]; endogenous intestinal production of PAF is up-regulated in response to various stimuli including LPS, hypoxia, and TNF-α[127,169–171]; and administration of PAF receptor antagonist, or PAF acetylhydrolase (PAF-degrading enzyme), reduces the risk for NEC.[170,172,173] In human studies, PAF acetylhydrolase activity has been demonstrated to be present in human breast milk; it has also been shown to be decreased in neonates, with levels approaching adult enzyme activity at around 6 weeks of life, and has been found to be deficient in infants with NEC.[99,174,175] In a prospective study of 164 infants at risk for NEC, Rabinowitz[176] monitored serial plasma levels of PAF and PAF-related lipids (PAF-LL) to investigate the changes that occur with NEC. There was a significantly higher peak in PAF-LL levels in infants in whom NEC developed than in controls. In addition, rising PAF-LL levels were positively correlated with progression of the severity of NEC; these levels returned to baseline levels during recovery. With the studies mentioned, a systematic review[56] of serologic tests in diagnosing NEC suggested that PAF is one of the better performing markers for NEC with a sensitivity of 92% and specificity of 84% despite the considerable heterogeneity between the studies.

Cyclooxygenase (COX) catalyzes the rate-limiting step of arachidonic acid metabolism into prostaglandins, leukotrienes, and thromboxanes.[177] Two isoforms of the COX enzyme have been identified. COX-1 is constitutively expressed in many tissues including the GI tract.[178] COX-2 is the inducible form that is expressed in inflammatory conditions of the GI tract such as inflammatory bowel disease.[179,180] Proinflammatory cytokines (IL-1, IL-6, TNF-α), as well as the proinflammatory transcription NF-κB, have been shown to increase COX-2 expression.[181] NF-κB is an important protein in the activation of a number of inflammatory mediators and cytokines.[182] A marked increase in COX-2 expression has been demonstrated in intestine resected from infants with severe NEC.[183] To elucidate the mechanisms involved in COX-2 expression in NEC,[183] Chung demonstrated a coordinated induction of NF-κB activation and COX-2 expression during the early phases of injury in a neonatal rat model of NEC.

LPS (endotoxin) is a bacterial product that has the capacity to produce potent inflammatory responses through the induction of various proinflammatory cytokines such as PAF and TNF. Recent studies suggest that LPS binds with pattern recognition receptors on the intestinal epithelial barrier, such as Toll-like receptors (TLRs), formylated peptide receptors (FPRs), or nucleotide-binding oligomerization domain-like receptors (NODs), to trigger mitogen-activated protein kinase (MAPK), nuclear factor kappa-B (NF-κB), and caspase-dependent pathways, thus leading to various inflammatory responses (Fig. 94-2).[184] Furthermore, Grishin[185] has demonstrated that LPS stimulates p38 MAPK-dependent expression of cyclooxygenase-2 (COX-2) in a rat model of NEC. Systemic injection of LPS has been shown to produce hypotension, shock, and severe intestinal necrosis.[25] It has been used in animal models of NEC to reliably generate intestinal injury that resembles NEC.[186]

## PATHOGENESIS

Despite many years of extensive investigation and the identification of several key risk factors, the precise pathogenesis of NEC remains elusive. The etiology is likely multifactorial and involves a combination of mucosal compromise, pathogenic bacteria, and enteral feedings that in a susceptible host results in bowel injury and an inflammatory cascade (see Fig. 94-2). Of the risk factors, prematurity is the most

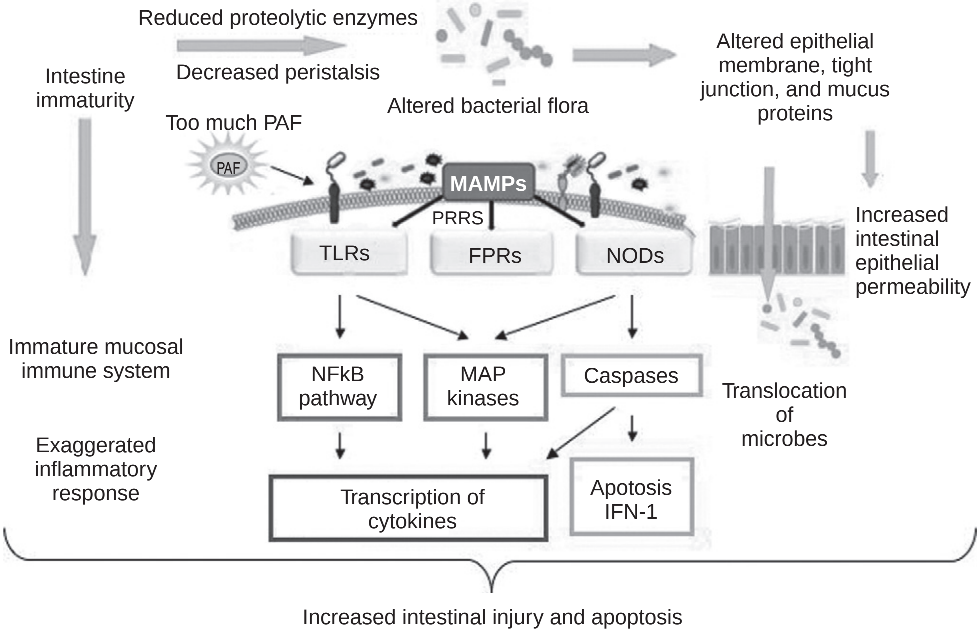

**FIGURE 94-2** Schematic summarizing the pathologic features that contribute to the pathogenesis of necrotizing enterocolitis.

consistent along with the enteral feeding of formula. Commercially available formulas lack many of the beneficial properties present in breast milk. These protective agents include gut trophic hormones, factors that induce intestinal maturation, factors that enhance colonization by nonvirulent bacteria, antiinflammatory mediators, vitamins, antioxidants, and components that support cellular and humoral immunity.[187–190]

### Evidence for an Impaired Gut Barrier

The preterm GI tract is characterized by an immaturity of cellular and humoral immunity,[191,192] increased permeability,[193] reduced gastric acid secretion,[194] reduced concentration of proteolytic enzymes,[195] incomplete innervation and decreased motility,[196,197] and immaturity of the intestinal epithelium and microvilli barrier function.[198] Decreased barrier function is evident in otherwise healthy preterm infants by their ability to systemically absorb and deliver undigested macromolecules, whole bacteria, and LPS.[199–201] Compromise of the intestinal epithelial barrier appears to be the first event leading to activation of the inflammatory cascade.

Reduced mucosal blood flow leading to cellular hypoxia and injury is one of the most frequently cited etiologic factors for NEC. Touloukian[202] emphasized the high incidence of perinatal physiologic stressors that may primarily or secondarily cause intestinal ischemia. Chief among these factors are hypoxic and hypotensive episodes, exchange transfusions through the umbilical vein, umbilical artery catheters, cardiovascular lesions, and serum hyperviscosity. The "diving reflex" in which blood is preferentially diverted away from the splanchnic circulation in order to maintain adequate perfusion of the heart and brain has been hypothesized to occur during these episodes.[203] During periods of low blood flow and subsequent reperfusion, Parks[204] found that a reaction among xanthine oxidase, hypoxanthine, and molecular oxygen results in a burst of superoxide radical production. These free radicals may cause damage to cellular and mitochondrial membranes and alter the permeability of the intestinal mucosal barrier. Although animal studies provide support for this theory, clinical correlation has been lacking, and prospective clinical trials have not been able to consistently establish an association between a hypoxic event and the development of NEC.[205]

Extensive investigation into the critical role of various inflammatory mediators in the pathogenesis of NEC has been conducted. Studies in animal models and human specimens have identified PAF, LPS, NO, and TNF-α as leading potential mediators of NEC.[160,168,169] Increased mucosal permeability and susceptibility allowing translocation of bacteria or bacterial toxin and activation of the inflammatory cascade are thought to be the critical steps leading to the final collapse of intestinal epithelial integrity.[206] Recent studies have suggested that the disruption in the intestinal mucosal barrier results from accelerated apoptosis. All of the key mediators identified in NEC (PAF, NO, LPS, TNF-α) have been shown to cause apoptosis of intestinal epithelial cells.[160,207–209] In a neonatal rat model of NEC involving formula-fed animals exposed to hypoxia and cold stress, Jilling[210] demonstrated a marked increase in apoptosis in the epithelial layer of the NEC group in comparison with mother-fed controls. The accelerated apoptosis was shown to precede gross morphologic changes in the intestinal epithelium. Administration of a pan-caspase inhibitor to inhibit intestinal apoptosis resulted in a significantly reduced rate of epithelial apoptosis, as well as a decreased incidence of NEC, thus suggesting that apoptosis was the underlying cause of the subsequent mucosal damage, ultimately leading to NEC.

Sustained overproduction of NO secondary to up-regulation of NOS-2 in the GI tract in response to an inflammatory stimulus has been suggested to induce cellular injury and disruption of the intestinal epithelial barrier through a variety of mechanisms.[156] Ford[160] demonstrated up-regulation of NOS-2 and NO in the intestinal wall of infants with NEC and increased apoptosis of enterocytes mediated by the potent oxidant peroxynitrite. This accelerated apoptosis is thought to result in a break in the villus tip of the intestinal mucosal barrier where bacteria may attach, translocate, and initiate an inflammatory cascade.[211] In addition, peroxynitrite has also been shown to inhibit the proliferation of intestinal epithelial cells in a rat model of NEC.[212] The data suggest that in conditions associated with sustained overproduction of NO or peroxynitrite (e.g., NEC), intestinal epithelial barrier dysfunction may result from an imbalance caused by accelerated epithelial injury and blunted tissue repair mechanisms.

### Role of Infectious Agents

The type of feeding and pattern of intestinal colonization may determine the risk for development of NEC. Breast-fed infants become colonized predominantly with bifidobacteria (gram-positive bacteria) that help control the growth of gram-negative bacteria.[213,214] In contrast, formula-fed infants become colonized predominantly by coliforms, enterococci, and *Bacteroides* species.[215]

The intestinal mucosa serves as a barrier to the largest microbial challenge to the human body. Beyond serving as a simple physical barrier, the dynamic interaction between the intestinal mucosa and colonizing microbes is an integral part of the innate immune system and is regulated by a system of pattern recognition receptors (PRR). During gut colonization, crosstalk between the system of PRR and commensal bacteria occurs, resulting in intestinal mucosal tolerance or hyporesponsiveness toward the enteric microbes in order to establish a symbiotic relationship. The PRR respond to microbial associated molecular patterns (MAMP) (i.e., LPS, flagellin, peptidoglycans) in order to modulate the cellular response through a variety of downstream signaling pathways (see Fig. 94-2). The PRR system includes the TLRs, which are largely responsible for sampling and interpreting the extracellular environment, and in this capacity, the TLRs have been implicated as an integral mechanism to the pathogenesis of NEC.[184] Hackam and colleagues have shown that the LPS receptor, TLR4, is integral to intestinal mucosal repair in rodent models of NEC through its effects on enterocyte apoptosis and migration.[216] Work by this same group has demonstrated increased expression of TLR4 in the human intestine that develops NEC. There is an intense and ongoing interest in this line of investigation as a primary determinant in establishing a symbiotic gut-microbe axis, which may provide protection against the development of NEC.

The importance of bacteria in the pathogenesis of NEC is supported by the following evidence: (1) NEC occurs in episodic and epidemic waves in which affected patients are

related in place and time or had the same infectious agent[217,218]; (2) during clustered occurrences, the identical microorganisms can be isolated from both afflicted babies and their caretakers[219]; (3) NEC can occur in infants with no known risk factors; (4) NEC can develop several weeks or months after a perinatal insult, when the GI tract is fully colonized and has had sufficient time to recover from any perinatal insult[220,221]; (5) administration of large doses of vitamin E (interferes with intracellular killing of bacteria by leukocytes) to premature infants has been linked with an increase in the incidence of NEC[222]; (6) a NEC-like disease occurs in vulnerable hosts after the ingestion of *Clostridium* species[223]; (7) lesions resembling NEC can be reproduced experimentally with the administration of LPS[169]; (8) endotoxemia is demonstrated in 80% of those with NEC and positive blood cultures for gram-negative bacteria[224]; and (9) pneumatosis intestinalis is a common radiographic finding and represents submucosal gas collections produced by bacterial fermentation.[225,226]

**FIGURE 94-3** Intraoperative photograph of intestine with necrotizing enterocolitis demonstrating areas of hemorrhagic necrosis and gangrene.

## Unifying Hypothesis for Necrotizing Enterocolitis

Taken together, empiric and experimental data suggest that NEC occurs in a vulnerable host that has become further compromised at the level of the gastrointestinal tract. Infant prematurity and care in the NICU conspire to result in the initiation of bacterial insult or invasion of the immature GI tract, whose key functions including barrier function and immune modulation are altered. As a result, the interaction among the enterocyte, immune effector cells, and resident microbiota initiates an inflammatory cascade that becomes unbalanced, resulting in progressive enteric mucosal injury and increased permeability. In recent years the key role of the gastrointestinal tract as an immune system organ has been increasingly documented.[227,228] Because the microbiota of the human GI tract has increasingly been identified as playing a key role in overall human health through this symbiotic relationship, gut colonization during the newborn period likely presents a particularly vulnerable time for innate immune system, human gut, and gut microbial community dysfunction to occur when this process is disrupted or delayed. The process of gut colonization has been elegantly documented to involve both environmental and genetic factors as evidenced by the findings in twins of similarities in gut microbiota.[229] Moreover, the process is active and dynamic, undergoing a significant shift even in well newborns and infants throughout the first year of life.

## Pathology

NEC may involve single (50%) or multiple (discontinuous) segments of intestine, most commonly in the terminal ileum, followed by the colon.[230] Involvement of both the large and small intestine occurs in 44% of cases. Pan involvement (pannecrosis, NEC totalis) is a fulminant form of NEC characterized by necrosis of at least 75% of the gut, and it accounts for 19% of all cases of surgically treated NEC and most of the deaths.[26]

At surgery, the gross appearance of NEC is fairly constant. The bowel is markedly distended with patchy areas of thinning (Fig. 94-3). The serosal surfaces are typically red to gray and may be covered by a fibrinous exudate. With frank gangrene, the serosal surface is black or, in the most advanced cases, bland gray to white, given the complete loss of perfusion. Subserosal gas collections are frequently encountered. The mucosal surface may be ulcerated with wide areas of epithelial sloughing. Bloody peritoneal fluid is seen when bowel necrosis is present, and brown and turbid fluid is seen when perforation has occurred.

Histologically, enteric inflammation is nearly ubiquitous in NEC (Fig. 94-4). The degree and nature, however, vary from one area to another. Acute and chronic inflammatory changes coexist in 60% of cases. The most common microscopic lesion is bland or coagulation necrosis of the superficial mucosa (89%).[231] Edema and hemorrhage of the submucosa follow complete mucosal necrosis (see Fig. 94-4). Pneumatosis intestinalis is initially seen in the submucosa and later in the muscularis and subserosa. Bacteria in the bowel lumen and wall are present in up to 40% of cases and are occasionally found in gas cysts. Transmural necrosis, characterized by hyaline eosinophilia and loss of nuclear detail in the muscular layers, is present in advanced disease. Epithelial regeneration, formation of granulation tissue, and early fibrosis are often present during the resolution of NEC. This suggests a suppurative process lasting at least several days. Granulation tissue with mucosal and submucosal fibrosis may be seen adjacent to areas of active mucosal and submucosal necrosis and may account, in part, for late stricture formation. Thrombi are sometimes noted in small mesenteric vessels and in small arterioles of the submucosa. Small-vessel thrombosis within necrotic tissue is considered a secondary change. Large-vessel thrombosis is a relatively rare finding at autopsy.

## Diagnosis

### CLINICAL FEATURES

NEC is commonly heralded by nonspecific clinical findings that simply represent physiologic instability.[231,232] These findings include lethargy, temperature instability, recurrent

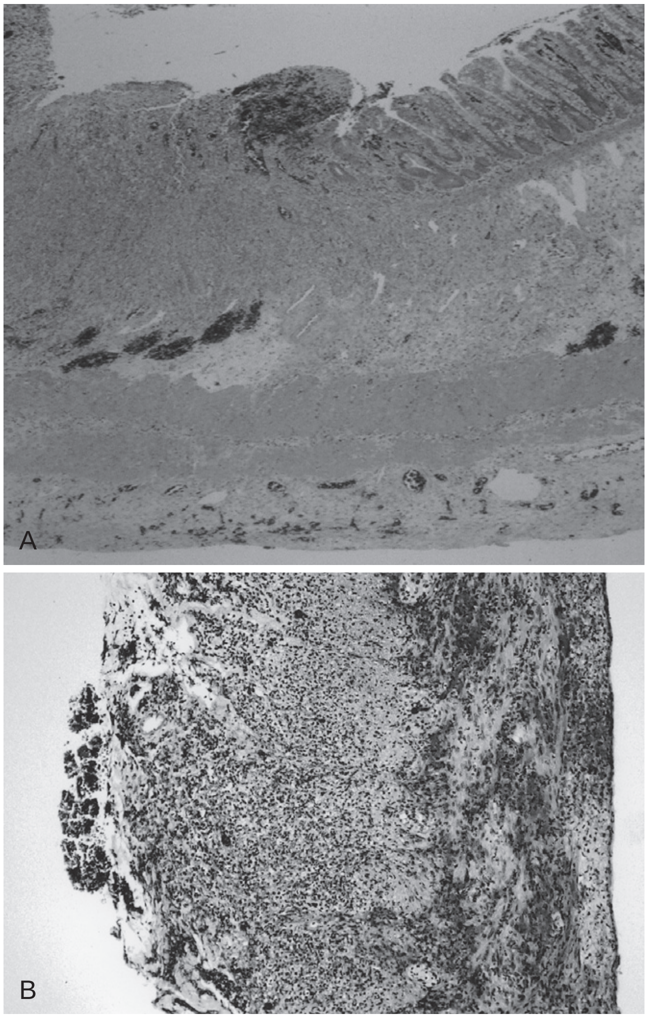

**FIGURE 94-4** **A,** Histologic section demonstrating early necrotizing enterocolitis with inflammation and pneumatosis intestinalis in the submucosa (hematoxylin-eosin stain, ×150). **B,** Histologic section demonstrating advanced necrotizing enterocolitis with transmural necrosis and loss of villus and crypt architecture (hematoxylin-eosin stain, ×150).

apnea, bradycardia, hypoglycemia, and shock. More specific symptoms related to the GI tract include abdominal distention (70% to 98%), blood per rectum (79% to 86%), high gastric residuals after feeding (>70%), vomiting (>70%), and diarrhea (4% to 26%). Gross blood in the stool is present in 25% to 63% of cases and occult blood in 22% to 59%. Rectal bleeding is seldom massive. Because the spectrum of disease severity varies, physical examination may initially demonstrate only subtle abdominal distention and minimal tenderness. As the disease progresses, abdominal palpation may elicit tenderness and demonstrate palpable bowel loops, a fixed or mobile mass, or abdominal wall crepitus. Edema and erythema of the abdominal wall as a result of the underlying peritonitis are present initially in approximately 4% of cases but are more common later in the course of the disease. In males, there may be discoloration of the scrotum, indicative of perforation. In a small subset of patients, the disease is rapidly progressive and the initial manifestation is heralded by florid clinical findings and death within 24 hours.

## LABORATORY FINDINGS

Infants with NEC usually have neutropenia, thrombocytopenia, and metabolic acidosis. The total leukocyte count may be elevated, but it is generally low. In one study, 37% of infants had absolute neutrophil counts less than 1500 cells/mm$^3$.[233] Infants with the lowest counts in this study had the worst prognosis. Neutrophil counts less than 6000 cells/mm$^3$ are most commonly associated with concomitant gram-negative septicemia. Some authors[234] have advocated that surgical treatment should be considered in infants older than 34 weeks' gestation if they have lower total neutrophil counts, a higher immature neutrophil number, and a greater immature-to–total neutrophil ratio at first presentation of NEC.

Thrombocytopenia is nearly universally present and seems to be associated with gram-negative sepsis and platelet binding by endotoxin. The incidence of thrombocytopenia in NEC is 65% to 90% and essentially unchanged from the earliest reports from the 1970s.[233,235] O'Neill[236] demonstrated that in a cohort of 40 infants who underwent surgery for NEC, 95% had platelet counts less than 150,000 cells/mm$^3$. Rowe and colleagues[237,238] found that platelet counts less than 150,000 cells/mm$^3$ were present in patients who had positive cultures for gram-negative organisms. The nadir platelet count during the course of the disease was noted to be lower in patients with more severe disease and in those who died.[239] A platelet count less than 104/L or a rapid fall is a poor prognostic indicator. A retrospective single-center study of 91 infants by Kenton[240] suggests that a platelet count less than 104/L within 3 days of the diagnosis of NEC should warrant surgical intervention to decrease the likelihood of bowel gangrene and its attendant morbidity and mortality.

## EMPIRIC AND EXPERIMENTAL INDICATORS OF NEC AND ITS SEVERITY

Metabolic acidosis is common (40% to 85% of patients with NEC) and is believed to result from hypovolemia and sepsis. It is not a specific indicator of intestinal necrosis. Stool samples are commonly positive for occult blood and reducing substances. Book[241] reasoned that intestinal mucosal damage from NEC leads to carbohydrate malabsorption. Poorly digested carbohydrates pass into the colon, where they are fermented and excreted in stool. The authors tested the stool of formula-fed infants for reducing substances with reagent (Clinitest) tablets and found that 71% of formula-fed infants in whom NEC developed had greater than 2+ reducing substances in their stool. Colonic bacterial fermentation increases the local production of D-lactate, which is absorbed and excreted by the kidneys. Garcia[242] could show elevated urinary D-lactate levels in infants with NEC but not in control infants. With recovery from NEC or administration of enteral antibiotics, D-lactate excretion decreased. Similarly, hydrogen excretion in the breath is elevated when fermentation is increased. This test is helpful in ruling out NEC. A negative result on a breath hydrogen test is 99% accurate in ruling out NEC.[243] Abubacker[244] indicated via a study of 24 infants with NEC that a preoperative blood lactate level of greater than 1.6 mmol/L carries a poor prognosis with mortality odds ratio of 22 (CI 1.54 to 314.3, $P = 0.04$). Finally, a multicenter study of 473 infants with NEC by Moss and colleagues[245] identified metabolic acidosis

at diagnosis (pH < 7.3 or bicarbonate < 16) as one of the 12 parameters that may assist in predicting the progression of NEC.

In an uncontrolled retrospective study comparing two centers' criteria for surgical intervention, Tepas[246,247] found that if three of seven critical metabolic derangements (positive blood culture within 96 hours of diagnosis, pH < 7.25 or receiving bicarbonate, bandemia > 20%, serum sodium < 130 mEq/L, platelet count < 50,000 cells/mm$^3$, MAP < gestational age or on any pressors, and absolute neutrophil count < 2000) were identified, this permitted earlier identification of infants needing exploration and resulted in better surgical outcomes (mortality and the need for postoperative parental nutrition) than did delaying operation until radiographic proven evidence of perforation by pneumoperitoneum.

C-reactive protein (CRP), an acute phase reactant, has been measured in an attempt to correlate its level with the presence, absence, or resolution of the disease.[248] CRP may serve as an early indicator of NEC when levels rise more than 10 mg/L within 48 hours of the suspected diagnosis (reported sensitivity, 92%; specificity, 81%). Failure of CRP to return to normal within 10 days was an indicator of abscess, stricture, or septicemia. A systematic review of various biomarkers for NEC[56] selected six qualified studies[248–253] on CRP that together indicated CRP is a relatively sensitive but nonspecific marker for NEC, yielding a combined diagnostic odds ratio (DOR) of 5.82 and an area under the curve (AUC) of 0.70. The diagnostic odds ratio expresses how much greater the odds of having the disease are for people with a positive test result rather than for the people with a negative test result. In this case, although the DOR is high, its AUC is only 70%, implying a weaker diagnostic performance.

*Intestinal fatty acid–binding protein* (I-FABP) is a small (14 to 15 kd) cytoplasmic protein of mature enterocytes. It is released into the circulation upon death of enterocytes, thus representing intestinal injury when detected in high concentration. Lieberman,[254] Edelson,[255] and Guthmann[256] have demonstrated an elevated level of I-FABP in the serum of neonates with NEC. Given its small size and its ability to pass through the glomerulus, urinary I-FABP has been detected as potential marker of NEC by Derikx.[257] Evennett[258] further characterized the release of urinary I-FABP by correlating its I-FABP-to-creatinine concentration with the severity of NEC. The I-FABP-to-creatinine concentration was significantly higher in infants with extensive disease than in those with focal disease (7.4 pg/mmol [2.1 to 35 pg/mmol] vs. 1.1 pg/mmol [0.3 to 1.7 pg/mmol], respectively, $P = .002$). Although studies have shown higher concentrations of I-FABP in infants with severe NEC, Thuijls[259] concluded urinary I-FABP not to be an effective screening tool for NEC given its ability to identify merely one third of neonates with NEC in a group of 226 neonates with no clinical suspicion of NEC originally. This study was performed on the basis of a cutoff point of 2.20 pg/nmol creatinine derived from testing urinary I-FABP on 35 neonates suspected of NEC. However, Thuijls[259] repeated the conclusion by Evennett[258] that urinary I-FABP is a promising prognostic marker for NEC.

Calprotectin, a calcium-binding protein found in neutrophils and macrophages, is a marker of inflammation of the gastrointestinal tract. It has been found in stool due to transepithelial migration of myeloid cells and has been a useful marker for exacerbation of inflammatory bowel disease in children.[260] Josefsson found fecal calprotectin to be elevated greater than 2000 μg/g feces in NEC with perforation with microscopic bowel inflammation but less than 2000 in cases with focal disease. Thus similar to I-FABP, it may be a useful marker for disease severity but not a strong screening tool.

# Microbiology

It has proven extremely difficult to identify common offending infectious agents in infants with NEC. Organisms recovered from the blood and stool of patients with NEC vary depending on the GI tract flora, the nosocomial flora, the site cultured, and the duration of previous antibiotic therapy. It is unclear whether the bacteria cultured represent pathogens causing NEC or, instead, secondary opportunistic invaders selected by the antibiotic regimen. Furthermore, lack of sufficiently matched controls and incomplete bacteriology data on other patients in similar environments makes study of the microbiology of NEC difficult.

## BACTERIOLOGY

Bacteriologic data for NEC have primarily been based on cultures obtained from the blood, stool, and peritoneal cavity. Blood cultures are positive in 30% to 35% of patients.[215] Cultures commonly grow *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Staphylococcus aureus, Staphylococcus epidermidis,* enterococci, *Clostridium perfringens,* and *Pseudomonas aeruginosa. K. pneumoniae* and *E. coli* cause the majority of positive blood cultures. The organisms most frequently cultured from stool specimens are *E. coli, K. pneumoniae, Enterococcus cloacae, P. aeruginosa, Salmonella species, coagulase-negative staphylococci (S. epidermidis), C. perfringens, Clostridium difficile,* and *Clostridium butyricum.*[261–263] Peritoneal cultures most commonly grow *Klebsiella species, E. coli,* coagulase-negative staphylococci, *Enterobacter* species, and yeast.[264]

## FUNGAL CULTURES

In contrast to bacteria, no data implicate a fungus as an initiating organism in the pathogenesis of NEC. Fungi are believed to be secondary invaders. Fungal septicemia with *Candida* species has been implicated in many late NEC deaths.[265,266] In a retrospective premortem and postmortem examination of body fluid and tissue cultures from 30 patients who died of NEC by Smith and colleagues,[265] 47% of patients had evidence of fungal infection and colonization was found in 20%.

## CLUSTERED EPIDEMICS

In most large series, sporadic cases have been followed by the sudden appearance of a cluster of a relatively large number of cases. In many of the epidemics, no specific pathogen has been identified. During these episodes, nursery personnel experienced concomitant acute GI illnesses.[21,267] In those few studies in which a specific pathogen is identified, it was in association with documented contamination of milk formula or milk fortifier that was used in the NICU.[268] Identified species have

included *E. coli, Salmonella species, C. difficile,* rotavirus, norovirus, torovirus, and a coronavirus-like organism.[217,268–274]

# Imaging

The cornerstone of the diagnosis of NEC remains plain anteroposterior and left lateral decubitus radiographs. Any or all of the following findings are associated with NEC: ileus pattern (nonspecific bowel distention), pneumatosis intestinalis (linear or cystic) (see Fig. 94-1), portal vein gas, pneumoperitoneum, intraperitoneal fluid, and persistently dilated, fixed loops.[275] Both pneumatosis and portal vein gas are often fleeting signs but are considered pathognomonic in the appropriate clinical setting of prematurity. In more recent years, there has been a trend and tendency toward the increased use of bedside ultrasound with Doppler imaging of the GI tract in an effort to identify more subtle findings like abdominal fluid, hyperemia, decreased blood flow to the gut, and pneumatosis intestinalis, all of which may not be well seen by plain radiograph.[276–291] Despite this trend, to date there have been few good comparative studies documenting the clinical utility of ultrasound in the diagnosis of NEC.

## BOWEL DISTENTION

Multiple gas-filled loops of intestine are the earliest and most common radiologic finding in patients with NEC (55% to 100% of cases).[292] As fluid and air accumulate, air-fluid levels are visible on the decubitus view. The degree of dilatation and the distribution of bowel loops are related to the clinical severity and progression of the disease. In some cases, nonspecific intestinal dilatation precedes clinical symptoms suggestive of NEC by several hours.

## PNEUMATOSIS INTESTINALIS

Demonstration of pneumatosis intestinalis (intramural gas) in the appropriate clinical setting is diagnostic of NEC (see Fig. 94-1). The air mainly comprises hydrogen, a byproduct of bacterial metabolism. The frequency of pneumatosis intestinalis ranges from 19% to 98%, although it may be absent in up to 14% of patients with NEC (even severe disease).[205] Conversely, extensive pneumatosis may be present with minimal signs; it often responds promptly to medical management. Pneumatosis is fleeting, may appear before the onset of clinical symptoms, and is commonly an early rather than a late finding. Pneumatosis is most frequently noted when infants have been fed (84%), in contrast to unfed babies (14%).[31] Pneumatosis intestinalis is not specific for NEC and has been noted in infants with enterocolitis of Hirschsprung disease, inspissated milk syndrome, pyloric stenosis, severe diarrhea, carbohydrate intolerance, and other disorders. Two forms of pneumatosis intestinalis are recognized radiographically: cystic and linear. The cystic form has a granular or foamy appearance and represents gas in the submucosa. It is often confused with fecal material in the large intestine. Linear pneumatosis consists of small bubbles collected within the muscularis and subserosa to form a thin linear or curvilinear gas pattern outlining the wall of a segment of the intestine.

## PORTAL VEIN GAS

Portal vein gas (PVG) appears as linear branching radiolucencies overlying the liver and often extending to its periphery (see Fig. 94-1). It represents gas dispersed through the fine radicles of the portal venous system. The presence of portal vein gas is fleeting, which perhaps accounts for the low reported incidence of 10% to 30%.[293] In most series the presence of portal vein gas is associated with a poor prognosis.[205] In cases with pan-intestinal involvement, PVG is present in 61% of patients. The genesis of portal vein gas may involve accumulation of gas in the bowel wall as a result of bacterial invasion, dissection into the venous system, and migration to the radicles of the portal vein. Alternatively, it may represent the action of gas-forming bacteria within the portal venous system itself.

## PNEUMOPERITONEUM

Free air in the peritoneal cavity associated with perforation of the intestine can be demonstrated in 12% to 30% of patients. It is best noted on the left lateral decubitus or cross-table lateral view. Upright radiography is unnecessary. A supine view of the abdomen can demonstrate free air by outlining the falciform ligament ("football sign"), the umbilical artery, or urachal remnants or by revealing the "double-wall" sign. This sign refers to visualization of air on both sides of the wall (lumen and peritoneal cavity). In patients who have intestinal perforation proven by surgery, radiographic evidence shows free air in only 63%, thus demonstrating that perforation can occur in a surprisingly high number of patients without evidence of pneumoperitoneum. One must also recall that pneumoperitoneum may occur without intestinal perforation from mechanical ventilation for severe lung disease. In this clinical situation, barotrauma may produce alveolar rupture with air dissection into the abdomen through the mediastinum. The patient's signs, symptoms, and laboratory findings will often differentiate the cause of the air. If one is unsure, abdominal paracentesis may be performed and any aspirated fluid analyzed. If there is no ascites, a water-soluble contrast study via the gastric tube may be performed to rule out gastric perforation.

## INTRAPERITONEAL FLUID

Several plain radiographic findings suggest free fluid in the peritoneal cavity that is amenable to paracentesis: (1) a grossly distended abdomen devoid of gas, (2) gas-filled loops of bowel in the center of the abdomen surrounded by opacity out to the flanks, (3) increased haziness within the abdomen, and (4) separation of bowel loops. These findings have been reported in 11% of cases. Both ascites and portal vein gas are radiographic findings associated with high mortality rates. Twenty-one percent of patients with surgically proven intestinal perforation have ascites. However, 16% of all patients with proven intestinal perforation have neither ascites nor pneumoperitoneum on plain radiographs.

## PERSISTENT DILATED LOOPS

The "persistent dilated loop sign" is a plain radiographic finding that was described by Wexler[294] in a study of five babies with NEC in whom a single loop or several loops of dilated bowel remained unchanged in position and configuration for 24 to 36 hours. Full-thickness necrosis subsequently developed in these patients. This finding, however, does not

always indicate bowel necrosis. Leonard[295] found a persistent loop in 33% of 21 patients with proven NEC. Fifty-seven percent of infants with a persistent loop had necrotic intestine at surgery or autopsy, but necrosis never developed in 43% and they recovered with nonoperative treatment.

### CONTRAST STUDIES

Radiopaque contrast studies of the upper GI tract may occasionally be useful to improve diagnostic accuracy in patients with equivocal clinical and radiologic signs of NEC. However, overdiagnosis by contrast radiography is possible and may lead to unwarranted treatment. Careful attention to the type of contrast agent used for the study is critical.[294] Barium should never be used because extravasation of a barium and stool mixture through a perforation may intensify the peritonitis. Unlike barium, water-soluble contrast agents are absorbed by both the bowel and the peritoneal cavity. The practical implication of this absorption is a transient (6 to 12 hours) increase in urinary specific gravity. Historically, water-soluble agents were hyperosmolar and caused dangerously large intraluminal fluid shifts, especially in premature patients. Current water-soluble agents are nonionic, have much lower osmolarity, and produce excellent opacification of the GI tract. NEC is suspected when intestinal contrast enhancement demonstrates bowel wall loops separated by edematous walls, an irregular mucosa with ill-defined margins, mucosal ulceration, bowel wall spiculation, or pneumatosis intestinalis. Currently, the use of contrast studies is usually reserved for interrogation of the GI tract after the acuity of NEC has resolved and in order to examine for stricture formation during or after recovery. Though advocated by some,[296] contrast enemas should not be performed because of the risk for rectosigmoid perforation. Unless there is colonic disease or reflux of contrast into a diseased distal ileum, the contrast enema will not be diagnostic of NEC. It may, in fact, overdiagnose NEC because contrast enemas have been shown to produce pneumatosis and transient portal venous air. In an infant who has recently completed a course of therapy for NEC but has persistent signs of partial small bowel obstruction or blood-tinged stools, contrast enemas may be useful in identifying strictures.

### ULTRASONOGRAPHY

Ultrasonography (US) has been used to identify necrotic bowel, intraperitoneal fluid, and portal venous air. However, abdominal sonography can depict the following findings highly suggestive of nonviable bowel over plain abdominal radiography: presence of intra-abdominal fluid, thinning of the bowel wall, reduction of bowel wall perfusion, abnormal bowel loops, and intermittent gas bubbles in liver parenchyma and the portal venous system.[297] The abnormal bowel loops on US are characterized by a hypoechoic rim with a central echogenic focus (“target sign”).[278] Appearing as pericholecystic hyperechogenicity, the intermittent gas bubbles in liver parenchyma and the portal venous system are believed to represent either pericholecystic venous gas or extension of the foamy inflammatory infiltrate of NEC into the pericholecystic space.[298,299]

Theoretically, US may have significant value if it can identify patients who require operation in a more sensitive and timely manner than is otherwise possible with conventional clinical and radiographic methods. Although Silver[299] has correlated seven sonographic findings with adverse outcomes needing surgical intervention, more studies are necessary to compare the sensitivity and specificity, as well as intraobservable and interobservable agreements between sonographic and radiographic findings. Thus at this time, the use of US for the diagnosis of NEC is most applicable to patients with questionable clinical and radiologic findings or to localize intra-abdominal fluid for paracentesis.

### MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is a noninvasive modality that has recently been used to identify infants with ischemic bowel secondary to NEC. Although MRI is capable of demonstrating the cardinal findings of NEC, its utility is limited.[300]

## Classification

To select the appropriate treatment (nonoperative vs. operative) and to determine the impact of therapy on survival and late outcomes, it is essential that investigators use comparable criteria for classifying the stages of NEC. Several classification schemes have been proposed. In 1978 Bell[8] introduced the now most commonly used three-stage classification system (suspected, definite, and advanced) that categorizes patients by historical factors, GI manifestations, radiologic findings, and systemic signs (see Table 94-1). The Bell staging criteria have been modified[220]; the three stages are still used, but subsets are included in an effort to identify specific prognostic factors. Infants with stage I disease have features suggestive of NEC, patients with stage II disease have definitive NEC without an indication for surgical intervention, and patients with stage III disease have advanced NEC with evidence of bowel necrosis or perforation.

## Management

### NONOPERATIVE

In the absence of intestinal necrosis or perforation, the mainstay of treatment for patients with NEC is supportive. Feedings are discontinued, the GI tract is decompressed through a sump gastric tube, and intravenous fluid resuscitation is initiated. A complete blood count, platelet count, blood gas analysis, and CRP and serum electrolyte levels are obtained. Blood and urine samples are sent for culture, and broad-spectrum intravenous antibiotic therapy is initiated. Until recently, most antibiotic regimens included a penicillin, an aminoglycoside, and an agent effective against anaerobic organisms. It seems logical that coverage for anaerobic organisms be included because these infants are usually 1 to 2 weeks old and have or are undergoing colonization by coliforms. To date, no controlled study has shown the efficacy of this regimen. The antibiotic regimen is best tailored not only to the most common organisms found with NEC but also to the nosocomial nursery flora. Because of recent reports of patients with stool and blood cultures positive for coagulase-negative staphylococci, some groups now empirically treat patients with a combination of vancomycin and gentamicin or vancomycin and a third-generation cephalosporin.[301] The incidence of fungal sepsis in infants who die of NEC is high, so a strong index of suspicion must be maintained and empirical antifungal therapy should be considered if the patient’s clinical course is prolonged. Historically, close clinical observation consists of frequent physical examination, two-view abdominal radiography

performed every 6 to 8 hours, serum platelet and leukocyte counts, and blood gas analysis. However, one could question the utility of the frequent use of plain radiographs at this interval, given the number of cases that have progressive NEC without pneumoperitoneum and depending on the individual practitioners' trigger for operative intervention.

Patients with definite disease of moderate severity (Bell stage II) are normally treated by bowel rest, decompression, and antibiotic therapy for at least 7 to 14 days. A central venous catheter may be placed for total parenteral nutrition. If the patient is clinically well, small amounts of formula may be restarted. The infant is constantly and carefully monitored for abdominal distention, vomiting, or nonspecific signs or symptoms of NEC. Once feedings resume, stools are tested for reducing substances and occult blood. Feedings are discontinued if the result of either test becomes positive. Infants who have undergone surgery receive 1 to 2 weeks of postoperative intravenous antibiotics. Feedings are initiated when the patient is clinically well and return of bowel function has been established.

## INDICATIONS FOR OPERATION

The principal goals of surgical intervention in the setting of NEC are to remove gangrenous bowel and preserve intestinal length.[302,303] On the basis of historical clinical experience, many argue that exploration should not be undertaken until gangrene is present but should be performed before perforation occurs. Unfortunately, no combination of clinical examination or adjunct testing has been shown to have high sensitivity for intestinal gangrene.[304,305] Thus there remains controversy regarding the indications for operation, the most appropriate timing of intervention, and the optimal surgical treatment strategy. The most widely accepted indication is the presence of pneumoperitoneum. Relative indications include a positive paracentesis, palpable abdominal mass, abdominal wall erythema, portal venous gas, fixed intestinal loop, and clinical deterioration despite maximal medical therapy.

In an attempt to identify characteristics that may serve as predictors of intestinal gangrene, Kosloske[304] reviewed 12 criteria used as indications for operation in 147 patients with NEC and stratified these criteria according to sensitivity, specificity, positive/negative predictive value, and prevalence. The "best" indicators (specificity and positive predictive value [PPV] approaching 100%, prevalence $> 10\%$) were pneumoperitoneum, positive paracentesis (aspiration of $> 0.5$ mL brown or yellow fluid containing bacteria on Gram stain), and portal venous gas. "Good" indicators (specificity and PPV approaching 100%, prevalence $< 10\%$) were a fixed intestinal loop, erythema of the abdominal wall, and a palpable abdominal mass. A "fair" indicator (specificity of 91%, PPV of 94%, prevalence of 20%) was "severe" pneumatosis intestinalis as graded by a radiographic system. "Poorer" indicators were clinical deterioration (PPV of 78%), platelet count lower than 100,000/mm$^3$ (PPV of 50%), abdominal tenderness (PPV of 58%), severe GI hemorrhage (PPV of 50%), and gasless abdomen with ascites (0%). Unfortunately, none of the indicators had sensitivity greater than 48%.

Instead of looking at indicators separately, Coursey[306] combined various radiologic findings into a 10-point Duke Abdominal Assessment Scale (DAAS) to improve intraobserver and interobserver agreement on diagnosing severe NEC. A subsequent validation study by the same authors[307] demonstrated that for every one-point increase in the DAAS score (AUC = 0.83), infants with NEC were significantly more likely to need surgical intervention. Although the study did not define a specific score cutoff for surgical intervention, 93% of the operated infants in this study had a score of 7 or above.

### Pneumoperitoneum

Infants in whom pneumoperitoneum develops during the management of NEC should undergo either laparotomy or peritoneal drain placement. Unfortunately, pneumoperitoneum is not always demonstrable in neonates with gut perforation, with one study reporting that only 63% of infants with perforation demonstrated free air.[308]

### Paracentesis

A positive result on paracentesis, defined as free-flowing aspiration of more than 0.5 mL of brown or yellow-brown fluid that contains bacteria on Gram stain,[156] is highly specific for intestinal necrosis. A negative result on paracentesis is rare with intestinal necrosis but can occur when a localized, walled-off perforation is present or a segment of bowel is injured but not perforated.[309] Currently, there is no absolute indication for paracentesis. Kosloske[304] recommends abdominal paracentesis for patients with extensive pneumatosis intestinalis or for those who do not improve with nonoperative management. If no peritoneal fluid is aspirated, peritoneal lavage is performed by instilling up to 30 mL/kg of normal saline solution into the peritoneal cavity, turning the patient from side to side, and then withdrawing the fluid. Ricketts and Jerles[309] reported a greater than 70% survival rate when a positive result on abdominal paracentesis was used as the indication for exploration in 51% of their patients; three false-negatives occurred. They performed paracentesis when there was erythema and edema of the abdominal wall, portal vein gas, a fixed and dilated loop on sequential abdominal radiography, a fixed and tender abdominal mass, or persistent clinical deterioration. The indications used for paracentesis in this report are considered indications for operation by many surgeons.

### Portal Venous Gas

To determine the significance of portal vein gas in relation to the presence and extent of bowel necrosis and mortality, Kurkchubasche[310] reviewed the experience of Children's Hospital of Pittsburgh, as well as the world literature. Of the 616 patients collected, 118 (19%) had portal vein gas on plain radiography. Of these 118 patients, 102 underwent operation, usually 24 hours after the radiographic appearance of portal vein gas. All 102 patients had full-thickness bowel necrosis, and 52% had necrosis of more than 75% of the length of the entire small intestine. The overall surgical mortality rate for patients with portal vein gas was 52%, and more than 90% of those with pan involvement died. Of the 15 patients who had portal vein gas and did not undergo immediate exploration, bowel necrosis requiring subsequent operation developed in 6 (40%) and 5 of the 6 died. In a separate study, Rowe[26] suggested that intestinal necrosis will develop in more than 90% of infants with portal venous gas, with pan involvement developing in 52%. More recently, in a review of 40 infants with NEC and portal venous gas,

Molik[311] reported a 54% overall operative mortality and pan involvement in 25%.

### Fixed Persistent Intestinal Loop

A fixed dilated intestinal loop is defined by persistent location and configuration for more than 24 hours. In a recent study, approximately half the patients with evidence of a fixed dilated loop recover without an operation.[312] The finding of a fixed loop is considered concerning by most observers as indicating a pregangrenous or severely compromised intestinal loop, yet to date there is little objective evidence to support that assumption. Moreover, at this time there is no general consensus on the utility of fixed loop in guiding operative management.

### Clinical Deterioration

Many criteria for operating on children who show continued clinical deterioration despite adequate supportive therapy exist,[313] but none by themselves are absolute indications. These criteria include abdominal wall erythema, peritonitis on physical examination, persistent/increasing acidosis, and persistent/progressive thrombocytopenia.

### Ascites

As mentioned, pneumoperitoneum may not always be evident with intestinal perforation. A gasless abdomen, suggestive of a fluid-filled abdominal cavity, may be the only indication of perforation. Frey[308] reported that in 21% of infants with intestinal perforation, the only radiographic evidence was ascites. They noted that radiographs are imprecise and that evidence of ascites in the appropriate clinical setting of NEC mandates paracentesis for further evaluation.

## OPERATIVE MANAGEMENT

Advanced disease requiring surgical intervention develops in up to 50% of infants with NEC.[314,315] Until recently, given the lack of quality prospective randomized trials, the optimal surgical treatment strategy for NEC remained controversial. Surgical goals are to remove gangrenous bowel and preserve intestinal length. Within this context, a number of different options exist, but most agree that the surgical approach should be determined by the extent of intestinal involvement. The patient's general condition should be optimized before operation with aggressive ventilatory support, treatment of shock, administration of broad-spectrum antibiotics, and correction of anemia and coagulopathy. Operative procedures may be performed in the NICU under appropriate conditions without an increase in complications.[316]

### Primary Peritoneal Drainage

Treatment of intestinal perforation in VLBW infants remains controversial. In 1977 Ein[317] reported the use of peritoneal drainage (PD) as a means of stabilizing and improving the systemic status of premature infants with perforation before laparotomy. Since then, primary treatment with PD has been used in a variety of settings, and some investigators have suggested that it may serve as definitive therapy. More recently, several studies have attempted to address this issue more rigorously.[318–333] Currently, most surgeons propose PD as the initial treatment in ELBW infants (<1000 g at birth) with perforated NEC to allow resuscitation and stabilization before definitive laparotomy. In an attempt to address this issue, two multicenter prospective randomized controlled trials were conducted. In the NECSTEPS trial of 117 infants (<34 weeks' gestation and < 1500 g) by Moss,[324] 19 of 55 infants with PD died (34.5%), as compared with 22 of 62 infants with laparotomy (LAP) (35.5%, $P = 0.92$) by 90 days postoperatively. The percentages of infants who became dependent on total parenteral nutrition were 17 of 36 (47.2%) in the PD group and 16 of 40 (40%) in the laparotomy group ($P = 0.53$). Although this study was originally designed to detect a reduction in 90-day mortality from 50% to 25% with a statistical power of 82%, it failed to enroll the desired number of study subjects in the time allotted to the study, thus reducing the power to 77% or less.

Three primary conclusions were drawn from this prospective randomized trial. The trial found that the type of operation performed for intestinal perforation in infants with NEC (1) does not significantly affect 90-day mortality, (2) does not affect rate of dependence on total parenteral nutrition at 90 days postintervention, and (3) did not affect the total length of hospital stay. The results of this trial have led to a follow-up study that seeks to determine the difference in median to long-term outcomes comparing the two surgical procedures with an emphasis on neurodevelopmental outcomes. Two years following the publication of the NECSTEPS trial results, Rees[323] published the results from the European NET trial that included 69 patients. Similar to the results in the NECSTEPS trial, there was no significant difference in the 6-month survival rate between infants undergoing either laparotomy or PD as primary treatment for perforated NEC. Six-month survival was 18 of 35 (51.4%) with PD and 21 of 33 (63.6%) with LAP ($P = 0.3$; Fisher exact text, difference 12%, Cl, (11, 34%). Cox regression analysis showed no significant difference between groups (hazard ratio for PD 1.6; $P = 0.3$; 95% CI, 0.7 to 3.4). However, in the PD group, delayed laparotomy was performed in 26 of 35 (74%) patients after a median of 2.5 days (range, 0.4 to 21) and did not improve 6-month survival compared with primary laparotomy (relative risk of mortality 1.4; $P = 0.4$; 95% CI, 0.6 to 3.4). Unlike the conclusion derived by the NECSTEPS trial, Rees concluded that PD is ineffective as either a temporizing measure or definitive treatment because of the high percentage of infants requiring "rescue" laparotomy.

Even though the two prospective studies did not demonstrate statistically significant differences in mortality between PD and LAP, the most recent meta-analysis by Sola[334] (273 PD, 250 LAP), which selected two clinical trials and three prospective cohort studies[325,326] out of the 12 studies reviewed, indicated an increased mortality of 55% with PD (OR 1.55, 95% CI, 1.08 to .22, $P = 0.02$) without statistical heterogeneity. Upon careful review, four of the five studies showed mortality rates of PD to be higher than LAP and the authors attributed the higher rates to more premature and smaller infants selected for the PD group. Thus controversies persist in initiating PD for stabilization before laparotomy. Currently, in an effort to address intermediate and long-term morbidity, a multicenter trial sponsored by the NICHD Neonatal Research Network was initiated in 2010. The primary objective of this trial is to determine the rate of primarily neurodevelopmental impairment at 2 years of age in ELBW infants with NEC who undergo either PD or laparotomy as primary treatment of perforated NEC.

### Laparotomy

At laparotomy, the extent of NEC may be classified as focal, multifocal, or pan-intestinal (<25% viable bowel). Depending on the extent of disease and patient characteristics at the time of surgery, a number of different surgical options may be undertaken including resection with enterostomy, resection with anastomosis, proximal enterostomy, the "clip-and-drop" technique, and the "patch, drain, and wait" technique. The abdomen is entered via a transverse supraumbilical incision with precautions taken to not injure the liver. Optionally, samples of peritoneal fluid may be harvested for culture of aerobic, anaerobic, and fungal organisms. The entire GI tract is systematically examined to assess the extent of disease and viability of the bowel. If clear demarcation of gangrenous bowel is encountered, it is resected. Marginally viable bowel can be preserved yet defunctionalized either through a proximal diversion (enterostomy) or clip-and-drop technique wherein the intestine is closed at either end using hemoclips in an effort to prevent further passage or leakage of the fecal stream. These latter techniques are particularly useful if the overall length of involved intestine is such that the infant would be rendered "short-gut" if all marginally involved intestinal length is removed. A second-look operative approach to extensive NEC involvement is currently not widely practiced. Infants tend to be quite ill with significant ongoing physiologic instability following most operative interventions for NEC. At the conclusion of the procedure, one should record the length of viable intestine remaining and note the presence or absence of the ileocecal valve.

A rarely cited complication of laparotomy for NEC is spontaneous intraoperative liver hemorrhage from injury caused by retractors or finger dissection. VanderKolk[335] reported this complication in 11.8% of operations for NEC over a 5-year period. The mean gestational age of those with liver hemorrhage was 28 weeks (mean weight, 1262 g). Only one of these patients survived. The authors identified low mean preoperative arterial pressure and high preoperative fluid administration over the preceding 24 hours as significant predisposing factors. This complication occurred shortly after the abdomen was opened, and the intestine was eviscerated. Liver congestion was followed by subcapsular hematoma and then free rupture.

### Focal Disease

When a single area of bowel is necrotic or perforated, only limited resection is necessary. Creation of a proximal enterostomy and distal mucus fistula has been the standard of care. Stomas can be created either through the ends of the incision or through a separate exit site on the abdomen. Factors to be considered when deciding on optimized stoma sites include mesentery that has been shortened by inflammation that may impede exteriorization, placement and fitting of future stoma bags without leakage, ease of future closure if diverting ends are placed in close proximity or remotely, and incidence of additional complications including wound infection and stoma prolapse. Most enterostomies are created by suturing the intestine to the fascia with interrupted sutures. About 2 cm of bowel are left protruding from the abdominal wall, and no attempt is made to "mature" the end of the intestine. If stoma viability is in question postoperatively, a small portion of the full thickness of the intestine is excised at the bedside and the cut ends are observed for bleeding.

Resection with primary anastomosis for isolated disease may be performed in carefully selected patients. Proponents of primary anastomosis cite the high morbidity associated with enterostomies in infants and no need for a second operation.[336] To safely perform this technique, the following criteria must be met: (1) a sharply localized, usually proximal segment of disease; (2) undamaged appearance of the remaining intestine; and (3) stable overall patient physiology without evidence of rapidly progressive sepsis or coagulopathy.

### Multisegmental Disease (>50% Viable)

If the patient has multiple areas of necrosis separated by viable bowel, several options are available. Historically, the surgeon excises each diseased segment individually and creates multiple stomas rather than performing a massive resection. Conversely, a single high stoma (proximal jejunum) may be created and the distal bowel "spliced" together, thereby avoiding multiple stomas. A proximal jejunostomy can cause significant fluid and electrolyte loss and peristomal skin complications, although aggressive skin care with measurement and replacement of stoma losses can avoid these potential complications. Anastomotic strictures are not uncommon and are addressed at the time of jejunostomy closure. Resection plus anastomosis has also gained increased acceptance as a valid treatment option for severe NEC and for multifocal disease.[303] In a study involving 46 infants with multifocal NEC, Fasoli[302] reported a higher survival rate after resection and primary anastomosis (85%) versus enterostomy (50%).

Moore[337] described a controversial approach termed the "patch, drain, and wait" procedure in 1989. The principles of this potentially bowel length–preserving method are transverse single-layer suture approximation of perforations (patch), insertion of two Penrose drains that exit in the lower quadrants (drain), and a commitment to long-term parenteral nutrition (wait). The Penrose drains capture fecal fistulas and function as de facto enterostomies as the peritoneal cavity is rapidly obliterated by adhesions.[338] This procedure does not address the issue of ongoing sepsis because necrotic bowel is not resected, the general peritoneal cavity is difficult to drain, and the thin-walled perforated bowel often cannot handle suture.

Vaughan[339] described a promising novel technique aimed at avoiding multiple enterostomies, circumventing the complications of a high jejunostomy, and preserving bowel length. The authors performed the "clip-and-drop-back" technique in three patients with NEC. In this procedure the obviously necrotic bowel is removed, and the cut ends are closed with titanium clips or staples. Reexploration is performed 48 to 72 hours later, the clips are removed, and all segments are reanastomosed without any stomas. In one of the three patients, reresection was required during the second-look operation, the bowel ends were clipped again, and a successful primary anastomosis was performed during a third operation. Follow-up for this small series was 6 months to 7 years with no anastomotic complications or delayed reoperations.

### Pan Involvement (NEC Totalis, <25% Viable)

Pan involvement develops in 19% of patients[310]; it poses an enormous treatment problem and remains a highly controversial management issue. The overriding consideration is to

spare as much intestine as possible. Treatment options include resection of all necrotic bowel with placement of proximal or multiple stomas or proximal diversion without bowel resection, with plans for a second-look procedure. The decision to forego any treatment is supported by studies that demonstrate a 42% to 100% mortality rate in patients with pan involvement, with almost all survivors left with short-bowel syndrome. The mortality rate is nearly 100% for infants who weigh less than 1000 g.

Diverting the intestinal stream by high proximal jejunostomy (without bowel resection) may facilitate healing of injured bowel through distal intestinal decompression, a reduction in its metabolic demands, and a decrease in the number of bacteria and possibly their byproducts. This technique was initially reported by Martin and Neblett[340] and involves performing a high jejunostomy without resection, with plans for a second-look operation after 6 to 8 weeks. In a series of 10 patients with pan involvement, Sugarman and Kiely[341] reported 8 infants surviving to undergo a second procedure. Resection of necrotic segments plus anastomosis was performed successfully, but the long-term survival rate was only 50%.

### Stoma Closure and Complications

There is neither an ideal weight and age nor a universally agreed-upon time at which intestinal continuity should be restored. The principal determinants are time since surgery, weight gain, and stoma output and need or effects of TPN on overall metabolic function (i.e., liver). In general, the enterostomy may be safely closed anytime after 4 weeks since the last operation. Attempted closure at less than 4 weeks postoperatively may be met with a peritoneal cavity that is obliterated by vascular adhesions and resolving inflammation. Before enterostomy closure, patency of the distal end of the bowel (i.e., colon) should be confirmed by either a retrograde or antegrade contrast study to rule out a stricture or strictures in the distal defunctionalized bowel. A study by Musemeche[342] examined the complication rate after stomas were closed less than 3 months after surgery, 3 to 5 months after surgery, and more than 5 months after surgery; no differences were found. They also noted no difference in complications between patients who underwent closure at a body weight less than 2.5 kg, 2.5 to 5 kg, or greater than 5 kg.

Although enterostomy in neonates may be lifesaving, it is also a major cause of morbidity. In recent studies, enterostomies in newborns had an associated complication rate ranging from 34% to 68%.[343,344] Complications included wound infections, wound dehiscence, stoma stenosis requiring revision, incisional hernia, parastomal hernia, prolapse or intussusception, and small bowel obstruction.

# Survival

Over the past decades, the survival of infants with NEC has progressively improved. This improvement has been attributed to earlier diagnosis and more effective supportive treatment for premature infants. Effective supportive treatment includes improved ventilatory strategies, surfactant therapy, total parenteral nutrition, improved understanding of the pathophysiology and management of critically ill newborns, and advancements in pediatric anesthesia. The increased survival has been most noticeable in infants who weigh less than 1000 g and are less than 28 weeks' gestational age. In a recent review of 754 premature infants born between 22 and 25 weeks' gestation, the overall survival rate was 63%, with a range of 14% at 22 weeks' gestation to 76% at 25 weeks' gestation.[19] Mortality was still significantly higher in VLBW infants than in larger patients. This is highlighted by studies that examined the outcome of VLBW infants in comparison with "standard" premature infants (>1000 g) with pan involvement NEC. Snyder[345] found that infants weighing less than 1000 g are more likely to require laparotomy (51% vs. 34%) and to eventually have pan involvement (10% vs. 4%) than infants greater than 1000 g. Pan involvement was associated with 100% mortality in both groups. In a retrospective study of 70 infants weighing less than 1000 g with perforated NEC, Erhlich[331] demonstrated that infant survival was independent of the type of surgical treatment (PD vs. laparotomy), but instead was inversely related to the number of comorbid conditions associated with the patient.

Taken together, it seems unlikely that the significant differences in mortality rates observed in various series are attributable to differences in the effectiveness of the treatment programs used. In different groups of patients, the disease varies from predominantly localized disease to extensive necrosis. The patient population differs between the various series. The mortality rate can vary considerably, depending on birth weight, coexisting disease, virulence of the disease process, and whether the patient is inborn locally versus transferred from another facility that has initiated therapy. The precarious state of patients at risk for NEC is emphasized by one series that compared patients who had NEC with matched controls, in which the mortality rate in controls was 33%.[346]

# Complications

## GASTROINTESTINAL

### Intestinal Strictures

The first clinical and radiologic description of intestinal stricture after recovery from acute NEC was reported in 1968 by Rabinowitz.[347] The reported overall incidence varies from 9% to 36%,[348,349] and stricture formation is more frequent after nonoperative treatment. The incidence of strictures after NEC is increasing as the mortality rate from the disease decreases. Strictures result from fibrotic healing of an area of severe ischemic injury. Regardless of whether the stricture follows operative or nonoperative therapy, the most common site of involvement has been the colon (80%). The next most common site is the terminal ileum (15%). Sixty percent of colonic strictures involve the left colon, and the most common colonic site is the splenic flexure (21%). Most patients have single strictures, but multiple strictures can occur (15%).[350] An intestinal stricture should be suspected after nonoperative management of NEC in an infant with failure to thrive, rectal bleeding, or bowel obstruction. These signs and symptoms occur in 50% of patients with strictures and should be evaluated with a contrast enema. If the study demonstrates a stricture in a symptomatic patient, elective resection with anastomosis is usually indicated.

### Intestinal Malabsorption and Short-Bowel Syndrome

Malabsorption may result from a variety of factors including decreased bowel length, decreased mucosal absorptive area, enzyme depletion, gut hypermotility, hypersecretion of gastric acid, bacterial overgrowth, decreased intestinal transit time, vitamin $B_{12}$ deficiency, and bile salt deficiency. Short-bowel syndrome (see Chapter 86) is the most serious long-term GI complication associated with surgically treated NEC. It occurs in up to 23% of NEC survivors who undergo surgical resection.[313]

### Cholestatic Liver Disease

Cholestatic liver disease results from a number of factors but primarily from prolonged administration of total parenteral nutrition. It is characterized by direct hyperbilirubinemia, hepatomegaly, and elevated aminotransferase levels. Although the condition is multifactorial, the most important contributing factor is probably prolonged fasting. It has been shown that the most effective treatment is establishment of early, small-volume enteral feeding that aids in bowel adaptation by conferring a trophic effect on the intestinal mucosa and by stimulating bile flow.

### Recurrent Necrotizing Enterocolitis

NEC can recur after operative and nonoperative management. The incidence of recurrence has been reported to be 4% to 6%.[309,351] No consistent association has been noted between recurrent NEC and the type or timing of enteral feeding, the anatomic site, or the method of initial management. Various case reports suggest supraventricular tachycardia, percutaneous transluminal angioplasty, and allergic enterocolitis to be associated with recurrent necrotizing enterocolitis.[352–354] Interestingly, Pickard[355] proposes that infants with congenital heart diseases and NEC have a decreased risk of having recurrent NEC (OR for CHD 0.58 [95% CI, 0.18 to 1.89], OR for PDA 0.49 [95% CI, 0.10 to 2.28], OR for all other congenital cardiac diseases 0.72 [95% CI, 0.15 to 3.34]) through a retrospective study of 202 infants with NEC. More than 70% of patients were successfully treated nonoperatively for recurrence by Stringer and colleagues.[351]

### Anastomotic Ulceration

A late complication that may occur many years after resection for NEC is the development of anastomotic ulceration. Sondheimer[356] reported six children who underwent ileocolonic resection and anastomosis in the neonatal period in whom lower GI bleeding developed at 5 to 13 years of age. Anastomotic ulceration was diagnosed by colonoscopy, and treatment entailed ulcer resection in five of six patients. Recurrence of marginal ulcers developed in four of five patients who underwent resection. Histologic examination revealed shallow ulcers penetrating only to the muscularis. The cause of the ulcers is unknown.

## NEURODEVELOPMENTAL COMPLICATIONS

The length of hospitalization of infants has been strongly associated with developmental progress at 1 to 2 years of age.[349] This probably reflects the adverse effects of medical and social factors on the developing brain. It is recommended that developmental screening be performed every 4 months during the first year and every 6 months during the second year of life as long-term follow-up data suggest that normal premature infants and survivors of severe NEC remain at high risk for neurologic developmental morbidity.

Approximately 50% of infants surviving NEC are neurodevelopmentally normal.[309,346] Historically, it was believed that any adverse neurodevelopmental outcome in a patient treated for NEC was due to underlying prematurity and comorbid conditions rather than NEC itself, but recent evaluations of surviving infants contest this assumption. Vohr[357] studied the neurodevelopmental, neurosensory, and functional outcomes of 1151 ELBW (401 to 1000 g) survivors at 18 to 22 months' corrected age and reported significant deficits in neurologic development (25%), a Bayley II Mental Developmental Index less than 70 (37%), a Psychomotor Development Index less than 70 (29%), vision impairment (9%), and hearing impairment (11%). NEC was specifically associated as a risk factor for both an abnormal neurologic examination and a low Bayley Psychomotor Development Index. In a study assessing the effect of NEC on neurodevelopment, Sonntag[358] compared VLBW infants with NEC with matched infants without NEC at 12 and 20 months' corrected age. Despite normal somatic growth in infants with NEC not complicated by short bowel syndrome, the authors demonstrated significant neurodevelopmental delay at both 12 and 20 months of age. Fifty-five percent of infants with NEC were noted to be severely impaired versus only 22.5% of infants without NEC. Furthermore, Hintz[359,360] demonstrated through the National Institute of Child Health and Human Development Neonatal Research Network Registry that among the ELBW infants (weight $<$ 10th percentile for gestational age), infants with surgical intervention but not medical treatment for NEC are at significant risk for Mental Developmental Index less than 70 (OR: 1.61, 95% CI, 1.05 to 2.50), Psychomotor Developmental Index less than 70 (OR: 1.95, 95% CI, 1.25 to 3.04), and neurodevelopment impairment (OR: 1.78, 95% CI, 1.17 to 2.73) compared with infants without NEC.

# Prevention

Attempts to reduce the incidence of or prevent NEC must consider the probable pathogenesis of the disease and some of the putative perinatal risk factors. Investigations into preventive measures for NEC including limiting the nosocomial spread of microorganisms, augmenting host defense, decreasing bacterial colonization and overgrowth in the GI tract, and providing factors that enhance intestinal maturation and attenuate the inflammatory cascade may be useful. Infection control measures, breast-feeding, cautious feeding of sick premature babies, immunoglobulin supplementation of feedings, corticosteroid therapy, administration of growth factors, and the use of inflammatory mediator antagonists are some of the preventive strategies that have been studied.

## INFECTION CONTROL MEASURES

Adoption of infection control measures in the nursery may limit the incidence and restrict the spread of infections, thereby potentially eliminating the epidemic waves of NEC.

It has been demonstrated that the initiation of infection control measures stops epidemics of NEC.[219,361] During clustered occurrences, identical microorganisms can be isolated from both the afflicted neonates and their caretakers.

## AUGMENTATION OF HOST DEFENSE

### Oral Immunoglobulin Preparations

The protective immunoglobulins, principally IgA, are deficient in the premature gut. In the absence of breast-feeding, there are only trace amounts of secretory IgA and gut-associated IgG and IgM. Secretory IgA acts by binding bacteria and preventing their attachment to the intestinal mucosa. Eibl[13] demonstrated that enteral administration of an IgG-IgA preparation decreases the incidence of NEC. Their randomized trial involved feeding 179 high-risk infants weighing 800 to 2000 g a human preparation of IgG and IgA with their formula, whereas controls received formula alone. Neither group received breast milk. No cases of NEC developed in the immunoglobulin group, but 6 cases developed in the 91 controls. In a recent study in rabbits, Dickinson[362] demonstrated that IgA supplementation in feedings prevented bacterial translocation by enhancing gut mucosal barrier functions. This effect was not seen with IgG or lactoferrin. In a randomized double-blind controlled trial, enteral IgG supplementation in infants failed to reduce the incidence of NEC.[363] A Cochrane review[364] of three eligible trials (total of 2095 infants) on oral administration of IgG or IgG/IgA combination for preventing NEC did not yield any statistically significant reduction in the incidence of definite NEC (RR 0.84, 95% CI, 0.57 to 1.25), suspected NEC (RR 0.84, 95% CI, 0.49 to 1.46), need for surgery (RR 0.21, 95% CI, 0.02 to 1.75), or death from NEC (RR 1.10, 95% CI, 0.47 to 2.59). Similarly, a meta-analysis of three trials using antistaphylococcal immunoglobulins (INH A-21 and Altastaph) indicated no significant differences in the risk of staphylococcal infection and NEC between either of the antistaphylococcal immunoglobulins with placebos.[365]

### Maternal Glucocorticoid Administration

Glucocorticoids have been shown to accelerate epithelial cell maturation and improve gut barrier function including reduced mucosal uptake of macromolecules, decreased colonization with aerobic bacteria, reduced bacterial translocation, and increased activity of enzymes such as lactase, maltase, sucrase, and Na/K-ATPase.[366,367] Glucocorticoids have also been shown to down-regulate the inflammatory response by stimulating the enzymatic degradation of PAF.[165] These observations have been made both experimentally and clinically.[13,14] Bauer[368] retrospectively noted a significant reduction in the incidence of NEC in babies born to mothers who received antenatal glucocorticoids for fetal pulmonary maturation as compared with controls (2% vs. 7%). This large, multicenter, placebo-controlled trial was well controlled for many potentially confounding variables. Halac[14] conducted a randomized controlled trial of prenatal glucocorticoid administration to mothers in preterm labor. The control mothers received placebos, but their infants received an immediate postnatal course of high-dose dexamethasone for 7 days. The rate of NEC within and between groups significantly decreased after prenatal and postnatal steroid treatment. Although postnatal therapy did not decrease the incidence as effectively as prenatal therapy did, it improved the clinical outcome of NEC; however, many potentially confounding factors were not assessed in this study. Confirmatory prospective data and assessment of potential postnatal toxicity are necessary. In a double-blind randomized controlled trial comparing perinatal morbidities between antenatal betamethasone and dexamethasone (299 women),[369] no significant differences were observed to exist in the incidence of NEC (0 of 181 for betamethasone, 2 of 178 for dexamethasone). Furthermore, another multicenter randomized controlled trial[370] of 502 pregnant women demonstrated no difference in the incidence of NEC between weekly administration and a single course of antenatal corticosteroids (RR 1.06, 95% CI, 0.44 to 2.56, *P* value = 0.90).

### Breast Milk

Breast milk decreases the risk for a number of neonatal infections including lower respiratory tract illness, otitis media, bacteremia, meningitis, and NEC.[187] Human milk provides an array of humoral and cellular antiinfectious factors, growth factors, and probiotics, as well as essential vitamins and nutrients. Milk factors include IgA, macrophages, lymphocytes, components of the complement system, lactoferrin, lysozyme, transferrin, interferon, EGF, alpha fetoprotein, erythropoietin, the probiotics *Bifidobacterium infantis* and *Lactobacillus acidophilus,* PAF acetylhydrolase,[174] and several inflammatory mediators.[188,371] Strong evidence exists for the protective role of secretory IgA, the main immune component of the enteromammary axis. Breast milk also inhibits the growth of *E. coli* by providing an acidic environment, promoting competitive growth of *Lactobacillus bifidus,* and iron binding (an element essential for the growth of *E. coli*).[372]

Because invasion by infectious agents seems to be a prime factor in the pathogenesis of NEC, breast milk appears to be ideally suited to protect the infant against the disease. Administration of breast milk prevents experimental NEC.[372,373] Formula-fed babies have four to six times the incidence of NEC as breast-fed infants do.[374] A meta-analysis done by Quigley of five trials demonstrated a statistically significantly higher incidence of NEC in the formula-fed group versus the donor breast milk group (RR 2.5, 95% CI, 1.2 to 5.1; risk difference 0.03, 95% CI, 0.01 to 0.06; number needed to harm 33, 95% CI, 17 to 100).[375] Subsequently, two more clinical trials were conducted. The analysis of 1272 infants in the National Institute of Child Health and Human Development Neonatal Network Glutamine Trial showed a reduction of the likelihood of NEC or death after 14 days of diagnosis by a factor of 0.83 for every 10% increase in the proportion of total intake of human milk. For every 100 mL/kg increase in human milk intake with the 14 days of diagnosis, there is a decreased risk of NEC or death (hazard ratio 0.87, 95% CI, 0.77 to 0.97).[376] Similarly, Sullivan[377] showed in a trial of 207 infants (500 to 1250 g) comparing an exclusively human milk–based diet with a diet of both human milk and bovine milk–based products that there was a reduction in NEC of 50% and in surgical NEC of almost 90% in infants fed an exclusive human milk diet. The numbers to treat with an exclusively human milk–based diet to prevent 1 case of NEC and 1 case of surgical NEC were 10 and 8, respectively. The last two trials imply a dose effect of human milk in the reduction of both medical and surgical NEC.

### Feeding Practices

There is little disagreement that NEC is more common in fed infants and that bacterial overgrowth is facilitated by the substrate provided by formula. Although the potential benefit of carefully regulated feeding practices to prevent NEC is widely accepted, randomized trials have failed to demonstrate any difference in the incidence of NEC related to fast versus slow, early versus delayed, or continuous versus intermittent bolus feeding.[35–39,378–381]

## METHODS TO DECREASE INTESTINAL BACTERIAL COLONIZATION AND OVERGROWTH

### Administration of Probiotics

Probiotic bacteria are defined as "live microbial supplements that colonize the intestine to provide benefit to the host."[382,383] The use of anaerobic bacterial supplementation in the treatment or prevention of GI disease has been well described. There has been increasing interest in using probiotics for the prevention of NEC. Probiotic microorganisms commonly used are strains of *Lactobacillus, Bifidobacterium, Streptococcus salivarius,* and *Saccharomyces boulardii.* Multiple randomized, controlled trials have attempted to address this issue, and several meta-analyses have been published. The most recent meta-analysis by Deshpande[384] analyzed 11 trials[385–395] ($n = 2176$) in which enteral probiotic supplementation was started within the first 10 days and continued for 7 or more days in VLBW neonates (<1500 g). Compared with the control group of no probiotics, significant reductions of risk were noted for developing definite NEC (RR 0.35, 95% CI, 0.23 to 0.55, $P < 0.00001$) and dying from all causes (RR 0.42, 95% CI, 0.29 to 0.62, $P < 0.00001$). Further sensitivity analysis, examination through the funnel plot, and trial series analysis supported a 30% reduction in the incidence of NEC (alpha = 0.05; power of 80%). However, risks for sepsis, death from NEC, and longer time to full feed (120 to 150 mL/kg per day enteral feeds or as per the prestated definitions by authors) did not differ significantly between both groups after adjustments were made for heterogeneity via a random-effects model.

Rachmilewitz[396] and Mackey[397] considered applying similar concepts used in probiotic feedings by treating infants with isolated microbe-associated molecular patterns (MAMPs) to induce protective responses that promote intestinal health. An MAMP is a molecular sequence or structure in any pathogen-derived molecule that directly interacts with TLRs on the intestinal epithelium. It has been shown to effectively improve symptoms of colitis in mice.[396] The idea of administering inactivated probiotics (heat-killed commensals) or bioavailable TLR ligands that can potentially induce beneficial TLR-mediated protective effects without the risk of infection from administering probiotics is being actively investigated.

### Administration of Prebiotics

Besides probiotics, other researchers have suggested administering prebiotics, which are nondigestible dietary supplements such as long chain carbohydrates or mucins that promote proliferation of beneficial commensal bacteria. A meta-analysis of four trials ($n = 126$) by Srinivasjois[398] examined the efficacy and safety of prebiotic oligosaccharide supplementation of formula in reducing the incidence of NEC and sepsis. The duration of the supplementation ranged from 14 to 33 days. The analysis indicated no NEC in one trial, but the rest did not report specifically on NEC or sepsis. Two of the four trials demonstrated a significant increase in bifidobacterial counts in the prebiotic supplemented group. The major advantage of prebiotic supplements is the lack of live microorganisms, which reduces the risk of infection that may exist for the use of probiotics.

### Administration of Postbiotics

Similar to prebiotics, postbiotics, which are bacterial metabolites, may also be a potential treatment for NEC by generating some beneficial effects on the intestinal flora. Butyric acid, a short-chain fatty acid produced by commensal bacteria in the colon through anaerobic catabolism of complex carbohydrates, is a major energy source for colonic enterocytes and has a widely recognized but poorly understood role in intestinal growth and differentiation,[399,400] inflammatory suppression,[401] and apoptosis.[402] It has been administered with limited success in human inflammatory bowel disease.[403]

### Enteral Antibiotics

Nonabsorbable broad-spectrum antibiotics that inhibit bacterial growth have been administered in an effort to prevent NEC. The use of an enteral aminoglycoside (e.g., kanamycin or gentamicin) has been proposed as a means to decrease the incidence of perforation during nonoperative treatment. However, randomized, controlled studies found no difference in the clinical course, complications, or mortality rate between infants who received the antibiotic and those who did not.[404,405] In addition, oral aminoglycosides may be absorbed across the damaged gut, which can lead to increased serum levels and thereby potentially contribute to drug toxicity. Resistant strains of bacteria emerged after treatment with enteral kanamycin,[404] and there is the omnipresent risk for promotion of the growth of fungal species. In a recent randomized placebo-controlled study of oral vancomycin in preventing NEC in preterm infants, Siu[16] reported a 50% reduction in the incidence of NEC in the vancomycin group in comparison with controls. A meta-analysis of five trials ($n = 456$) by Bury[406] suggested that prophylactic enteral antibiotics resulted in a statistically significant reduction in NEC (RR 0.47 [0.28, 0.78]; RD −0.10 [−0.16, −0.04]; NNT 10 [6, 25]) and in NEC-related deaths (RR 0.32 [0.10, 0.96]; RD −0.07 [−0.13, 0.01]; NNT 14 [8, 100]). However, the summary analysis of three trials gave an increase in the incidence of colonization with resistant bacteria that was just significant (RR 1.73 [1.00, 2.97]; RD 0.07 [0.00, 0.13]). Furthermore, a subsequent retrospective cohort analysis of 5693 neonates (<1000 g) from the NICHD database by Cotton[407] demonstrated that for every antibiotic treatment day, there was at least a 4% increase in the odds of an infant having NEC or dying, especially when antibiotics were initiated in the first 3 postnatal days for 5 or more days of treatment.

The available studies do not support the routine administration of enteral antibiotics to all high-risk premature infants, many of whom have poor intestinal motility. Effectiveness has not been proved, and resistant organisms may develop.

Administering specific antibiotics to infants may be indicated in nurseries in which an outbreak of NEC is associated with a specific organism.

## METHODS TO DETER THE INFLAMMATORY CASCADE

### Inflammatory Mediator Antagonists

The effects of PAF are mediated by receptors, and many compounds that function as receptor antagonists or enzymes that degrade these proteins have been described. Animal experiments using PAF antagonists or PAF-degrading enzyme (PAF acetylhydrolase) have demonstrated the capacity to prevent bowel injury produced by the administration of endotoxin or hypoxia in rats.[47,115] PAF acetylhydrolase is also known to be present in breast milk. Despite promising results in animal models, no human trials using PAF antagonists or degrading enzymes in the treatment of NEC have been reported.

### Arginine

While NO has been linked to the pathogenesis of NEC, it may be beneficial to neonate intestine by regulating mucosal blood flow, inflammatory signaling, barrier function, and wound healing.[408] Arginine, a substrate for the production of NO, has been shown to be in low level in neonates with NEC as well.[153,409] Thus researchers tested the effect of arginine supplementation on the incidence of NEC. In the 2007 Cochrane Review[155] one trial[154] on arginine supplementation was reported to reduce the incidence of all stages of NEC (RR 0.24, 95% CI, 0.10 to 0.61; RD -0.21, 95% CI, -0.32 to -0.09), but further studies are necessary to confirm and elucidate the mechanism of this benefit.

### Epidermal Growth Factor

As discussed in previous sections, EGF is a growth factor that exerts its effects by binding to the EGF receptor. It has multiple effects including healing of damaged mucosa by inducing mucosal enzyme and trefoil peptide expression and inhibiting effects on gastric acid secretion.[62,65–67] Clark demonstrated intestinal protection by accelerating goblet cell maturation and mucin production and normalizing expression of tight junction proteins in a neonatal rat model. One prospective randomized controlled study[410] of eight neonates with NEC showed measurable trophic effects on the gastrointestinal mucosa and no significant difference in clinical safety between a 6-day continuous intravenous infusion of EGF and placebo. The administration of EGF is still at the testing stage. Further studies are necessary before any clinical use.

CHAPTER 95

# Crohn's Disease

Obinna O. Adibe and Keith E. Georgeson

Crohn's disease (CD) is a debilitating chronic inflammatory bowel disorder with no known cure. The disease affects the entire digestive tract. The original article by Crohn, Ginzberg, and Oppenheimer described *regional ileitis* as the formation "of ulcers and hyperplastic inflammation in which the terminal loops of the small intestine, just proximal to the ileocecal valve, are implicated."[1,2] CD and ulcerative colitis (UC) comprise the vast majority of patients exhibiting a wide spectrum of clinical pathology under the broad heading of *inflammatory bowel disease* (IBD). The estimated annual health care cost of IBD in the United States is about $1.7 billion.[3] Approximately 10% of Americans with IBD are children and adolescents.[3]

The etiology of CD is unknown. However, it is believed that its pathogenesis is multifactorial, encompassing environmental, genetic, and immunologic causes.[4] Diagnosis requires a thorough history and physical examination, along with diagnostic imaging, histologic, and laboratory evaluations. Despite various pathognomonic features such as transmural inflammation, aphthous ulcers, and granulomas, CD may be indistinguishable from UC. In children the reported percentage of cases of IBD diagnosed as indeterminate colitis ranges from 4% to 23%.[5]

The natural history of CD is characterized by quiescence with symptomatic flare-ups leading to severe physical and social impairment,[6] as well as the long-term risk of colorectal cancer. Both medical and surgical therapies are used to combat the wide range of symptoms in children and adolescents with CD. It is imperative, therefore, that this disease is diagnosed and treated in a multidisciplinary fashion.

## Epidemiology

The worldwide incidence of pediatric CD is 0.2 to 8.5 per 100,000.[7,8] A prospective study of a Wisconsin population reported an incidence of 4.56 per 100,000.[9] It is more common in countries in the northern hemisphere and in industrialized nations.[7] The highest rates of CD are found in Scandinavian countries and Scotland, followed by England and southern Europe.[8,10] There has been a noticeable rise in the incidence of CD after World War II[10]; Scotland had a threefold increase in childhood CD between 1968 and 1983,[10] and northern France had an increased incidence of pediatric CD cases, from 2.1 to 2.6 per 100,000 between 1988 and 1999.[11] There is a positive family history of CD in more than 10% of patients,[11] with a high rate of concordance for monozygotic twins.[7] Although there is a higher percentage of boys diagnosed with CD in childhood, the proportions even out in adulthood. Twenty-five to 30% of patients with CD are younger than age 20 at the time of diagnosis.[7]

## Etiology

The etiology of CD remains unknown; however, there seems to be a complex interaction of environmental, genetic, and immune factors that lead to its development.[7] Some experts have suggested that a triggering event such as a bacterial infection or other immunogenic stimulus in a genetically predisposed individual can result in the onset of CD.[12]

In one recent study, 22% of patients with CD had an affected family member,[10] suggesting a genetic predisposition. Concordance for CD has been reported to range from 36% to 48% in monozygotic twins, compared with 4% of dizygotic twins.[13] The gene for the nuclear oligomerization domain 2 (NOD2) and the caspase activation and recruit domain 15 (CARD15) are located on chromosome 16.[14] Mutations in NOD2/CARD15 overexpress NF-$\kappa\beta$, a critical mediator of the inflammatory responses that control the transcription of genes for proinflammatory cytokines.[6,10] Mutations in this gene have been associated with ileocecal and stricturing disease phenotypes,[6] earlier disease onset, and early need for operative intervention.[3,10,12,15–17] Mutations of this gene have been identified in 30% to 43% of Caucasian North American CD patients.[10] Another gene, *IBD5,* located within chromosome 5q31, has been associated with CD-linked perianal disease.[6,7,10]

A recently discovered gene variant of *ATG16L1,* an autophagy gene, may be associated with CD.[16,18,19] This mutation results in defective macroautophagy in the Paneth cells of the intestines (within the crypts of Lieberkühn), resulting in the ineffective elimination of invasive pathogens.[19,20] This mutation also results in higher levels of interleukin $1\beta$, making intestinal cells more susceptible to an abnormal inflammatory response.[21] This *ATG16L1* gene variant opens a possible new mechanism for treating CD patients, focusing efforts on gene therapy, cytokine neutralization, and Paneth cell rejuvenation.[19]

## Pathology and Clinical Features

Within the pediatric population, disease involving both the small bowel and proximal colon (ileocecal) occurs in more than two thirds of patients; disease isolated to the small bowel occurs in about 20% of patients and is restricted to the colon in 10% of patients.[11] Endoscopic evidence of inflammation in patients with ileocolic disease has been noted on upper endoscopy in up to 40% of patients.[12]

CD initially manifests itself as small mucosal ulcerations (aphthous ulcers).[22] These ulcers subsequently coalesce to form linear ulcerations that surround islands of edematous mucosa, producing the "cobblestone" appearance.[22] Mucosal ulcers sometimes achieve transmural penetration, creating sinuses, abscesses, and fistulas (Fig. 95-1).[22]

The inflammation progresses through all layers of the bowel wall. "Creeping fat" forms from thickening of the mesentery, with proliferation of the surrounding fat on the serosal surface. With acute inflammation, the bowel becomes edematous and hyperemic.[22] As the inflammation becomes chronic, fibrotic scarring leads to bowel thickening and eventual stricture formation (Fig. 95-2).

Histologic examination reveals neutrophilic and eosinophilic inflammatory cell infiltration of the edematous, fibrotic submucosa (Fig. 95-3). Noncaseating granulomas are pathognomonic for CD but are seen in only half of resected specimens (Fig. 95-4).[22]

Common presenting signs and symptoms of CD include crampy abdominal pain, diarrhea, decrease in appetite, weight loss, growth delay, and delayed sexual maturation.[12] Abdominal pain is usually located in the right lower quadrant, associated with tenderness and fullness.[12] Failure to thrive can be present in nearly half of children diagnosed with CD.[23]

In 1998 a CD Working Party was organized to classify the behavior of this disorder into three subtypes: (1) nonstricturing, nonpenetrating; (2) stricturing; and (3) penetrating.[24] However, the clinical course of CD is often erratic and disease phenotypes often change as the duration of disease lengthens.[6] Location of CD in the gastrointestinal (GI) tract has also been broadly classified into four areas: (1) terminal ileum; (2) colon; (3) ileocolic; and (4) upper GI.[24]

Perianal disease may be the primary presenting sign of CD.[12] Anal fissures, perianal fistulas, or abscesses precede or present simultaneously with diagnosis of CD in many

patients.[8] The incidence of perianal fistulas in children with CD is approximately 10%.[25] Fistulas are classified as *simple* or *complex*. Treatment is discussed later in the chapter.

Musculoskeletal involvement is the most common extraintestinal manifestation seen in patients with CD. The incidence of peripheral arthropathy (arthritis or arthralgia) in CD is approximately 20%.[26] Erythema nodosum presents as tender, red nodules, usually on the extensor surfaces of the lower extremities, and is seen in about 10% of patients.[26] Pyoderma gangrenosum manifests itself as erythematous skin nodules that develop into ulcers, and it occurs in about 5% of patients with CD.[26] Episcleritis and uveitis also occur in about 5% of patients with CD.[26] Episcleritis is a painless hyperemia of the sclera and conjunctiva, whereas uveitis is a painful manifestation associated with blurring and photophobia. Nephrolithiasis, composed of uric acid and calcium oxalate stones, occurs in up to 5% of patients.[26] Hepatobiliary manifestations associated with CD include primary sclerosing cholangitis, gallstones, chronic hepatitis, and steatosis.

## Diagnosis

A thorough history often provides the clinician with important clues to the diagnosis of CD in children. Intermittent crampy abdominal pain, food intolerances, diarrhea, fever, family history of IBD, and perianal disease may be reported.[27] Physical examination should include an abdominal evaluation with special attention paid to the right lower quadrant for masses.

A rectal examination may reveal obvious perirectal disease. However, a thorough examination is sometimes difficult in an anxious pediatric patient. In these cases, an examination under anesthesia (EUA) is the gold standard,[28] providing a thorough assessment of the perirectal area. The accuracy of an EUA may be enhanced by the use of an anorectal endoscopic ultrasound (EUS) to help detect abscesses.[8]

Growth evaluations are an important aspect of the physical examination[7,12] because weight loss is present in most children with CD at diagnosis.[7,29] A Tanner assessment of pubertal status should be performed to identify delayed sexual development. The clinician should also look for signs of extraintestinal manifestations (skin rash, joint pain, eye pain).

A complete blood count (CBC) should be obtained, specifically looking for anemia, leukocytosis, and thrombocytosis.[12] The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) increase with acute disease activity.[27] Baseline nutritional laboratory tests (albumin, prealbumin, and transferrin) should be performed.[23] Detection of IgA and IgG anti-saccharomyces cerevisiae antibody (ASCA) is highly specific for CD in children.[6,7,12,30] Patients presenting with diarrhea should have stools checked for leukocytes, occult blood, and infectious etiologies *(Clostridium difficile, Giardia, Salmonella, Escherichia coli O157:H7, Campylobacter, Rotavirus, Shigella)*.[7,12,27]

An upper GI contrast study with small bowel follow-through assists in assessing existence, location, and extent of the disease.[12] Computed tomography (CT) and ultrasound (US) can evaluate for terminal ileal inflammation and intra-abdominal abscesses. In a recent study, gadolinium-enhanced magnetic resonance imaging (MRI) was shown to be highly specific and sensitive for the identification of proximal small bowel disease.[31]

Ileocolonoscopy and upper endoscopy are necessary for direct observation and biopsies of the terminal ileum, colon,

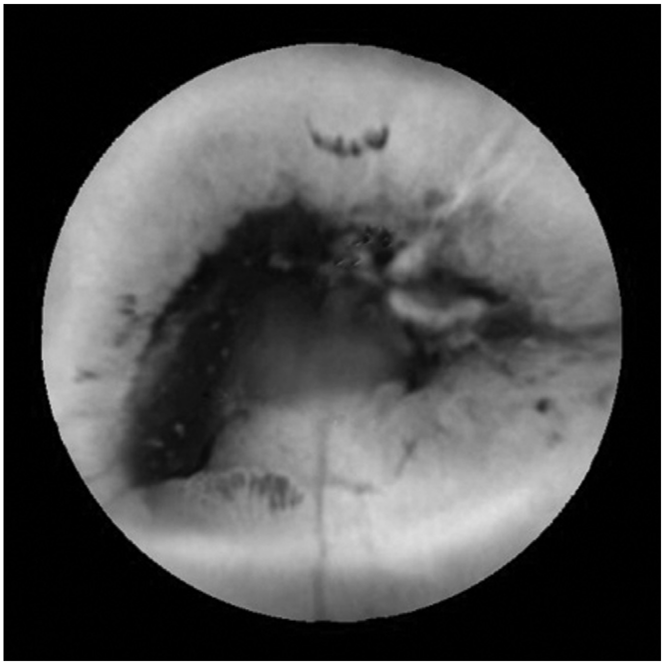

**FIGURE 95-5** Jejunal ulceration and bleeding via capsule endoscopy. (Courtesy Dr. Shehzad Saeed, Department of Gastroenterology, The Children's Hospital of Alabama.)

and stomach. Endoscopy may reveal skip lesions, rectal sparing, aphthous ulcers, and terminal ileal inflammation. Capsule endoscopy has gained popularity for identification of proximal small bowel disease (Fig. 95-5).[32] An upper GI contrast study with small bowel follow-through is recommended before capsule endoscopy to rule out strictures that may lead to capsule retention. In a retrospective study, capsule retention occurred in 3 of 207 pediatric patients (1.4%) without small bowel abnormalities, compared with 37.5% in patients with known strictures noted on prior small bowel series.[32]

## Medical Therapy

The goals of medical treatment are to (1) achieve remission of active disease, (2) promote growth through adequate nutrition and suppression of inflammation, and (3) decrease the need for surgical intervention.[6]

Systemic corticosteroid induces clinical remission and is standard of care for treatment of moderate to severe CD.[6,12] Corticosteroids decrease the transcription of proinflammatory cytokines (IL-1$\beta$, IL-6, tumor necrosis factor $\alpha$ [TNF-$\alpha$]).[33] Up to 90% of pediatric patients with moderate to severe CD show rapid improvement of symptoms when prednisone or a prednisone equivalent (i.e., prednisolone) of 1 to 2 mg/kg/day is given (maximum dose 40 to 60 mg/day).[33–35] Rectal steroid therapy as enemas and foam-based preparations may be administered for left-sided colitis.[12] About 50% of patients develop corticosteroid dependency, which is characterized by frequent relapses and a requirement for chronic corticosteroid use.[6] Long-term corticosteroid use is associated with osteopenia, weight gain, glucose intolerance, pubertal retardation, striae, acne, and many other well-described side effects.[6,33] It is therefore not recommended for maintenance therapy.[12,36] All patients on corticosteroids should be given

calcium and vitamin D supplements.[33] Budesonide, an alternative steroid therapy with a high affinity for intestinal glucocorticoid receptors, has been reported to have an enhanced first-pass therapeutic effect with a lesser systemic corticosteroid exposure causing fewer side effects.[33] As a timed-release oral medication, budesonide is indicated for ileal and right-sided colonic disease,[12,34] although it is not as effective as prednisone in achieving clinical remission in children.[6]

Mesalamine (an aminosalicylate) is the first-line therapy for mild to moderate active CD.[6] It is not effective in moderate to severe disease or in maintaining remission.[12] Asacol tablets provide mesalamine with an enteric coating that delays systemic release until it reaches the terminal ileum and colon.[33] Pentasa is mesalamine with an ethylcellulose carrier for time-release throughout the small and large intestine.[33] The mechanism of action of mesalamine is largely unknown. Adverse effects include rash, elevated liver enzymes, and renal impairment.

Azathioprine (AZA) and 6-mercaptopurine (6-MP) are thiopurine antimetabolite immunomodulators that inhibit the inflammatory response via immunosuppression. AZA is converted to 6-MP in plasma. The thiopurines are among the most effective treatments available for long-term maintenance of CD.[34] They are usually given as an “exit strategy” after induction of remission with corticosteroids to avoid dependency on the steroids.[6] Thiopurines can reduce the rate of corticosteroid dependence and resistance from 50% to less than 20%.[6] It has also been shown to decrease the rate of postoperative recurrence of CD following bowel resection.[37] Because of its slow onset of action (3 to 6 months), thiopurines should be administered early in the treatment of moderate to severe CD. Adverse effects include leucopenia, pancreatitis, and hepatotoxicity.[8]

Methotrexate is a second-line immunomodulator therapy for patients who do not tolerate 6-MP or AZA.[34] It is a dihydrofolate reductase inhibitor with corticosteroid-sparing effects.[33] Adverse effects include bone marrow, pulmonary, and liver toxicity.[33] As a known teratogen, women of childbearing age should not be administered this drug.

Infliximab is a chimeric (human/murine) monoclonal antibody against TNF-α.[7] In adults with moderate to severe disease, infliximab produces excellent symptom improvement and remission rates for refractory CD and chronic perianal or abdominal fistulas.[12,23,38–40] Infliximab is administered via infusion at 5 mg/kg given every 8 weeks after an initial loading period. A multicenter, randomized, open-label study of infliximab in pediatric patients with moderate to severely active CD demonstrated 88% of patients with a clinical response and 58.9% with clinical remission compared with placebo.[41] Concomitant use of an immunomodulator during therapy may help maintain clinical response to infliximab.[42] Infliximab has also been shown to decrease corticosteroid use[43] and improve height velocity.[44] The drug may also be used in the initial treatment of perianal disease in children and adolescents.[8] Crandall and colleagues[45] have shown that a majority of pediatric patients respond to infliximab for perianal disease. Adverse events from infliximab use include infusion reaction (flushing, rash, headaches); delayed hypersensitivity reaction; and an increase in the overall rate of infection (tuberculosis, histoplasmosis, PCP pneumonia, sepsis).[6,8] All patients should undergo testing for latent tuberculosis before infliximab therapy. Continued use of infliximab may lead to development of antibodies against itself, causing a diminished clinical response.[46,47] Infliximab is contraindicated in patients with intra-abdominal or perirectal abscesses.[48]

Adalimumab is a subcutaneously administered, recombinant, fully human, immunoglobulin G1 monoclonal antibody that binds with high affinity and specificity to human TNF-α.[49] In a randomized, phase III, double-blind, placebo-controlled trial, adalimumab was shown to be effective in induction and long-term maintenance of clinical remission in adults with CD.[49] A multicenter, retrospective study was performed to evaluate the safety and efficacy of adalimumab in children; it demonstrated a 70% clinical response rate that sustained at 6- and 12-month follow-ups.[47] A prospective study performed in a single tertiary institution consisting of 23 patients age 9 to 20 with moderate to severe CD treated with adalimumab showed a 65.2% clinical remission and a 91% clinical response for 48 weeks of treatment.[46] Adalimumab may be used to treat those who no longer respond or have experienced adverse effects to infliximab.[28,47] The recommended dosage for pediatric patients who weigh more than 15 kg is 20 to 40 kg every other week. The most common adverse event reported is pain at the injection site.[46] As with infliximab, patients may be required to undergo testing for latent tuberculosis before initiation of therapy.

Metronidazole and ciprofloxacin appear effective in children with mild to moderate active ileocolonic CD.[7,33] These antibiotics may also be used as first-line therapy for the induction of healing of perianal fistulae.[28,48] The addition of infliximab may promote a synergistic effect in healing the fistulae.[28] Metronidazole may delay anastomotic recurrence after surgery[50] with long-term use, but relapse often occurs soon after discontinuation.[33] Dosage of metronidazole should not exceed 40 mg/kg/day. Adverse effects of metronidazole include a metallic taste, glossitis, nausea, pancreatitis, neutropenia, and distal peripheral sensory neuropathy.[8,33] Ciprofloxacin should be administered cautiously to children due to the reported risk of Achilles' tendon rupture in animal studies.[33]

Enteral therapy (total liquid formula diet) has been used for both nutritional support and as a method of treatment for CD.[23] Exclusive enteral nutrition (EEN) can induce remission in up to 85% of newly diagnosed patients.[29] In 1995 two meta-analyses of randomized controlled trials comparing EEN with corticosteroids demonstrated that steroids were more effective than enteral nutrition for treatment and induction of remission in patients with CD.[51,52] However, a more recent meta-analysis focusing on pediatric studies suggests that enteral nutrition is as effective as corticosteroids in both the induction of remission and the treatment of CD.[53,54] This study also documented that pediatric patients with CD given enteral nutrition often experience improved growth.[34,53] Enteral formulas with transforming growth factor-β (TGF-β) and omega-3 fatty acids have been shown to increase mucosal healing[29,55] and may also have an immunomodulatory effect.[54] The improved growth and nutrition status that EEN provides, while avoiding the side effects of steroids, make it the preferred choice for first-line therapy in some centers.[29] However, because palatability necessitates use of a feeding tube,[4] compliance becomes a major issue. Most patients relapsed 12 months after discontinuation of EEN.[54]

Several studies suggest efficacy and safety of stem cell transplantation (SCT) in the treatment of CD.[56] In a retrospective review of 11 IBD patients (7 patients with CD, 4 patients with UC) who underwent allogeneic SCT for hematologic malignancies (age mean 41, range 27 to 55; median follow-up 34 months), 10 had relief of symptoms after transplantation.[57]

In another study, four of five patients with CD and leukemia who underwent allogeneic marrow transplantation remained free of CD after a follow-up of 4.5 to 15.3 years.[58] In an experiment observing the actions of hematopoietic stem cells (HSCs) and mesenchymal stem cells (MSCs) in colitis-induced rats, both HSCs and MSCs migrate to and repopulate damaged GI epithelium.[56] In a phase I clinical trial using autologous HSC transplantation in adult patients with CD, 11 of 12 subjects showed sustained remission after a median follow-up of 18.5 months.[59] Another phase I trial suggests that autologous MSCs harvested from adipose tissue can treat fistulizing CD.[60,61] More rigorous clinical trials, especially in the pediatric population, will need to be conducted before this form of therapy becomes mainstream.

## Surgical Therapy

Unlike UC, there is no surgical cure for CD. Operative interventions should be reserved for (1) failure of medical therapy, (2) complications of the disease, (3) severe dysphagia, (4) cancer, and (5) stagnated growth and development.[62] Medical failure can be secondary to noncompliance or long-term steroid dependency.[4,62] Many patients with CD will require surgery at some point in their therapy.[4,7]

Children often present with right lower quadrant pain and/or fullness, commonly associated with fever and vomiting. Imaging studies are indicated to look for a phlegmon, abscess, perforation, fistula, megacolon, or obstruction caused by strictures. Abscesses are best treated by image-guided drainage and a course of antibiotics, with a delayed resection if necessary. A few patients present with free perforation,[62] requiring an immediate operation. Fistulas entering the bladder, uterus, or other intestinal segments are treated with limited bowel resection and repair of the adjacent organ. Severe acute colitis and toxic megacolon affects about 5% of CD patients.[62] A trial of intravenous steroids may be cautiously initiated, but surgical resection is sometimes necessary.

Obstruction is the most common indication for surgery in children with CD, usually secondary to stricture formation. Many obstructions can be treated medically. Operative intervention is indicated when the risks of continued medical therapy outweigh its benefits. The type of operation depends on the length of the involved bowel and the number of strictures. The surgical goal is to alleviate the cause of the mechanical obstruction, while minimizing the loss of bowel length[7,63] to avoid the numerous complications of short-bowel syndrome.[64] Strictures up to 10 cm in length may be managed by resection or a Heineke-Mikulicz strictureplasty (Fig. 95-6) using a longitudinal incision through the stricture, with transverse closure of the defect. Longer strictures, up to 25 to 30 cm, may be treated by resection or a Finney strictureplasty (Fig. 95-7) using a

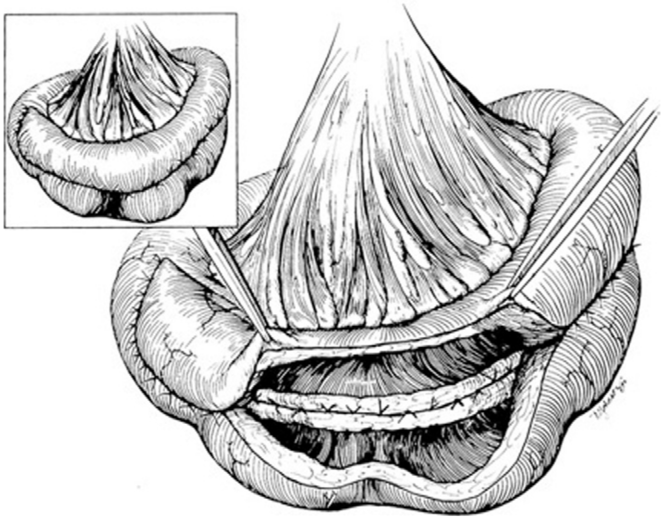

FIGURE 95-8 Side-to-side isoperistaltic strictureplasty. (From Michelassi F: Side-to-side isoperistaltic strictureplasty for multiple Crohn's strictures. Dis Colon Rec 1996;39:345-349.)

longitudinal incision through the strictured area, followed by a side-to-side anastomosis. Long segment bowel stenosis caused by CD may also be treated by the Michelassi technique, where the stenotic intestine is sectioned transversely at the midpoint of the stenosis, the mesentery is divided, a longitudinal incision is made on both loops, the proximal loop is advanced over the distal loop, and a side-to-side anastomosis is performed (Fig. 95-8).[65] Yamamoto and colleagues[66] performed a meta-analysis of studies on strictureplasty outcomes. They reported a 13% complication rate for patients who underwent jejunoileal strictureplasties. Complications included anastomotic leak, fistula, abscess, hemorrhage, wound infection, and bowel obstruction.[66] These complications are similar in type and incidence as seen after resection.[66] Risk factors for these complications included preoperative hypoalbuminemia, emergency operations, low hemoglobin level, and preoperative weight loss.[66] Steroid use was not a risk factor for complications.[66] There was no difference in recurrence rate after strictureplasty versus resection.[66] Resection is recommended for diseased bowel or multiple concurrent strictures greater than 30 cm.

Endoscopic balloon dilatation has been gaining popularity for treatment of ileal and colonic Crohn strictures. Dilations are carried out under fluoroscopic guidance using contrast-filled balloons. Intralesional injections of triamcinolone acetonide (Kenalog) have also been performed.[67] Tapering doses of prednisolone may be administered after dilatations.[68] After a mean follow-up of 81 months, Stienecker and colleagues reported a success rate of 80% and a perforation rate of 3% with balloon dilatation.[68] Others have reported similar results.[67]

Ileocecectomy is the treatment of choice for patients with isolated ileocecal disease. It often provides a disease-free interval of at least 2 to 3 years.[7] Traditionally, this operation has been undertaken via an open approach. However, laparoscopic resection has gained acceptance in the pediatric surgical arena. In a retrospective review comparing 12 laparoscopic and 16 open pediatric resections, the time to full feeds and hospital length of stay were shorter, while complication rates were similar.[69] In another study of 15 children and adolescents with ileocecal CD, the authors concluded that laparoscopic resection is safe and effective.[70] In an observational study from a prospectively collected database of 109 patients, Soop and colleagues[71] reported a complication rate of 11% after laparoscopic ileocecal resection. Prolonged ileus was the most common complication. No anastomotic leaks were reported, and the median hospital length of stay was 4 days.[71] Data collected from 2000-2004 via the Nationwide Inpatient Sample comparing laparoscopic and open ileocecal resections demonstrated an overall complication rate of 8% with the laparoscopic approach and 16% with the open approach.[72] Finally, a meta-analysis of 14 studies comparing laparoscopic and open ileocecal resection for CD demonstrated a shorter hospital length of stay, faster recovery of bowel function, and decreased morbidity with the laparoscopic approach.[73]

Resection is the definitive treatment for Crohn colitis refractory to medical therapy. Operative options depend on disease location; they include segmental resection, total abdominal colectomy with ileorectal anastomosis, and proctocolectomy with end ileostomy. In 2005 a prospective study involving 179 patients from the University of Chicago was reported comparing these three options; after 10 years, a segmental resection was associated with a 50% recurrence rate, while the recurrence rates for a total abdominal colectomy and total proctocolectomy were 30% and 20%, respectively.[74] Table 95-1 demonstrates the type of surgery, location of disease, and patients continuing medical therapy 1 year after their respective surgery.

Although we and others[74,75] do not recommend restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA) in patients with CD, there is some evidence in favor for this option. In 2008 the Cleveland Clinic reported their long-term outcomes of 204 patients with CD who were offered a primary IPAA.[76] In their analysis of a prospectively maintained database, selected patients (highly motivated, preoperative diagnosis, isolated colon involvement, no ano-perineal fistulous disease) achieved an 85% pouch retention rate after a median follow-up of 7.4 years.

Perianal disease is seen in about one third of children with CD. It is more commonly associated with colonic CD than in patients with CD of the small bowel.[77] It may be the only presenting symptom in up to 5% of patients.[77] As

**TABLE 95-1**

**Type of Surgery in Relation to Extent of Disease, Location of Disease, and Long-term Medical Therapy After the First Year of Follow-up**

| *Procedure* | *>2 Segments* | *Distal Involvement* | *Taking Medication* |

From Fichera A, McCormack R, Rubin MA, et al: Long-term outcome of surgically treated Crohn's colitis: A prospective study. Dis Colon Rectum 2005;48:963-969.

in intra-abdominal CD, perianal disease refractory to medical therapy requires operative intervention. Perianal CD usually presents as an abscess or a fistula. Superficial abscesses should be drained surgically. Simple incision and drainage with irrigation and debridement are recommended.[8] The cavity may be packed with gauze, which is then removed after 24 to 48 hours. Another option is to insert a small drain into the cavity, which is secured to the skin with a rapidly absorbing suture, allowing the drain to fall out with the passage of time. For deep abscesses, incision and drainage are also required, followed by insertion of a noncutting seton if a fistula is present or a self-retaining catheter if a fistula is not identified.[8] The catheter may stay in place for weeks. In most cases, incision and drainage should be attended by a course of antibiotic therapy.

Perianal fistulas may be classified as low/simple (superficial, low intersphincteric, low transsphincteric) or high/complex (high intersphincteric, high transsphincteric, suprasphincteric, extrasphincteric). The principles of fistula management are listed in Table 95-2. Evaluation of perianal fistulas in patients with CD requires an EUA to identify strictures, abscesses, and/or tracts.[63] The accuracy of EUA in detecting fistulas is about 90%, which can approach 100% with the use of an endoscopic ultrasound (EUS).[77,78] Sigmoidoscopy is also recommended to assess for any rectal disease. Low/simple fistulas are treated by fistulotomy,[8,63,77] with excellent healing rates but a recurrence rate of 20%.[8,77] For low/simple fistulas associated with rectosigmoid disease and for high/complex fistulas, placement of a noncutting seton is strongly recommended[8,62,63,77,79] because both fistulotomy and fistulectomy in these circumstances are associated with high rates of incontinence and nonhealing.[8,28] The seton can be left in place indefinitely. Better control of nonhealing high/complex perianal fistulas may be achieved via EUS-guided placement of the noncutting seton, in combination with an infliximab regimen.[28] Alternative treatments for high/complex fistulas include fibrin glue instillation,[80] fibrin glue with adipose-derived stem cell instillation,[81] and intralesional infliximab.[82] A diverting colostomy is recommended for patients who have failed medical management. An ostomy takedown may be considered after 1 year has elapsed with apparent healing of the fistula.

In a retrospective, multivariate analysis of 100 resective surgeries in 68 children with CD, there was a 17% symptomatic recurrence rate after 1 year, a 38% recurrence rate after 3 years, and 60% after 5 years.[83] Recurrence after partial colon resection was associated with a higher risk of recurrence than after an ileocecal resection (median, risk-free interval 1.16 years for colonic resection vs. 4.36 years for ileocecal resection).[83] After an ileal or ileocecal resection, second operations have been reported in 5% of patients after the first year, 11% to 32% of patients after 5 years, and 20% to 44% of patients after 10 years.[84,85] Strictureplasty has been shown to be both safe and effective in the treatment of CD, while reducing the risk of short-bowel syndrome. The complication rate and long-term recurrence rate after ileocecal strictureplasty are similar to the rates reported after resection.[63]

After a colectomy for CD, patients with an end ileostomy have lower recurrence rates than those with an ileorectal anastomosis.[85] Smoking in the postoperative period is a major risk factor for disease recurrence.[84,86] Genetic factors (NOD2/CARD15 carriers) may also increase the risk of recurrence.[84] Medications such as 6-MP, AZA, and metronidazole have been shown to decrease postoperative recurrence slightly.[84,85,87] Patients taking these medications before resection should continue them postoperatively.[83,84] Resection of diseased bowel often results in a rapid, postoperative increase in linear growth in children with CD.[7,29,83]

## Cancer

The ongoing inflammatory process involved in CD predisposes patients to a relatively high risk of malignancy. A population-based study comparing IBD patients to a normal population showed an increased incidence rate (IR) of colon cancer (IR = 2.64, 95% confidence interval 1.61 to 4.12) and small bowel cancer (IR 17.4, 95% confidence interval 4.16 to 72.9) in patients with CD.[88] The risk of future colorectal and small bowel cancers may increase when IBD presents in the pediatric years.[89] One study demonstrates a 22-fold, lifelong increase in the incidence of colorectal cancer among men younger than age 32 at the time of diagnosis.[90] Screening guidelines for colorectal cancer in IBD include (1) a screening colonoscopy 10 years after onset of symptoms; (2) continued surveillance every 3 years in the second decade, then every 2 years in the third decade, then every year; and (3) patients with an IPAA should undergo yearly endoscopic surveillance of the pouch with biopsies.[89]

# CHAPTER 96

# Ulcerative Colitis

Jeremy Adler, Arnold G. Coran, and Daniel H. Teitelbaum

Early descriptions of ulcerative colitis (UC)-like illnesses date back to the late eighteenth century.[1] However, the first clear description of UC is believed to have been made by Wilkis and Moxon in 1859.[2]

By the end of the nineteenth century, fecal diversion became standard practice for severe cases, although improvement was rarely more than transient. In the early twentieth century, tube appendicostomy and frequent colonic lavage with bicarbonate solution was recommended.[3] Total fecal diversion by ileostomy, as advocated by Browne in 1913,[4] became widely practiced despite significant morbidity and mortality. Until the mid-1940s, ileostomy appliances were primitive and routinely associated with soiling and skin irritation. Surgery was usually delayed until the patients were critically ill; subsequent closure of the ileostomy commonly resulted in reactivation of disease.

It was not until 1944 that Strauss and Strauss introduced proctocolectomy with ileostomy for treatment of severe UC.[5] A three-stage operation with ileostomy followed by subtotal colectomy and sigmoid colostomy and then abdominoperineal rectal resection was recommended by Cattell in 1948.[6] Shortly thereafter, a two-stage operation evolved with initial ileostomy and simultaneous subtotal colectomy that, by 1951, was associated with a mortality of only 4.4%.[7] Ripstein in 1952[8] followed by Goligher in 1954[9] recommended ileostomy with one-stage proctocolectomy, which is now considered the standard elective operation for patients with UC.

Although total proctocolectomy with ileostomy provided a permanent cure for UC, delay in patient acceptance of a permanent ileostomy resulted in delaying surgery until most patients had advanced disease, were malnourished, and had complications from the extended medical therapy. Factors instrumental in improving the quality of life with an ileostomy include the eversion technique of ileostomy construction recommended by Brooke in 1952[10] and the development of successful adhesive ileostomy appliances. Subsequent improvements in peristomal skin care by Turnbull[11] and others, together with the development of nurses with special expertise in stomal care, has made it possible for most patients to leave the appliance attached to the skin for 4 to 6 days. For the goal of developing a continent ileostomy that required no stoma appliance and could be irrigated at a convenient place and time, Kock[12] developed the intra-abdominal reservoir with a nipple valve in the ileostomy stoma in 1969.

The search for a sphincter-saving operation for patients with UC began more than 50 years ago when Devine of Melbourne[13] recommended a staged ileosigmoidostomy. Aylett of London[14] became the leading proponent of colectomy with ileoproctostomy, and in 1966 he reported excellent results with 300 patients and a mortality rate of only 5.7%. Parc and colleagues[15] reviewed 17 studies comprising 1206 patients with colectomy and ileorectal anastomosis for UC and found that patients averaged 4.5 bowel movements per day and that 99% were continent. Proctectomy was eventually required in 15%. The risk for subsequent development of cancer in the retained rectum ranged from 2% to 20%. Ileoproctostomy is now used only in patients with minimal rectal disease.

In 1947 Ravitch and Sabiston[16] modified the previously unsuccessful procedure of ileoanal anastomosis and added the technique of rectal mucosectomy. Most patients who had this procedure had defecation frequency and urgency of unacceptable degree such that the operation was rarely used during the ensuing 3 decades.[17] In 1964 Soave[18] described a colonic pull-through procedure after distal rectal mucosectomy for Hirschsprung disease and reported good clinical results. Application of distal rectal mucosal stripping was combined with a total colectomy and a straight endorectal ileoanal anastomosis by Safaie-Shirafi and Soper[19] in 1973 in four young patients with familial polyposis coli. In 1977 Martin, Le Coultre, and Schubert[20] reported satisfactory results in young patients with UC.

The ileoanal pull-through procedure has undergone many modifications during subsequent years, the most important of which was the use of a pouch constructed from the distal ileum and placed immediately proximal to the anastomosis to reduce stool frequency and urgency. The development of the ileal reservoir was based on canine studies by Valente and Bacon in 1955[21] with a triple-limb ileal pouch, by Karlan, McPherson, and Watman[22] with a double-barrel isoperistaltic pouch, and by Ferrari and Fonkalsrud[23] with an S-shaped pouch and an ileoanal anastomosis. In 1978 Parks and Nicholls[24] combined an S-shaped ileal reservoir with rectal mucosectomy and a pouch-anal anastomosis and reported acceptable results in adult patients. Total colectomy with the ileoanal pouch procedure (restorative proctocolectomy) is now widely accepted as the most favorable option for the surgical treatment of UC in patients of all ages.[25–27]

# Etiology

UC is a chronic immune-mediated inflammatory condition of the colon. The precise etiology of UC remains elusive. Historically, theories of etiopathogenesis involved implicating specific pathogenic organisms as causative agents. Early theories of infectious etiologies were encouraged by the observation of the response of UC to sulfonamides and antibiotics.[28] No organism is consistently found in individuals with UC. And epidemiologic studies do not support an infectious etiology. After the discovery of UC's responsiveness to adrenocorticotropic hormone (ACTH), and later to glucocorticoid steroids, research focused on an immunologic etiology of UC.[28] The current understanding of pathogenesis involves an exaggerated immune response to commensal luminal flora.[29]

Early observations of familial patterns of disease have supported the expectation that there is a genetic basis for increased susceptibility to UC. Among individuals with UC, 13.8% have a first-degree relative with inflammatory bowel disease (IBD), predominantly UC.[1] In twin studies, the rate of UC in a twin sibling is 14% to 19% when one sibling is affected. The rate is decreased to 0% to 7% when nonidentical twins are considered (either dizygotic twins or nontwin siblings).[30]

Recent advances in genetic research have identified numerous genetic mutations that are associated with IBD. Early studies identified an increased risk associated with the presence of HLA-B27. More recently, genome-wide association studies have identified mutations in the nucleotide-binding oligomerization domain containing 2 (NOD2) and interleukin-23 receptor (IL23R) genes, which appear to be associated with an increased risk of developing UC, though the association is not strong.[31–33]

# Epidemiology

The incidence of UC in pediatric populations varies across the globe. Rates in industrialized countries are seen in the range of 2.2 to 4.5 per 100,000.[34,35] Though there is a clear increasing trend in the incidence of Crohn disease over time, the change in incidence of pediatric UC is less clear.[36,37] Males and females have an equal incidence of UC. Children are more likely to present with involvement of the entire colon (pancolitis) then their adult counterparts.[38] This is especially true in the youngest cohorts of patients.[39,40]

Environmental factors that modify the risk of UC include tobacco smoke and appendicitis. Tobacco exposure is associated with a lower incidence of UC in adults, and there is a higher rate of developing UC in former smokers.[41] The same protective association has been observed of secondhand smoke in children.[42] This is opposite the observed association of smoking and increased risk in Crohn disease.[41] Prior studies suggested a protective effect of appendectomy on the development of UC.[43] It appears, however, that it may be appendicitis itself, and not appendectomy, that is associated with a decreased incidence of the development of UC.[44]

# Pathology

UC is a chronic inflammatory disease of the rectal and colonic mucosa. The inflammation is limited to the superficial tissue layers including the epithelium and lamina propria. The muscularis mucosa may be involved, but the inflammation does not extend to the muscularis propria. The rectum is involved in more than 95% of cases, and the inflammation extends proximally in a contiguous manner without skipping regions.[45,46]

When the entire colon is present (pancolitis), the most severe changes usually occur in the rectum and sigmoid colon. However, cases of more severe involvement of the proximal colonic segments have been described and may be consistent with UC.[46,47] Children are more likely to present with pancolitis at diagnosis than are adults, who are more likely to present with more limited left-sided colitis or proctosigmoiditis.[38]

Limited inflammation of the ileum can be seen with UC. The ileal inflammation of UC is generally limited to the distal 10 cm of ileum and consists of villous atrophy and superficial inflammation with crypt abscesses and without granulomas.[47] Ileal inflammation with UC is present only in pancolitis and is not present in limited left-sided colitis.[48] More extensive ileal inflammation, or ileal involvement without pancolitis or ileal stenosis or the presence of granulomas, should raise the suspicion of Crohn disease.[48]

The characteristic microscopic appearance of UC consists of crypt architectural distortion with crypt abscesses that lead to mucosal ulceration with undermining of adjacent mucosa. Mucosal bridging with pseudopolyp formation often develops in a circumferential pattern, in contrast to granulomatous colitis in which ulceration is usually more linear and located on the mesenteric side of the colonic lumen (Fig. 96-1).

As the disease progresses in the acute phase, the colon distends, peristalsis decreases, and the muscularis becomes thin and diffusely hemorrhagic; severe disease may progress to acute dilatation, bacteremia, peritonitis, and rarely perforation (toxic megacolon). The incidence of toxic megacolon is increased with severe UC. The use of systemic corticosteroids and antimotility agents (including narcotics) increase the probability of developing toxic megacolon.[49]

With chronic UC, however, the muscularis becomes thickened with flattening of haustral folds and reduction of meaningful peristaltic contractions.[50–52] The mucosa becomes atrophic and may become dysplastic in long-standing disease. The colonic mesentery becomes shortened, and the

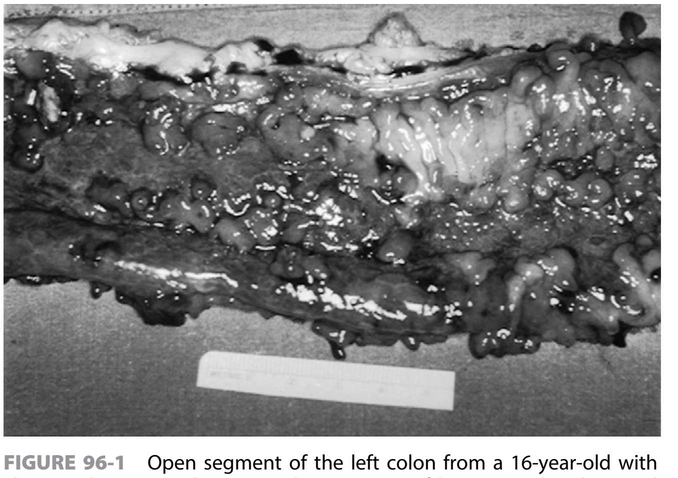

**FIGURE 96-1** Open segment of the left colon from a 16-year-old with chronic ulcerative colitis. Note the presence of large pseudopolyps and the absence of normal mucosal folds.

serosal surface often develops increased superficial vascularity and an overabundance of adipose tissue. In remission, the mucosa may return to a nearly normal appearance on microscopic examination. Mucosal biopsy is helpful in confirming the diagnosis of UC and in assessing disease activity.

## Clinical Manifestations

Approximately 25% of patients diagnosed with UC had the initial presentation of their disease during childhood. Of pediatric patients diagnosed with UC, by one retrospective estimate 38% were diagnosed before the age of 10 years.[38] In a later prospective multicenter study, of patients with childhood onset, 21.6% have onset before 6 years of age.[40] An additional 46.1% have the onset of disease between 6 and 12 years of age, and 32.3% have onset between 13 and 18 years of age.[40]

Symptoms typically present insidiously with persistent diarrhea followed by the appearance of blood, mucus, and pus in the stools. An intermittent, cramping lower abdominal pain, tenesmus, and anemia are common. Anorexia, weight loss, and growth retardation can occur in up to 38% of children with UC.[34] The etiology of anorexia is multifactorial and may be due to increased circulating cytokines or may be due to pain associated with peristalsis or tenesmus. Growth failure can also be associated with prolonged use of systemic corticosteroids.[53]

Children often feel tired as a result of anorexia and/or anemia. Additionally, there is evidence of disturbed sleep patterns in children with UC due to nighttime bowel movements and other factors such as an increased incidence of restless leg syndrome.[54] Children with UC may also limit their social interactions due to fecal urgency and fears of fecal incontinence.[55–58]

Without treatment, most children develop remitting colitis with periodic relapses.[59,60] Over time, many progress to chronic colitis with shorter and less frequent remissions. Approximately 10% of patients develop chronic symptomatic colitis.[38] Rarely, patients may experience a single attack of colitis with subsequent complete remission (11% to 16% in historical literature).[59,60] Relapses may be precipitated by intercurrent infections. Emotional stress does not trigger exacerbations of disease, though stress may worsen perceived symptoms.[61]

Approximately 10% to 15% of children with UC initially present as fulminating disease with profuse bloody diarrhea, severe abdominal cramps, fever, and occasionally sepsis, necessitating prompt treatment.[25] Most of these patients improve with medical therapy, although patients occasionally (5%) develop toxic megacolon that requires emergency surgery. Historically, the colectomy rates for pediatric UC were approximately 50% by 5 years after diagnosis.[60] More recent estimates of colectomy rates are around 25% after 5 years.[38] These rates do not take into account any potential change in colectomy rate since the advent of tumor necrosis factor (TNF)-α antagonist therapy. An accurate estimate of rates of colectomy after therapy with infliximab remains to be determined.

Carcinoma of the colon or rectum has been reported in 3% of patients during the first 10 years of disease and increases by approximately 10% to 15% in each subsequent decade.[62] Malignant conditions may develop even in patients with apparent remission of colitis. Cancer is more common in patients who have pancolitis, those whose symptoms began in childhood, and those who have frequent exacerbations of disease.[63,64] Evidence of dysplasia of the colonic mucosa on biopsy indicates a high risk for subsequent carcinoma.[65,66]

Extracolonic manifestations of UC include growth retardation, arthralgias, delay of sexual maturation, skin lesions, anemia, osteoporosis, primary sclerosing cholangitis, nephrolithiasis, uveitis, and stomatitis (Fig. 96-2). Growth retardation with delay in bone development frequently accompanies chronic UC in adolescence.[34] Delayed sexual maturation may be caused in part by abnormally low levels of urinary gonadotropins.[67,68] Growth hormone levels are usually in the normal range for the patient's age.

Arthralgias occur in approximately 15% of children with UC and commonly involve the knees, ankles, wrists, fingers, and hips.[69,70] Joint symptoms, which occasionally precede the onset of intestinal symptoms, may be confused with juvenile idiopathic arthritis.[71] Symptoms are more common with active UC. But patients may have symptomatic arthralgias or arthritis with quiescent colitis as well.[69]

The most common skin lesions are erythema nodosum of the lower extremities and occasionally the trunk. Pyoderma gangrenosum (i.e., chronic ulceration of the skin) most often occurs on the lower limbs and occurs in less than 5% of children with UC.[72] These lesions are often resistant to local or systemic therapy and frequently do not heal until the patient goes into remission or the disease is surgically corrected. Pyoderma gangrenosum may persist after remission of colitis. Pyoderma may be successfully treated with infliximab.[73] Primary sclerosing cholangitis (PSC) is uncommon in children, although it may occur in up to 15% of adult patients with chronic UC.[74] Approximately 50% to 80% of children with PSC will develop UC.[75,76] Development of PSC may precede the develop of colitic symptoms. PSC may also develop simultaneously with UC or may develop after colectomy. Anemia is common and usually results from overt or occult blood loss in the stools. Patients may also develop anemia of chronic disease as well.

Osteopenia may occur from decreased calcium absorption associated with diminished uptake of fat-soluble vitamins and by increased urinary losses of calcium resulting from steroid therapy.[77] However, the exact risk of fracture is difficult to estimate in childhood where fractures are not uncommon in active healthy children. It is unclear whether the risk of fracture is increased in association with UC.[78,79] Nephrolithiasis occurs in approximately 8% of patients with UC, largely because of inadequate fluid intake to compensate for fluid loss through diarrhea.[80] Uveitis (i.e., inflammation of the iris) occurs in less than 2% of patients but may be severe and can permanently compromise vision.[81,82] Uveitis may present with painless red eyes or may cause photophobia with pain. Aphthous stomatitis is common in patients with UC, particularly during disease exacerbations.

## Clinical Examination

Children with active UC may present with a range of complaints. In mild colitis, patients may present with diarrhea with small amounts of blood. Tenesmus may be present and occasionally may be the primary complaint. With more severe presentations, patients may have grossly bloody diarrhea.

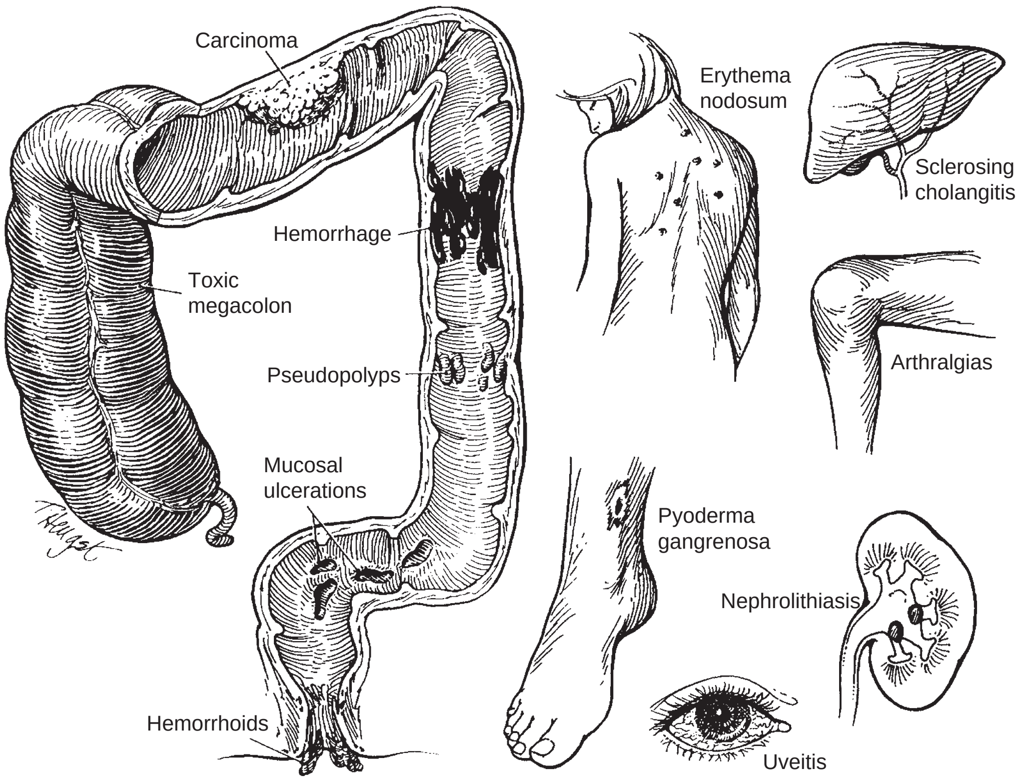

**FIGURE 96-2** Manifestations of ulcerative colitis in the colon and rectum. Extracolonic disorders occur in more than 60% of children with ulcerative colitis.

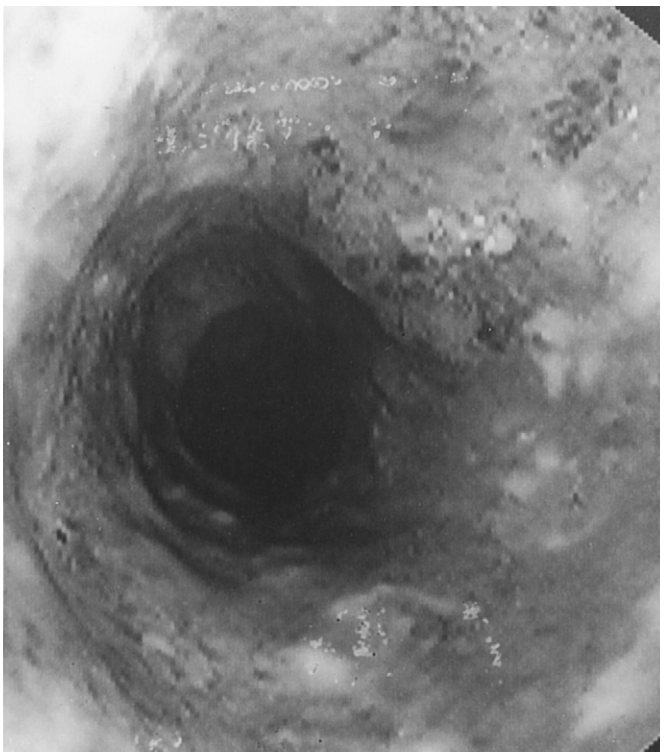

**FIGURE 96-3** Appearance of the transverse colon from an 18-year-old boy with severe ulcerative colitis as viewed through a colonoscope. Note the mucosal ulceration and loss of mucosal folds.

With severe or fulminant colitis, children may become profoundly anemic and may present with pallor, weakness, and weight loss. Constitutional symptoms such as fever, weakness, and listlessness may be present. Stools may vary from watery with scant blood in mild colitis to grossly bloody, liquid stools with mucus and little solid content.

Children with mild UC or who are in remission may manifest few positive findings for disease on physical examination, although endoscopy may demonstrate friable and edematous colonic mucosa with a thin, purulent exudate. Children with chronic UC often show delayed growth in height, delayed sexual maturation, anemia, and pallor. With long-term corticosteroid therapy, children may develop Cushingoid features. With acute disease, fever, dehydration, and systemic toxicity are common. Pain is often elicited by palpation over the sigmoid colon. External hemorrhoids frequently develop from frequency of defecation; however, anal fistulas, fissures, and abscesses are rare and, if present, suggest Crohn disease. Sigmoidoscopy or colonoscopy often shows an edematous and hemorrhagic mucosa that contains superficial ulcers and is covered with a purulent, bloody exudate (Fig. 96-3).

Anemia from blood loss occurs in approximately two thirds of patients. The erythrocyte sedimentation rate is typically elevated as is the C-reactive protein. Hypoalbuminemia frequently develops secondary to protein loss from weeping colonic mucosa. Hyponatremia and hypokalemia often occur with protracted diarrhea. Stool cultures are consistently negative for pathogenic bacteria and parasites. However *Clostridium difficile* infection may coincide with the onset of colitis, may complicate the clinical picture, and may delay diagnosis of UC.

Barium enema radiographs in a patient with chronic UC may show a shortened, narrow, and rigid colon with loss of haustral folds and extensive formation of pseudopolyps (Fig. 96-4). In acute colitis, the intestinal contour may have an irregular serrated border from mucosal ulcerations. The edematous mucosa between areas of ulceration appear as pseudopolyps. Because a contrast enema can stimulate acute manifestations of colitis and because more meaningful information can be obtained from colonoscopy, contrast enemas are now used much less frequently. Upper gastrointestinal barium contrast study with small bowel follow-through is more commonly used to image the small bowel. This is frequently performed to assess the small bowel to rule out small bowel involvement of Crohn disease and in support of the diagnosis of UC. CT enterography (CTE) can provide more detailed assessment of the small bowel; however, CTE typically exposes patients to larger doses of ionizing radiation than a small bowel follow-through (Table 96-1).[83]

The Pediatric Ulcerative Colitis Activity Index (PUCAI) was recently developed for assessing pediatric UC disease activity (see Table 96-1). This scoring method was prospectively validated and is useful both as a research tool, as well as a clinically useful means of assessing patients.[84,85] The total score ranges from 0 to 85. A score of less than 10 is consistent with remission of disease, 10 to 34 indicates mild disease, 35 to 64 moderate disease, and 65 to 85 severe disease. A clinically significant response is defined as a PUCAI decrease of greater than or equal to 20.[86] A PUCAI score of greater than 45 on the third day of illness is predictive of a high likelihood of failure of systemic corticosteroid therapy. And by day 5 of illness, a PUCAI score greater than 65 to 70 suggests the need to escalate medical therapy.[87]

**TABLE 96-1**
**Pediatric Ulcerative Colitis Activity Index (PUCAI) from the Hospital for Sick Children, Toronto**

| *Item* | *Points* |
|---|---|
| **Abdominal Pain** | |
| No pain | 0 |
| Pain can be ignored | 5 |
| Pain cannot be ignored | 10 |
| **Rectal Bleeding** | |
| None | 0 |
| Small amount only (<50% of stools) | 10 |
| Small amount with most stools | 20 |
| Large amount (>50% of the stool content) | 30 |
| **Stool Consistency of Most Stools** | |
| Formed | 0 |
| Partially formed | 5 |
| Completely unformed | 10 |
| **Number of Stools per 24 Hours** | |
| 0-2 | 0 |
| 3-5 | 5 |
| 6-8 | 10 |
| >8 | 15 |
| **Nocturnal Stools (Any Episode Causing Wakening)** | |
| No | 0 |
| Yes | 10 |
| **Activity Level** | |
| No limitation of activity | 0 |
| Occasional limitation of activity | 5 |
| Severe restricted activity | 10 |
| Sum of PUCAI (0-85) | |

**FIGURE 96-4** Barium enema radiograph from a 17-year-old girl with chronic ulcerative colitis. Note the shortening of the colon and loss of haustral markings, which give the colon a characteristic "lead-pipe" appearance.

## Medical Management

Therapy for UC is aimed at symptom relief and prevention of exacerbations of disease. Historically, medical treatment options were limited to sulfasalazine and corticosteroids. Systemic corticosteroids are effective at inducing remission in approximately 54% to 77% of patients.[88] However, toxicities prevent steroids from being useful for long-term management. 5-Aminosalicilates (5-ASAs) are as effective as sulfasalazine for UC.[89] 5-ASAs are generally effective for induction of remission in mild UC.[90] And 5-ASAs are better than placebo at maintaining remission for patients with mild to moderate disease.[49] In cases of limited rectosigmoid disease, rectal preparations of mesalamine may be effective, whereas the combination of oral and rectal preparations is often superior to either one alone.[91,92]

Azathioprine is not effective for use in acute disease. However, for patients with steroid dependent UC, azathioprine is more effective than mesalamine at inducing remission and allowing patients to maintain remission without systemic corticosteroids.[93]

Infliximab has been demonstrated to be effective at inducing remission in 27% to 39% of adults with moderate to severe UC. In the same study by Rutgeerts and colleagues,[94] 26% to 37% of adult patients with moderate to severe UC maintained remission for up to 30 weeks. In pediatric studies, infliximab has been demonstrated to spare corticosteroid use.[53] And

infliximab induces both short-term remission in 82% of patients and long-term remission in up to 67% of pediatric patients after 9 months of therapy.[95] A recent study by Hyams and colleagues[96] demonstrated maintenance of steroid-free remission in 21% of pediatric patients with UC at 2 years.

In the case of fulminant colitis, Järnerot and colleagues[97] demonstrated 17 of 24 (71%) remained in remission after 90 days of infliximab therapy compared with 7 of 21 (33%) in the placebo control group.

Adherence to medical therapy is critically important to maintaining long-term remission. Adherence to therapy in patients with UC who were in remission on mesalamine monotherapy has been extensively reviewed. Over 24 months, 89% of patients who took 80% of their medication remained in remission, although only 39% of those patients who took less than 80% of their medication remained in remission after 24 months.[98]

For patients who develop acute exacerbations of disease, a course of corticosteroids (prednisone) for 2 to 3 months may induce remission.[99] Steroid doses are typically tapered, and alternate-day therapy is initiated as soon as possible. Prolonged use of steroids in young patients is often associated with side effects including growth failure, osteopenia, and Cushingoid features. Rectal steroids (hydrocortisone) or mesalamine enemas may be helpful in treating colitis confined to the rectum and lower left colon with lower systemic absorption than systemic steroids. Steroids should be accompanied by gastric acid suppression with H2-blocking drugs (cimetidine, ranitidine) or proton pump inhibitors (lansoprazole, pantoprazole, omeprazole) to reduce the incidence of peptic ulcer or gastritis.

Antidiarrheal medications such as diphenoxylate hydrochloride with atropine sulfate (Lomotil) or loperamide hydrochloride (Imodium) may reduce the number of bowel movements and decrease rectal spasm but should be used cautiously because the drugs, as well as opiates, may occasionally induce toxic megacolon.[100] Antibiotics are occasionally used for treatment of mild symptoms, though there is little evidence for their efficacy.[101,102]

Though patients frequently identify dietary factors that they feel influence their disease activity, there is little evidence that diet affects the course of UC.[103,104] However, at least one study suggests an association between red meat consumption and exacerbations of UC.[105]

Psychotherapy may help patients with chronic UC adjust to the disease, its complications, and its side effects. Even more important is the ready availability of a sympathetic and interested physician and an understanding family on whom the patient can rely.

During acute exacerbations of UC, most patients require hospitalization with intravenous fluids and increased doses of steroids. These measures commonly correct metabolic deficits and reduce clinical symptoms but often do not alter the course of the colitis. Progression of the colitis or failure to respond to therapy is an indication for emergency surgery. If patients do not tolerate enteral nutrition or if malnutrition is present, parenteral nutrition may be beneficial. However, there is little evidence to support the routine recommendation of bowel rest or hyperalimentation for treatment of UC or for anticipation of surgery.[106–108]

Complications following surgical management of UC in children increase with the duration of the disease and the length and dosage of immune-suppressing medications.[26,109] Surgical treatment in children receiving high doses of corticosteroids and immunosuppressive drugs is associated with a relatively high complication rate that is further increased in children who have received longer courses of therapy.[25]

Although intravenous cyclosporine therapy may be rapidly effective for patients with severe corticosteroid-resistant UC, the need for colectomy in more than 60% of patients within 6 months after discontinuation of cyclosporine therapy suggests that the drug merely delays colectomy.[110] Furthermore, cyclosporine is associated with a high rate of nephrotoxicity and other systemic toxicities.

Steroids have been demonstrated to have an adverse effect on healing of colonic anastomosis.[111] Furthermore, aggressive medical therapy for UC has increased the incidence of emergency-staged colectomy with a resulting increase in morbidity, hospital stay, and cost and a less optimal functional result.[109] Restorative proctocolectomy, however, may be safely carried out in selected patients requiring emergency surgery for severe acute UC. In many cases, medical management should be abbreviated if prompt control of colitis cannot be achieved.[112]

## Surgical Management

Although medical therapy often induces remission for varying periods, UC can be cured by removing the diseased colon and rectum; up to 40% of patients will require surgical intervention. Because the operative resection has provided excellent long-term results, colectomy should be seriously considered for any patient with UC before severe disability and major complications develop. Elective resection is done for patients with persistent symptoms of UC despite medical therapy, growth retardation, severe limitation of activities, and an unacceptable quality of life. It is often distressing for both the patient and family when the child misses many days of school and must limit participation in physical and social activities because of severe symptoms. Emergency operation is indicated for patients (approximately 20%) with fulminant disease that is refractory to medical therapy, extensive rectal bleeding, or toxic megacolon. Children with UC are more likely to have an acute onset and more severe symptoms from UC than adults. Growth potential is the main differentiating consideration in adolescents compared with adults. Thus for children, consideration should be given for colectomy while the epiphyses are still open to allow for optimal growth and development. A recent study showed that the cumulative rates of colectomy were 8% at 1 year, 15% at 3 years, and 20% at 5 years. Predictors of increasing the risk of colectomy were the presence of extraintestinal manifestations (EIMS) at diagnosis and in the first 5 years after diagnosis of UC, resulting in 20% of these children undergoing a colectomy.[132]

Surgical options should be discussed in detail with the patient and parents. It may be helpful for the patient to speak to another child who has been operated on, in order to alleviate fears and concerns about an ileostomy and to support the decision. A preoperative discussion with an enterostomal therapist will help prepare the child and parents for an ileostomy. Although care of an ileostomy is usually easily mastered by a child, the presence of a stoma appliance often creates embarrassment during physical and social activities. Impotence and bladder dysfunction after proctocolectomy in

children are uncommon; however, these major concerns have caused many children, parents, and physicians to delay surgical resection until the colitis becomes debilitating or medical therapy results in systemic complications. Another important issue to discuss with families is what the immediate and long-term stooling frequency and patterns are postoperatively (see later).

Anemia, hypoalbuminemia, and electrolyte abnormalities should be corrected preoperatively. Corticosteroid therapy is maintained to avoid an acute flare-up; however, should the amount of steroids remain high, it may influence the surgical approach. Oral intake is restricted to clear liquids for 48 hours preoperatively. Cathartics should be avoided. However, a gentle administration of hyperosmolar polyethylene glycol solutions such as Golytely may be used. Cleansing enemas are avoided because they may stimulate an acute flare-up of colitis. Oral antibiotics (erythromycin and neomycin) are given the day before, and intravenous broad-spectrum, second-generation cephalosporin antibiotics should be given within 1 hour of skin incision.

Historically, total proctectomy with permanent ileostomy has been the standard surgical treatment of UC that is refractory to medical therapy for more than 50 years. This procedure cures the disease, is associated with a relatively low rate of complications, and has good long-term results. Nevertheless, patients of all ages often find the need to wear an ileostomy appliance for life disturbing, and this is particularly troublesome for pediatric patients. Furthermore, approximately 30% of patients with ileostomies experience appliance-related problems including skin discomfort, skin irritation, leakage, and odor. In the United States, it is estimated that ileostomy maintenance costs at least $1000 per year. Currently, few patients select proctocolectomy with permanent ileostomy when given a choice of available surgical alternatives. The Kock continent ileal reservoir with a nipple valve obviates the need for wearing an ileostomy drainage bag and has been reported to provide a good alternative to permanent ileostomy for several years.[113] Because of the need for multiple drainages each day, need for frequent reoperation, and pouch complications related to the nipple valve and stagnant loop syndrome,[114] unless an ileo-anal pull-through is contraindicated, a Kock pouch is generally now avoided. Subtotal colectomy with ileorectal anastomosis should not be considered because active colitis will typically persist in the rectum of most of these patients and often eventually requires total surgical removal. The remainder of this section concentrates on the ileo-anal pull-through—the standard approach for children and adults today.

## APPROACHES TO THE ILEO-ANAL PULL-THROUGH

The key principle for this procedure is the removal of the entire colon. To avoid an extensive dissection in the deep pelvis, with potential injury to the nervi erigentes, a mucosectomy is then carried down through the distal rectum to within a centimeter above the dentate line. Dissection in this fashion allows for avoidance of injury to the internal anal sphincter and preserves continence. Additionally, this approach leaves the patient the ability to discriminate between gaseous, liquid, and solid contents.[115] Two general approaches may be taken: a straight pull-through of the ileum or creation of an ileal pouch with anal anastomosis. Both are described later, along with their overall long-term results.

## STRAIGHT PULL-THROUGH

One of the initial operative approaches was the straight endorectal ileal pull-through technique. Although the initial passage of stool on closure of an ileostomy will be fairly high and associated with moderate degrees of urgency, patients' symptoms improve over the first 2 years after pull-through. Reported experience with the straight endorectal pull-through technique has produced results roughly similar to those seen with the various pouch procedures.[117,118] The straight endorectal ileal pull-through technique retains peristaltic contractions and generates spike waves down to the anal anastomosis. From a technical standpoint, the procedure is easier than the creation of a pouch as well. One particular advantage of a straight pull-through is that if a child has a foreshortened ileal mesentery, the surgeon may well be faced with a situation where a J pouch (which after folding the bowel back on itself becomes inherently shorter) will not afford an adequate length to bring the ileum down to the anus. In this case a straight pull-through may be an ideal option and should be considered. Another advantage of a straight pull-through is the markedly reduced incidence of pouchitis (see later).

## ILEOANAL POUCH PROCEDURE

The ileoanal pouch was developed to create a reservoir just above the anus. This reservoir allows for the retention of stool and fewer number of bowel movements per day compared with the straight pull-through.[27] Regardless of the type of reservoir used, as long as the lower 4 cm of the rectal muscle is not damaged and the internal anal sphincter is not excessively stretched, the resting and squeezing pressure of the anal sphincter will approach normal values within 3 months.[120] The number of bowel movements, however, will remain much higher than normal values (see Outcomes later).

Four pouch configurations have been used clinically: the lateral and S-, J-, and W-shaped pouches (Fig. 96-5). Both the S- and W-shaped pouches are hand sutured and require a longer operating time than the J-shaped and lateral pouches, which are usually constructed with a stapling instrument. Stasis is more common in these large pouches, and an irrigating

catheter is occasionally required for adequate emptying. After several months, all pouches commonly enlarge; however, if the ileal spout of the S-shaped or lateral pouches is created too long (>2 cm) or if it elongates, pouch enlargement and stasis may be pronounced.

The J-shaped pouch configuration, which was first described by Utsunomiya and colleagues,[123] has been used most widely, is the simplest to construct, and produces the fewest long-term complications in children and adults. The lateral ileal reservoir has been used extensively in the past for children and achieves good long-term results, provided that the ileal spout between the lower end of the pouch and the anus is short.[25] The lateral pouch has been used infrequently in recent years, but this approach, like the straight pull-through, may be used for patients with a short ileal mesentery in whom it is difficult to obtain sufficient length for a J-shaped pouch (i.e., it cannot reach the anus without tension). One key consideration of pouch configuration is to keep the total length of the pouch short, usually around 8 cm. This allows for efficient evacuation of stool and a presumably lower incidence of pouchitis.

# Ileoanal Pouch Construction

## OPEN OPERATIVE APPROACH

For most patients, the ileoanal pouch procedure is performed in two stages. During the first operation, the patient is given general anesthesia and then placed in the lithotomy position. A nasogastric tube and bladder catheter are placed. Positioning for this procedure requires great attention with careful padding of the lower extremities so as to avoid neurovascular injury. In general the area of the peroneal nerve is left completely free, and weight of the lower extremity is placed on the volar aspect of the feet. A long midline incision is made from the pubis to just above the umbilicus. The abdominal colectomy proceeds in routine fashion. The colon is then divided at the rectosigmoid junction. The peritoneal reflection of the rectum is incised, and the endorectal dissection is begun.

Endorectal dissection is generally begun with a low-energy cautery in a circumferential fashion. Gaining entry into the submucosal space may be quite difficult with UC, particularly when there has been an acute flare-up. Should one encounter an undissectable plane, one should restart the dissection several centimeters more distal. As the rectal muscular cuff is developed, countertraction on the mucosal/submucosal tube in an upward fashion and outward traction on the muscular cuff helps the dissection, which should be taken down to just above the dentate line (Fig. 96-6, *A*). Placement of a suction catheter into the rectum (from below) may also make more distal dissection easier. Once the endorectal dissection is completed, one of the surgeons moves to the foot of the table. Narrow retractors are placed at the anal mucocutaneous junction, and a clamp is inserted into the rectum. An assistant working in the abdominal field places the end of the mucosal-submucosal tube into this clamp. The segment is then everted outside the perineum. The end of the everted tube is placed in a clamp and held on traction by an assistant to assist the anastomosis. The submucosal-mucosal tube is incised on the anterior one half, 1 cm proximal to the dentate line. A Kelly clamp is inserted into this opening, and the ileum is brought down to this point by grasping two previously placed traction sutures (Fig. 96-6, *B*). Great care must be taken not to twist the bowel as it is brought through the muscular cuff. A standard anastomosis is performed to the ileum, as either a pouch or straight pull-through. Rectal examination at this point should show a well-formed anastomosis 1.5 to 2 cm above the anodermal junction. Gloves are then changed, and attention is directed to the abdominal field. The pulled-through ileum is attached with seromuscular sutures to the muscular cuff to prevent it

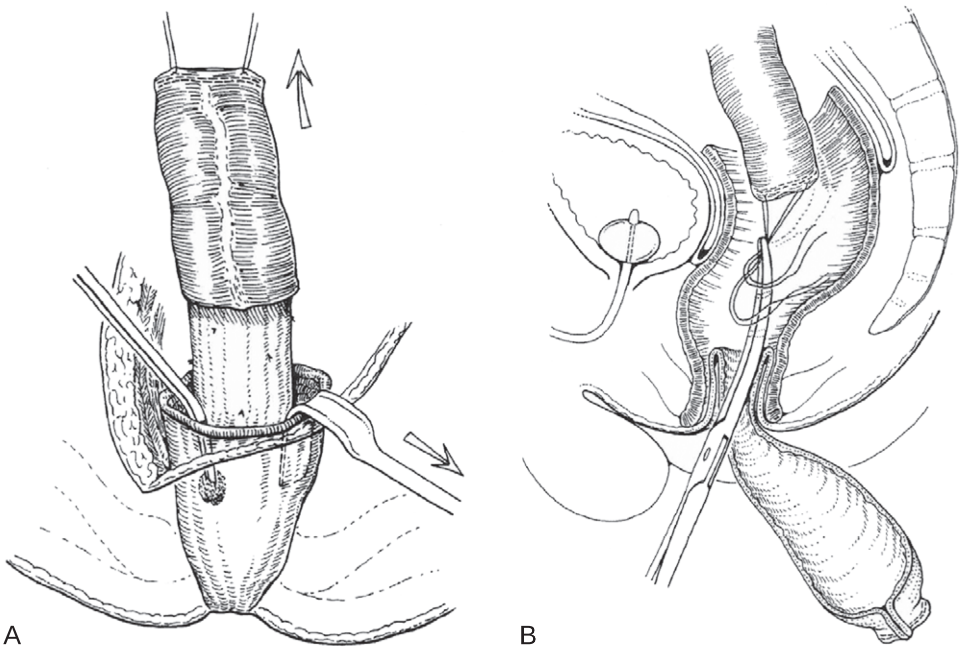

**FIGURE 96-6** **A,** Technique for the endorectal dissection. Note that dissection is assisted with appropriate traction on the cuff and the rectal stump *(arrows)*. **B,** The ileum is pulled through an incision in the submucosal tube. Note that care is taken to avoid twisting of the bowel (in this case shown as a straight pull-through).

from prolapsing in the early postoperative period. In general, a reperitonealization should be done. A temporizing loop ileostomy is typically created in a spot previously marked by an enterostomal nurse. It is important to carefully inspect this site to ensure there is no kinking or twisting of this stoma. Additionally, only peritoneal sutures are placed because this will greatly ease takedown of this stoma after healing has taken place. The loop may be suspended using a red-rubber-type catheter, and this can be removed in approximately 2 weeks. Once the abdomen and skin are closed, the stoma is opened.

# J Pouch Construction

The ileal mesentery is mobilized adjacent to the superior mesenteric vessels into the upper abdomen to provide sufficient length for the distal ileum to reach the anus without tension. A good measure is the ability to easily drag the small bowel (after pouch creation) over the most distal portion of the pubic symphysis. For the J pouch, the ileum is folded back on itself for a length of 8 to 10 cm. The bowel is opened at the apex of the J pouch, and an automatic stapling device is fired to create the anastomosis. In general 2.5-mm staples appear to yield a satisfactory anastomosis. Typically, a small section of ileum will remain separated at the proximal side of the J. An additional firing of the stapling device will allow the remaining portion of the pouch to be anastomosed. Leakage and bleeding along the staple lines is not uncommon. Eversion of the stapled line will allow for inspection and control of any bleeding. Following this, seromuscular sutures at the top of the suture line will take tension off of this critical area. Note that the length of the J pouch has become progressively shortened because longer-length pouches tend to lead to increased stool stasis and higher rates of pouchitis.[133]

# Modification of the Pull-Through

Over the past several years our group and others have made several modifications to this standard open pull-through procedure.[134] One of the major restrictions in performing a J pouch pull-through is the difficulty in bringing down the end of the pouch sufficiently out of the anal canal to perform a hand-sewn anastomosis. Strategies of placing the patient in reverse Trendelenburg and extensive dissection of the mesenteric vessels may help; however, in some cases this may not be sufficient. To address this, the mucosal/submucosal everted tube is stapled outside of the patient approximately 1 cm above the dentate line (Fig. 96-7, *A*). The residual anorectum is placed back into the anal canal, and the largest possible circular end-to-end anastomosing (EEA) stapler is inserted. The assisting surgeon from the abdominal field places the anvil of the EEA device into an opening in the end of the J pouch and secures a purse-string of absorbable, monofilament suture around this opening. Care is taken to ensure that this opening is away from mesenteric vessels, which may be injured during the subsequent anastomosis. The J pouch is guided down, and an anatomosis is created within the anal canal. This allows for a much more rapid anastomosis and much less traction to be placed on the anastomosis (Fig. 96-7, *B* and *C*). Both tissue donuts are inspected, and in some patients a sigmoidoscope with air insufflation is performed to assess the integrity of the completed anastomosis. EEA-type anastomoses commonly narrow down and must be digitally dilated two to three times during the interim 2 months while the child has a protective ileostomy. Once the child begins stooling, the anastomosis generally stays patent.

## LAPAROSCOPIC APPROACH

Minimally invasive surgical (MIS) approaches to a proctocolectomy and pull-through have been advanced over the past decade. Two general approaches have been taken. The first is to perform the entire proctocolectomy, mucosectomy, and pull-through via an MIS approach, with the colon being brought out either through the rectal canal or through a small lower incision.[135] This method has the advantage of excellent cosmetic results but may be time consuming. An MIS alternative approach is to perform the dissection of the colon including mobilization and ligation of mesenteric blood vessels via a laparoscopic approach, followed by a transverse lower incision for the mucosectomy and pull-through procedure.[136] In our experience, we have noted a significantly lower operative time and less blood loss with this modified approach.
